Some families of trees arising in permutation analysis[*]

Mathilde Bouvel[†], Marni Mishna[‡], Cyril Nicaud[§]

Abstract

We extend classical results on simple varieties of trees (asymptotic enumeration, average behavior of tree parameters) to trees counted by their number of leaves. Motivated by genome comparison of related species, we then apply these results to strong interval trees with a restriction on the arity of prime nodes. Doing so, we describe a filtration of the set of permutations based on their strong interval trees. This filtration is also studied from a purely analytical point of view, thus illustrating the convergence of analytic series towards a non-analytic limit at the level of the asymptotic behavior of their coefficients.

Keywords: permutations, simple varieties of trees, random generation, tree parameters, asymptotic formulas.

1 Introduction

The idea of viewing permutations as enriched trees has been around for several decades in different research communities. For example, the recent enumerative study [1] of pattern avoiding permutations, in which *(substitution) decomposition trees* play a crucial role. Also, the analysis of some sorting algorithms is very linked to tree representations of permutations: *PQ trees* [6] appear in the context of graph algorithms and *strong interval trees* arise in comparative genomics [7, and references therein, for instance].

The focus of this article is the study of strong interval trees (a.k.a. decomposition trees). Their typical shape (under the uniform distribution) has been described in [7], showing that they have a very flat, somehow degenerate, shape. Strong interval trees are an essential tool to model and study genome rearrangements. But contrary to what this average shape shows, the trees associated to permutations that arise in the comparison of mammalian genomes seem to have a richer, deeper structure. This suggest that trees coming from permutations under the uniform distribution do not adequately represent the trees that arise in genomic comparisons.

In [7], Bouvel *et al.* considered a subclass of strong interval trees –selected because they represent what is known as *commuting scenarios* [3]– that correspond to the class of *separable permutations*. This is a first step towards a more relevant model of permutations which arise in genome comparison. By studying asymptotic enumeration and parameter formulas for

separable permutations, they proved that the complexity of the algorithm of [3] solving the *perfect sorting by reversals* problem is polynomial time on separable permutations, whereas this problem is NP-complete in general. Furthermore they were also able to describe some average-case properties of the perfect sorting scenarios for separable permutations.

Ultimately, a clear understanding of the properties possessed by the strong interval trees that represent the comparison of actual genomes might tell us something about the evolutionary process. Bouvel *et al.* [7] conclude their study on separable permutations with a suggestion for the next step: strong interval trees with degree restrictions on certain internal nodes. It is a very controlled way to introduce bias in the distribution of strong interval trees. This is precisely what we do in this work; namely, we study strong interval trees where the prime nodes have a bounded number of children. In this work, we focus on the combinatorial analysis of these restricted sets of trees. They can be completely understood combinatorially and analytically, and so we have access to enumeration and analysis of some tree parameters that are ultimately related to the complexity of computing perfect sorting scenarios, or to properties of these scenarios.

Although our initial motivation is the application of combinatorial analysis to a better understanding of models for genome rearrangements, we believe our study has ramifications of independent interest in analytic combinatorics. Indeed, our work reveals a very lush substructure of permutations whose study from an analytical point of view allows us to formulate new questions on the convergence of sequences of combinatorial series.

Specifically, we define nested families of trees (which are almost simple varieties of trees) whose limit is the set of all strong interval trees. The components are then families of trees to which we are able to apply a very complete set of tools: asymptotic analysis, parameter analysis, random generation. But the complete set of strong interval trees is not even close to be a simple variety of trees, so that these tools are inaccessible to the full class without working through the size preserving bijection between strong interval trees and permutations. The question that we ask is then to understand at the analytical level the convergence of algebraic subclasses of a non-analytic class towards the full class. As we explain in details in our work, this question is naturally asked for strong interval trees, but it could also be considered for other classes such as k-regular graphs [13] or λ-terms of bounded unary height [5].

The organization of this article is as follows. First, in Section 2 we present some very general theorems for asymptotic enumeration and parameter analysis in families of trees counted by leaves, that are widely applicable. Then in Section 3 we describe strong interval trees, a decomposable combinatorial class of trees counted by leaves, in bijection with permutations. Next, in Section 4 we introduce a filtration of strong interval trees, where we bound the arity of so-called *prime* nodes. As discussed in Section 4, this filtration has applications in bio-informatics for the study of genome rearrangements. But it also witnesses an intriguing analytic phenomenon: the convergence of a sequence of (well-behaved and algebraic) families of trees towards the (transcendental and non-analytic) class of permutations. Section 5 establishes some first results in the exploration of this phenomenon.

2   When the size of a tree is the number of leaves

There are many works which study the average case behavior of tree parameters, where the size of a tree is the number of internal nodes or of both internal nodes and leaves. The generating functions of these trees satisfy a functional equation of the form $T(z) = z \cdot \Phi(T(z))$, and

Asymptotic number of trees with n leaves	$\sqrt{\frac{\rho}{2\pi\Lambda''(\tau)}} \cdot \frac{\rho^{-n}}{n^{3/2}}$
The average number of nodes of arity κ in trees with n leaves	$\frac{\lambda_\kappa \tau^\kappa}{\rho} \cdot n$
The average number of internal nodes in trees with n leaves	$\frac{\Lambda(\tau)}{\rho} \cdot n = \frac{\tau - \rho}{\rho} \cdot n$
The average subtree size sum in trees with n leaves	$\sqrt{\frac{\pi}{2\rho\Lambda''(\tau)}} \cdot n^{3/2}$

Table 1: A summary of parameters of trees given by $T = z + \Lambda(T)$. The value τ is the unique solution to $\Lambda'(\tau) = 1$ between 0 and $R_\Lambda < 1$, and $\rho = \tau - \Lambda(\tau)$.

when Φ satisfies certain conditions, such as analyticity, then there are formulas for inversion, resulting in explicit enumerative results. A class of trees amenable to this treatment is said to be a *simple variety of trees*. The subject is exhaustively treated in Section VII.3 of [12].

If, instead, we define the size of a tree as the number of leaves, the generating function satisfies a relation of the form $T(z) = z + \Lambda(T(z))$. The same general theorems on inversion still work, and it suffices to apply them and unravel the results. Even though they are less frequent, these have also been studied in the literature, and the applicability of the inversion lemmas is noted in Example VII.13 of [12]. In this section we do this explicitly. In this work, when refering to simple varieties of trees, we mean a family of trees where the size is defined as the number of leaves, and whose study falls into the scope of the results of the present section.

Table 1 summarizes the results of this section. We determine asymptotic formulas for number of trees, and several key parameters. The shape of the formulas are, unsurprisingly, not unlike those that arise in the study of trees counted by internal nodes.

2.1 Asymptotic number of trees

Our entire analysis is roughly a consequence of the Analytic Inversion Lemma and Transfer Theorems. The version to which we appeal is given and proved in [12]. Citations to original sources may be found therein. The following theorem is a slight adaptation of Proposition IV.5 and Theorem VI.6 of [12] to combinatorial equations of the form $\mathcal{T} = \mathcal{Z} + \Lambda(\mathcal{T})$ instead of $\mathcal{T} = \mathcal{Z} \cdot \Phi(\mathcal{T})$.

Theorem 1. *Let Λ be a function analytic at 0, with non-negative Taylor coefficients, and such that, near 0,*

$$\Lambda(z) = \sum_{n \geq 2} \lambda_n z^n.$$

Let R_Λ be the radius of convergence of this series. Under the condition $\lim_{x \to R_\Lambda^-} \Lambda'(x) > 1$, there exists a unique solution $\tau \in (0, R_\Lambda)$ of the equation $\Lambda'(\tau) = 1$.

Then, the formal solution $T(z)$ of the equation

$$T(z) = z + \Lambda(T(z)) \tag{1}$$

is analytic at 0, its unique dominant singularity is at $\rho = \tau - \Lambda(\tau)$ and its expansion near ρ is

$$T(z) = \tau - \sqrt{\frac{2\rho}{\Lambda''(\tau)}} \sqrt{1 - \frac{z}{\rho}} + \mathcal{O}\left(1 - \frac{z}{\rho}\right).$$

Moreover, if T is aperiodic, then one has

$$[z^n]T(z) \sim \sqrt{\frac{\rho}{2\pi\Lambda''(\tau)}} \cdot \frac{\rho^{-n}}{n^{3/2}}.$$

Proof. The conditions on Λ imply that both $\Lambda(x)$ and $\Lambda'(x)$ are increasing functions for x in the real interval $(0, R_\Lambda)$. Since $\Lambda'(0) = 0$ and since $\lim_{x\to R_\Lambda^-} \Lambda'(x) > 1$, there exists $R' \in (0, R_\Lambda)$ such that $\Lambda'(R') > 1$. Hence there exists a unique $\tau \in (0, R')$, and thus on $(0, R_\Lambda)$, such that $\Lambda'(\tau) = 1$.

Now observe that Equation 1 admits a unique formal power series solution $T(z)$, which has non-negative coefficients, by bootstrapping the coefficients. By Analytic Inversion [12, Lemma IV.2], this solution is analytic at $z = 0$ and with $T(0) = 0$: Equation 1 can be rewritten $\Psi(T(z)) = z$, with $\Psi(x) = x - \Lambda(x)$, and $\Psi'(0) \neq 0$.

By Pringsheim's Theorem, a dominant singularity of $T(z)$, if any, lies on the positive real axis. Let $r \in (0, +\infty]$ be the radius of convergence of $T(z)$ at 0, and set $T(r) \in (0, +\infty]$ be defined by $T(r) = \lim_{x\to r^-} T(x)$. Following almost exactly the proof of Proposition IV.5 in [12, p. 278], we get that $T(r) = \tau$. Since T and Ψ are inverse functions, we get by continuity that $T(z)$ has a unique dominant singularity at $\rho = \tau - \Lambda(\tau)$.

The remainder of the proof follows almost readily the one of Theorem VI.6 in [12, p. 405], using our specific equations. $\qquad\square$

2.2 Parameter Analysis

In the case of trees counted by internal nodes, the study of recursively defined parameters is very straightforward, starting from generating function equations. We can describe analogous versions for trees counted by leaves. In particular, we consider additive parameters, and describe a Modified Iteration Lemma, adapted to our notion of size. We illustrate the lemma on number of internal nodes, subtree size sum and number of nodes of a given arity.

2.2.1 General additive parameters

Our focus is on tree parameters that can be computed additively by parameters of subtrees. More precisely, we consider a parameter $\xi(t)$ for trees $t \in \mathcal{T}$ which satisfy the relation

$$\xi(t) = \eta(t) + \sum_{j=1}^{\deg(t)} \sigma(t_j),$$

where $\deg(t)$ is the arity of the root, t_j are its children, η is a simpler tree parameter, and σ is either ξ or a simpler tree parameter. Let $\Xi(z)$, $H(z)$ and $\Sigma(z)$ be the associated cumulative functions of ξ, η and σ. That is,

$$\Xi(z) = \sum_{t\in\mathcal{T}} \xi(t)z^{|t|}, \quad H(z) = \sum_{t\in\mathcal{T}} \eta(t)z^{|t|} \quad \text{and} \quad \Sigma(z) = \sum_{t\in\mathcal{T}} \sigma(t)z^{|t|}.$$

Lemma VII.1 in [12] has an analogue for trees counted by their leaves, and it is proved in a very similar way.

4

Lemma 2 (Iteration Lemma for trees counted by their leaves). *Let $\mathcal{T}$ be a class of trees satisfying $\mathcal{T} = \mathcal{Z} + \Lambda(\mathcal{T})$. The cumulative generating functions are related by*

$$\Xi(z) = H(z) + \Lambda'(T(z))\,\Sigma(z).$$

In particular, if $\sigma \equiv \xi$, one has $\Xi(z) = \frac{H(z)}{1-\Lambda'(T(z))} = H(z) \cdot T'(z)$.

Proof. Unraveling the definition of $\xi(t)$, we have

$$\Xi(z) = H(z) + \widetilde{\Xi}(z) \quad \text{with} \quad \widetilde{\Xi}(z) = \sum_{t \in \mathcal{T}} z^{|t|} \sum_{j=1}^{\deg(t)} \sigma(t_j).$$

Splitting the sum defining $\widetilde{\Xi}(z)$ according to the value r of the degree of the root of t, we get:

$$\begin{aligned}
\widetilde{\Xi}(z) &= \sum_{r \geq 1} \lambda_r z^{|t_1|+\ldots+|t_r|}(\sigma(t_1) + \ldots + \sigma(t_r)) \\
&= \sum_{r \geq 1} \lambda_r \left(\sigma(t_1)z^{|t_1|}z^{|t_2|+\ldots+|t_r|} + \ldots + \sigma(t_r)z^{|t_r|}z^{|t_1|+\ldots+|t_{r-1}|} \right) \\
&= \sum_{r \geq 1} \lambda_r \times r \times \Sigma(z)T(z)^{r-1} = \Lambda'(T(z))\,\Sigma(z).
\end{aligned}$$

In the case $\sigma \equiv \xi$, $\Xi(z) = \frac{H(z)}{1-\Lambda'(T(z))}$ is derived immediately. The last equality is a consequence of $T'(z)(1-\Lambda'(T(z))) = 1$, which is obtained by differentiating $T(z) = z + \Lambda(T(z))$ with respect to z. $\qquad\square$

Note that if $\sigma \equiv \xi$, the parameter is said to be *recursive*. Most basic parameters are recursive, and in what follows we shall use this case only.

Note also that when analytic treatment applies, $T(z)$ has a square-root singularity (see Theorem 1), so that $T'(z)$ has an inverse square-root singularity (by analytic derivation). Therefore, whenever $H(z)$ tends to a positive real when $z \to \rho$ (under some analytic conditions), then the Transfer Theorem yields an asymptotic equivalent of the mean value of the parameter of the form $c \cdot n$. This is for instance the case for the number of nodes of fixed arity and the number of internal nodes, as shown below.

2.2.2 Three applications

Number of nodes with exactly κ children. We "mark" nodes of arity κ by setting

$$\eta(t) = \begin{cases} 1 & \text{if the root of } t \text{ is of arity } \kappa, \\ 0 & \text{otherwise.} \end{cases}$$

Hence if $\kappa \geq 2$, $H(z) = \sum_{t \in \mathcal{T}} \eta(t)z^{|t|} = \sum_{t_1,\ldots,t_\kappa \in \mathcal{T}} \lambda_\kappa z^{|t_1|+|t_2|+\ldots+|t_\kappa|}$ so that $H(z) = \lambda_\kappa T(z)^\kappa$. Now,[1] if $\kappa = 0$, then $H(z) = z$ which is not interesting since it is simply counting the number of leaves *i.e.* the size of the tree.

---

[1] This is the only other possibility since there can be no unary nodes in a proper specification.

By Lemma 2, for any $\kappa \geq 2$ one has $\Xi(z) = \lambda_\kappa T(z)^\kappa \cdot T'(z)$. Since the singular expansion of $T(z)$ near ρ is

$$T(z) = \tau - \gamma\sqrt{1 - z/\rho} + o\left(\sqrt{1 - z/\rho}\right), \text{with } \gamma = \sqrt{\frac{2\rho}{\Lambda''(\tau)}} \tag{2}$$

then near ρ, one has $T(z)^\kappa = \tau^\kappa + \mathcal{O}\left(\sqrt{1 - z/\rho}\right)$. Using the Singular Differentiation Theorem we have

$$T'(z) = \frac{\gamma}{2\rho\sqrt{1 - z/\rho}} + o\left(\frac{1}{\sqrt{1 - z/\rho}}\right), \text{ so that } \Xi(z) = \frac{\lambda_\kappa \gamma \tau^\kappa}{2\rho\sqrt{1 - z/\rho}} + o\left(\frac{1}{\sqrt{1 - z/\rho}}\right),$$

from which we get the asymptotics of the cumulative generating function

$$[z^n]\Xi(z) \sim \frac{\lambda_\kappa \gamma \tau^\kappa \rho^{-n-1}}{2\sqrt{\pi n}}.$$

The asymptotics of the average value across all trees of size n is then

$$\frac{[z^n]\Xi(z)}{[z^n]T(z)} \sim \frac{\lambda_\kappa \gamma \tau^\kappa \rho^{-n-1}}{2\sqrt{\pi n}} \cdot \sqrt{\frac{2\pi\Lambda''(\tau)}{\rho}} \frac{n^{3/2}}{\rho^{-n}} \sim \frac{\lambda_\kappa \tau^\kappa}{\rho} \cdot n,$$

as reported in Table 1.

Number of internal nodes. For this parameter, just take the following definition for η:

$$\eta(t) = \begin{cases} 0 & \text{if } t \text{ is just one leaf,} \\ 1 & \text{otherwise.} \end{cases}$$

One has $H(z) = \sum_{t \in \mathcal{T}} \eta(t) z^{|t|} = T(z) - z$, and therefore (with the γ of Equation (2))

$$\Xi(z) = (T(z) - z)\, T'(z) = \frac{\gamma(\tau - \rho)}{2\rho\sqrt{1 - z/\rho}} + o\left(\frac{1}{\sqrt{1 - z/\rho}}\right).$$

It follows that

$$[z^n]\Xi(z) \sim \frac{\gamma(\tau - \rho)\rho^{-n-1}}{2\sqrt{\pi n}} \quad \text{and} \quad \frac{[z^n]\Xi(z)}{[z^n]T(z)} \sim \frac{\tau - \rho}{\rho} \cdot n.$$

Subtree size sum. We are interested in the subtree size sum parameter, defined by $\eta(t) = |t|$. This implies that $H(z) = zT'(z)$, so that

$$\Xi(z) = zT'(z)^2 = \frac{\gamma^2}{4\rho(1 - z/\rho)} + o\left(\frac{1}{1 - z/\rho}\right) \quad \text{and} \quad [z^n]\Xi(z) \sim \frac{\gamma^2}{4\rho} \cdot \rho^{-n}.$$

Unlike the two previous examples, this is not an inverse of square-root singularity. In this case, for the average value of the subtree size sum, we find

$$\frac{[z^n]\Xi(z)}{[z^n]T(z)} \sim \frac{\gamma^2}{4\rho}\rho^{-n} \cdot \sqrt{\frac{2\pi\Lambda''(\tau)}{\rho}} \frac{n^{3/2}}{\rho^{-n}} \sim \sqrt{\frac{\pi}{2\rho\Lambda''(\tau)}} \cdot n^{3/2},$$

that is, an asymptotic equivalent in $n^{\frac{3}{2}}$. This behavior is typical for such path length related parameters.

There are many other tree parameters that we could consider in a similar fashion.

3 Strong Interval Trees

Our interest in trees counted by leaves is spawned by *strong interval trees*. Strong interval trees are in a size preserving bijection with permutations. They have been introduced in the early 2000's in a bio-informatics context [14, 4]: they are a very effective data structure for algorithms in reconstruction of genome evolution scenarios, as we briefly mentioned in Section 1. Under a different name, and roughly at the same time, these objects also made their appearance in combinatorics, in the study of permutation patterns: strong interval trees (rather called (substitution) decomposition trees) are a tree representation of the block decomposition of permutations described by Albert and Atkinson [1]. Although the proper definition of strong interval trees is relatively recent, it can be traced to older notions of decomposition (of graphs in particular): it is a close relative of the modular decomposition trees of permutation graphs [4] and even has origins in the PQ-trees of Booth and Lueker [6].

In this section, we review the definition of strong interval trees and the bijection with permutations. Then, we turn to a presentation of these objects as a constructible combinatorial class, in the flavor of what is done in Section 2.

3.1 Definition and bijection with permutations

Strong interval trees are most often defined via the bijection that relates them to permutations. Different presentations of this bijection can be found for instance in [1, 4, 7]. For the reader who is not familiar with these objects, we review the definition of strong interval trees, and the correspondence with permutations below.

In the context of our work, a permutation of size n is a word containing exactly once each symbol in $\{1, 2, \ldots, n\}$.

An *interval* of a permutation σ is a factor of σ, such that the underlying set of symbols is an interval of integers. For instance, 7 9 10 11 13 8 12 and 3 1 5 4 2 are intervals of the permutation 6 7 9 10 11 13 8 12 3 1 5 4 2, but 10 11 13 is not (12 is missing). For every permutation σ of size n, the singletons i (for $1 \leq i \leq n$) and σ itself are intervals of σ. They are called *trivial* intervals of σ.
A permutation is said to be *simple* when its only intervals are the trivial ones. Note that our convention will be that 1, 1 2 and 2 1 are not simple permutations, although they satisfy the above definition. It is immediate to check that there is no simple permutation of size 3 (each permutation of size 3 containing an interval of size 2), and that there are 2 simple permutations of size 4, namely 2 4 1 3 and 3 1 4 2. A larger simple permutation is for instance 3 5 7 1 4 2 6. We will go back to the enumeration of simple permutations in the next subsection.

Two intervals of σ *overlap* when their intersection is neither empty nor equal to one of them. Returning to our example of 6 7 9 10 11 13 8 12 3 1 5 4 2, the intervals 6 7 and 7 9 10 11 13 8 12 overlap (their intersection is 7), but 10 11 and 5 4 don't. A *strong* interval of σ is an interval that does not overlap any other interval of σ. The trivial intervals are obviously strong. On our running example, the non-trivial strong intervals are

5 4 ;   3 1 5 4 2 ;   9 10 11 ;   9 10 11 13 8 12   and   6 7 9 10 11 13 8 12.

From their definition, it follows immediately that the inclusion order on the set of strong intervals of a permutation σ induces a tree structure, where the leaves are the singletons, and the root is the σ itself. This is the *strong interval tree* of σ.

From there, and depending on the context, the definition of the strong interval tree may vary. For us, these trees are *embedded in the plane*, by imposing the order of the leaves. Namely, from left to right, the leaves (corresponding to singletons of σ) are required to appear in the same order as in σ. The strong interval tree of our running example would then be:

6 7 9 10 11 13 8 12 3 1 5 4 2

6 7 9 10 11 13 8 12   3 1 5 4 2

6   7   9 10 11 13 8 12   3   1   5 4   2

9 10 11   13   8   12   5   4

9   10   11

From this tree, there is a last step that we perform before obtaining what we refer to as the strong interval tree in our work. It relies on an important remark, proved for instance in [9]. To state it, we first need to describe how to associate a permutation of size k to each node of the strong interval tree with k children.

Note first that given several disjoint strong intervals, the natural order on integers induces an order among them: the smaller the elements contained in the interval, the smaller the interval itself. On our running example, we have for instance that 5 4 is smaller than 8 which is itself smaller than 9 10 11. Consider now a non-singleton strong interval, corresponding to an internal node of the strong interval tree. Its children (assume there are k of them) are also strong intervals, and they are disjoint. So they can be ordered as described above. To this node of the tree, we associate a permutation τ of size k built as follows: $\tau_i = j$ if the i-th child from the left is the j-th smallest one. For instance, the permutation τ associated with the node labeled 9 10 11 13 8 12 in our running example is 2 4 1 3 since 8 is smaller than 9 10 11, itself smaller than 12 and 13.

The permutations labeling the node enjoy a remarkable property (see [9], or in a somewhat different presentation [1]): they are either increasing $(1\,2\ldots k)$ or decreasing $(k\ldots 2\,1)$ or simple. In the reminder of this article, when speaking about strong interval trees, we mean the plane tree whose structure has been described above, but whose internal nodes are only labeled by $\oplus, \ominus$ (corresponding to increasing or decreasing permutations respectively), or by a simple permutation. In particular, the leaves carry no label. Nodes labeled by $\oplus$ or $\ominus$ are called *linear*, whereas those labeled by simple permutations are called *prime*. Figure 1(a) shows the strong interval tree of our running example. Figure 1(b) represents this tree for a simple permutation. What can be observed on this example is true in general: the trees corresponding to simple permutations consist of a single prime node labeled by the permutation itself, with pending leaves.

In a strong interval tree, it is impossible for a node labeled by $\oplus$ (resp. $\ominus$) to have a child carrying the same label. This property appears (although in disguise) in [1], but is simply proved by contradiction: assuming that a parent and a child both carry the label $\oplus$ (resp. $\ominus$) contradicts that the child is a strong interval (indeed, it overlaps an interval resulting from the union of one of its own children with one of its siblings).
Figure 1: Two permutations and their associated strong interval trees

With this in mind, strong interval trees are now just plane trees, where internal nodes are of arity at least 2 and carry labels $\oplus$, $\ominus$ or τ for any simple permutation τ, with the additional conditions that a node labeled by $\oplus$ (resp. $\ominus$) does not have a child carrying the same label, and that the number of children of a node labeled by a simple permutation τ is exactly the size of τ.

It turns out (and the proof follows immediately from [1]) that any such tree is the strong interval tree of a permutation. Moreover, the above construction provides a bijection between permutations and strong interval trees. Note that the bijection is completely constructive, and that it can be computed in linear time, although this is quite difficult to achieve, see [4].

3.2 Strong interval trees as a constructible class

From now on, we denote $\mathcal{P}$ the class of strong interval trees. As we have seen above, this class is a set of trees where some internal nodes are signed and others are enriched with a simple permutation. More precisely, the characterization of strong interval trees given above can be rephrased as show in the following theorem.

Theorem 3 (Reformulated from [1])**.** *The class of permutations is in a size-preserving bijection with the combinatorial class $\mathcal{P}$ of strong interval trees. These are enriched trees defined by the following relations, where size is given by the number of leaves:*

$$\begin{aligned}
\mathcal{P} &= \mathcal{Z}_\square + \mathcal{N}_\oplus \cdot \mathrm{Seq}_{\geq 2}\, \mathcal{U}_\oplus + \mathcal{N}_\ominus \cdot \mathrm{Seq}_{\geq 2}\, \mathcal{U}_\ominus + \mathcal{N}_\bullet \cdot S(\mathcal{P}), \\
\mathcal{U}_\oplus &= \mathcal{Z}_\square + \mathcal{N}_\ominus \cdot \mathrm{Seq}_{\geq 2}\, \mathcal{U}_\ominus + \mathcal{N}_\bullet \cdot S(\mathcal{P}), \\
\mathcal{U}_\ominus &= \mathcal{Z}_\square + \mathcal{N}_\oplus \cdot \mathrm{Seq}_{\geq 2}\, \mathcal{U}_\oplus + \mathcal{N}_\bullet \cdot S(\mathcal{P}).
\end{aligned} \tag{3}$$

Above, the class $\mathcal{Z}$ is an atomic class with a single element of size 1, the $\mathcal{N}$ classes are all epsilon classes containing a single element of size 0, marking internal nodes, and the function $S(z) = \sum_{j \geq 4} s_j z^j$ is the generating function for simple permutations.

Notice that $\mathcal{U}_\oplus$ and $\mathcal{U}_\ominus$ define combinatorial classes which are in size-preserving bijection. In the following, in order to deal with one class instead of two, we replace them by the equivalent class $\mathcal{U} = \mathcal{Z}_\square + \mathcal{N}_\circ \cdot \mathrm{Seq}_{\geq 2}\, \mathcal{U} + \mathcal{N}_\bullet \cdot S(\mathcal{P})$. Doing so, we change the labels of the linear nodes having a linear parent (replacing them by $\circ$). This does not affect the enumeration of the class. Indeed, these labels are determined since a linear node and its linear parent have different labels.

It is not hard to view $\mathcal{U}$ as a family of trees not unlike those of studied in Section 2:

Corollary 4. *The following combinatorial equivalences are true:*

9

$$\mathcal{P} \equiv \operatorname{Seq}_{\geq 1} \mathcal{U} \qquad and \qquad \mathcal{U} \equiv \mathcal{Z} + \operatorname{Seq}_{\geq 2} \mathcal{U} + S(\operatorname{Seq}_{\geq 1} \mathcal{U}).$$

Consequently, $\mathcal{U}$ is in bijection with a class of Λ-trees, or in other words its generating function $U(z)$ satisfies $U(z) = z + \Lambda(U(z))$, for $\Lambda(x) = \frac{x^2}{1-x} + \sum_{j \geq 4} s_j \left(\frac{x}{1-x} \right)^j$, where s_j is the number of simple permutations of size j.

Proof. This equivalence is derived from Equation (3), the fact that $\mathcal{U} \equiv \mathcal{U}_{\oplus} \equiv \mathcal{U}_{\ominus}$, and the intermediary equivalence $\mathcal{P} \equiv \mathcal{U} + \operatorname{Seq}_{\geq 2} \mathcal{U}$. $\qquad \square$

There is however an important difference between $\mathcal{U}$ and the set of classes that are covered by Theorem 1: the function Λ defined by $\Lambda(x) = \frac{x^2}{1-x} + \sum_{j \geq 4} s_j \left(\frac{x}{1-x} \right)^j$ is not analytic at the origin. This is due to $S(z)$, the generating function for simple permutation, not being analytic at the origin. This somewhat undesirable property follows from an enumerative study of simple permutations done by Albert *et al.* [2]. We can, however, make use of their asymptotic enumeration formulas, which we recall below.

Recall that s_n denotes the number of simple permutations of size n. The sequence (s_n) has label A111111 in the On-Line Encyclopedia of Integer Sequences [15]. This sequence is not P-recursive, but it does satisfy a simple functional inversion formula (see [2]), and we have calculated exact values of s_n for $n < 800$. Albert *et al.* [2] determined the following bounds:

$$\frac{n!}{e^2} \left(1 - \frac{4}{n} \right) \leq s_n \leq \frac{n!}{e^2} \left(1 - \frac{4}{n} + \frac{2}{n(n-1)} \right). \tag{4}$$

Here are the first few terms in the generating function for simple permutations:

$$S(z) = 2z^4 + 6z^5 + 46z^6 + 338z^7 + 2926z^8 + 28146z^9 + 298526z^{10} + 3454434z^{11} + \dots$$

Because $S(z)$, and hence $\Lambda(x)$, are not analytic at the origin, neither $\mathcal{P}$ nor $\mathcal{U}$ are simple varieties of trees whose analysis is covered by Section 2. Of course, $\mathcal{P}$ being in bijection with permutations, this gives access to a very good understanding of $\mathcal{P}$ (in particular, enumeration results and random generation tools).

However, very shortly we propose a different strategy for studying $\mathcal{P}$: we describe a filtration $(\mathcal{P}^{(k)})_{k \geq 4}$ such that each $\mathcal{P}^{(k)}$ is built in a straightforward manner from a simple variety of trees $\mathcal{U}^{(k)}$. This makes these subclasses $\mathcal{P}^{(k)}$ easy to analyze, particularly given the generic analysis we have completed in Section 2. This is done in Section 4. Next, we view the entire class $\mathcal{P}$ as the (combinatorial) limit of the filtration. As explained in further details in Section 5, one of our goals is to understand how much this strategy can yield concerning the asymptotic behavior of $\mathcal{P}$, from that of the subclasses $\mathcal{P}^{(k)}$.

4 Prime-Degree Restricted Strong Interval Trees

The filtration of the class of trees $\mathcal{P}$ that we consider consists in bounding the maximal arity of prime nodes. As we shall see, the results of Section 2 are applicable to the subclasses of $\mathcal{P}$ where the arity of prime nodes is bounded. Our motivation for studying this restriction of strong interval trees is twofold.

First, as indicated above, this gives an example of a non-analytic class which is the limit of a sequence of families of trees which are almost simple varieties of trees: we believe this

example is instructive and opens the way to adapting this strategy to study other non-analytic classes, as we discuss in Section 5.

Our second motivation comes from the study of genome rearrangements, specifically in the model of perfect sorting by reversals. Indeed, as shown in [3, 7], the algorithmic complexity of finding an evolutionary scenario in this model depends heavily on the maximal arity of prime nodes in the strong interval trees of the permutations that encodes the genomes (recording the order of the genes): the smaller this maximal arity, the more efficient the algorithm. Based on biological data for mammalian genomes [11], it appears that prime nodes occur relatively rarely, and are of small arity. In [7], the combinatorics of strong interval trees without any prime nodes was investigated, resulting in a better understanding of the so-called *commuting scenarios*. Now allowing some prime nodes to occur, but with a bounded arity, we are going a step further in this analysis, while focusing on subclasses of strong interval trees that seem to represent well the biological data.

4.1 The filtration for permutations

We define the class $\mathcal{P}^{(k)}$ as follows, where $S^{\leq k}(z) = \sum_{j=4}^{k} s_j z^j$:

$$\mathcal{P}^{(k)} = \mathcal{Z} + 2\operatorname{Seq}_{\geq 2} \mathcal{U}^{(k)} + S^{\leq k}(\mathcal{P}^{(k)}) \qquad \text{and} \qquad \mathcal{U}^{(k)} = \mathcal{Z} + \operatorname{Seq}_{\geq 2} \mathcal{U}^{(k)} + S^{\leq k}(\mathcal{P}^{(k)}).$$

That is, only prime nodes of arity at most k are allowed. We refer to the classes denoted by $\mathcal{P}^{(k)}$, as *prime-degree restricted* strong interval trees.

The containment $\mathcal{P}^{(k)} \subset \mathcal{P}^{(k+1)}$ is straightforward, and since $\mathcal{P}_n^{(k)} = \mathcal{P}_n$ when $k \geq n$, we can derive the limit of combinatorial classes $\lim_{k\to\infty} \mathcal{P}^{(k)} = \mathcal{P}$.

Furthermore, by the same manipulations as for the full class, we derive:

$$\mathcal{P}^{(k)} \equiv \operatorname{Seq}_{\geq 1} \mathcal{U}^{(k)} \qquad \text{and} \qquad \mathcal{U}^{(k)} \equiv \mathcal{Z} + \operatorname{Seq}_{\geq 2} \mathcal{U}^{(k)} + S^{\leq k}(\operatorname{Seq}_{\geq 1} \mathcal{U}^{(k)}). \tag{5}$$

Again similarly to the case of the full class, remark that $\mathcal{U}^{(k)}$ is isomorphic to a Λ_k-tree with $\Lambda_k(x) = \frac{x^2}{1-x} + \sum_{j=4}^{k} s_j \left(\frac{x}{1-x}\right)^j$. This class is certainly algebraic and is a simple variety of trees. The enumerative analysis of Section 2 applies directly to these families of trees $\mathcal{U}^{(k)}$, then giving access to enumeration and parameter average behavior for $\mathcal{P}^{(k)}$ also, even if $\mathcal{P}^{(k)}$ is not itself a simple variety of trees. This is done in the remaining part of this section, focusing on applications to the study of genome rearrangements. Also, keeping in mind our next goal of letting k go to infinity to recover the class $\mathcal{P}$, we would like to preserve k as much as possible in the formulas.

4.2 Asymptotic enumeration

The equations (5) allow us to directly apply Theorem 1 to determine asymptotic formulas for the coefficients of the generating functions $P^{(k)}$ of the classes $\mathcal{P}^{(k)}$.

Theorem 5. *For fixed k, the number of prime-degree restricted strong interval trees of size n, denoted $P_n^{(k)}$, grows asymptotically like*

$$P_n^{(k)} \sim \frac{\gamma_k}{(1-\tau_k)^2} \rho_k^{-n} n^{-3/2} \quad \text{as } n \to \infty, \quad \text{where} \quad \gamma_k = \sqrt{\frac{\rho_k}{2\pi \Lambda_k''(\tau_k)}}. \tag{6}$$

Here, $\Lambda_k(x) = \frac{x^2}{1-x} + \sum_{j=4}^{k} s_j (\frac{x}{1-x})^j$, τ_k satisfies $1 - \Lambda_k'(\tau_k) = 0$ and $\rho_k = \tau_k - \Lambda_k(\tau_k)$.

Table 2: Computed approximate values for ρ_k and τ_k for small values of k.

Proof. First, we note that since $\sum_{j=4}^{k} s_j(\frac{x}{1-x})^j$ is a polynomial in $\frac{x}{1-x}$, Λ_k is certainly analytic at 0. The radius of convergence of Λ_k is easily seen to be 1, and $\lim_{x \to 1^-} \Lambda'_k(x) = +\infty$. Hence, Theorem 1 gives that at ρ_k, it holds that:

$$U^{(k)}(z) = \tau_k - \beta_k \sqrt{1 - \frac{z}{\rho_k}} + \mathcal{O}(1 - z/\rho_k) \quad \text{with } \beta_k = \sqrt{\frac{2\rho_k}{\Lambda''(\tau_k)}}.$$

Note that the enumerative formulas of the first section also yield the asymptotic estimate $U_n^{(k)} \sim \gamma_k \rho_k^{-n} n^{-3/2}$ where $\gamma_k = \frac{\beta_k}{2\sqrt{\pi}} = \sqrt{\frac{\rho_k}{2\pi\Lambda''(\tau_k)}}$.

Next, we note that by the first relation in Equation (5), $P^{(k)}(z) = \frac{U^{(k)}(z)}{1 - U^{(k)}(z)}$. By Theorem 1, the value of $U^{(k)}(z)$ at its dominant singularity ρ_k is τ_k. Moreover, τ_k is less than the radius of convergence of Λ_k, *i.e.*, $\tau_k < 1$. So the composition $P^{(k)}(z) = \frac{U^{(k)}(z)}{1 - U^{(k)}(z)}$ is subcritical (see [12, paragraph VI.9]): this implies that the dominant singularity of $P^{(k)}(z)$ is also ρ_k, and that at ρ_k, we have:

$$
\begin{aligned}
P^{(k)}(z) &= \frac{\tau_k - \beta_k\sqrt{1 - \frac{z}{\rho_k}} + \mathcal{O}(1 - z/\rho_k)}{1 - \tau_k + \beta_k\sqrt{1 - \frac{z}{\rho_k}} + \mathcal{O}(1 - z/\rho_k)} \\
&= \frac{\tau_k}{1 - \tau_k}\left(1 - \frac{\beta_k}{\tau_k}\sqrt{1 - \frac{z}{\rho_k}}\right)\left(1 - \frac{\beta_k}{1 - \tau_k}\sqrt{1 - \frac{z}{\rho_k}}\right) + \mathcal{O}(1 - z/\rho_k) \\
&= \frac{\tau_k}{1 - \tau_k} - \frac{\beta_k}{(1 - \tau_k)^2}\sqrt{1 - \frac{z}{\rho_k}} + \mathcal{O}(1 - z/\rho_k).
\end{aligned}
$$

The classic Transfer Theorem of asymptotic enumeration then gives

$$P_n^{(k)} \sim \frac{\beta_k}{(1 - \tau_k)^2}\frac{1}{2\sqrt{\pi n^3}}\rho_k^{-n} = \frac{\gamma_k}{(1 - \tau_k)^2}\rho_k^{-n} n^{-3/2} \quad \text{as claimed.} \qquad \square$$

Note that along the proof of Theorem 5, we have seen that $\tau_k < 1$, an inequality that will be useful in Section 5 to bound the asymptotic estimate of Equation (6).

Table 2 contains numeric approximations for τ_k and ρ_k in the range $k = 4 \ldots 13$. Using these estimates gives good asymptotic approximations and the enumerative formulas given in Equation (6) converge quickly for fixed k. For example, when $k = 8$, our asymptotic formula is within 2% of the correct value at $n = 10$.[2]

<div align="center">Table 3: A summary of asymptotic behavior of parameters for trees in $\mathcal{P}^{(k)}$.</div>

4.3 Parameter analysis

The average shape of general strong interval trees was described in [7]. This study is essentially based on Equation (4), which shows that simple permutations make up about 1/9 of all permutations. As a consequence, general strong interval trees have a very flat shape with probability tending to 1, and this shape governs the average case behavior of any tree parameter. However, the prime-degree restricted trees are much more rich in this regards, and parameter analysis follows from Section 2.

We focus here on some parameters which are to some extent linked to the perfect sorting scenarios for σ, that is, to parsimonious evolutionary scenarios in the model of perfect sorting by reversals (see [7] for a detailed explanation of this connection). We will be specifically interested in the number of internal nodes (which is related to the number of reversals in a scenario), the number of prime nodes (since the complexity of computing a parsimonious scenario depends on it) and the average subtree size (which has a tight connection to the average reversal size). These parameters give important insight into the average case analysis of perfect sorting by reversals.

We have seen above that the generating function of $\mathcal{U}^{(k)}$ satisfies $U^{(k)}(z) = z + \Lambda_k(U^{(k)}(z))$ with $\Lambda_k(x) = \frac{x^2}{1-x} + \sum_{j=4}^{k} s_j \left(\frac{x}{1-x}\right)^j$. Consequently, $\mathcal{U}^{(k)}$ is a simple variety of trees, and this allows to apply directly the results of Section 2 for the average number of internal nodes or the average subtree size sum in $\mathcal{U}^{(k)}$ trees. The average number of prime nodes in $\mathcal{U}^{(k)}$ trees can also be derived using the general framework developed in Section 2. Then, the behaviour of these parameters in $\mathcal{P}^{(k)}$ trees is deduced from the already observed identity

$$\mathcal{P}^{(k)} = \mathcal{U}^{(k)} + \mathrm{Seq}_{\geq 2}\, \mathcal{U}^{(k)}. \tag{7}$$

Note that even though $\mathcal{P}^{(k)}$ is not a simple variety of trees, the behaviour of the studied parameters are of the same order as in such families of trees.

The results proved in this section are summarized in Table 3.

4.3.1 Number of internal nodes

Let $U^{(k)}(z,y)$ (resp. $P^{(k)}(z,y)$) be the bivariate generating function of $\mathcal{U}^{(k)}$ trees (resp. $\mathcal{P}^{(k)}$ trees), where z counts the size (*i.e.*, the number of leaves) and y counts the number of internal nodes. It follows from Eq. (7) that

$$P^{(k)}(z,y) = U^{(k)}(z,y) + y \cdot \frac{U^{(k)}(z,y)^2}{1 - U^{(k)}(z,y)}.$$

Consequently, we have

$$
\begin{aligned}
\frac{\partial}{\partial y} P^{(k)}(z,y)\Big|_{y=1} = \;& \frac{\partial}{\partial y} U^{(k)}(z,y)\Big|_{y=1} + \frac{2U^{(k)}(z,1)}{1-U^{(k)}(z,1)} \frac{\partial}{\partial y} U^{(k)}(z,y)\Big|_{y=1} \\
& + \frac{U^{(k)}(z,1)^2}{1-U^{(k)}(z,1)} + \frac{U^{(k)}(z,1)^2}{(1-U^{(k)}(z,1))^2} \frac{\partial}{\partial y} U^{(k)}(z,y)\Big|_{y=1}. \quad (8)
\end{aligned}
$$

Near ρ_k, we know that $U^{(k)}(z,1) = U^{(k)}(z) = \tau_k - \beta_k\sqrt{1-z/\rho_k} + \mathcal{O}(1-z/\rho_k)$. The weaker estimate $U^{(k)}(z) = \tau_k + \mathcal{O}(\sqrt{1-z/\rho_k})$ gives $\frac{1}{1-U^{(k)}(z)} = \frac{1}{1-\tau_k} + \mathcal{O}(\sqrt{1-z/\rho_k})$, and these are enough to estimate all rational fractions in $U^{(k)}(z)$ that appear in Eq.(8). Moreover, the generating function $\frac{\partial}{\partial y} U^{(k)}(z,y)\Big|_{y=1}$ counts $\mathcal{U}^{(k)}$ trees weighted by their number of internal nodes. As seen in Section 2, it then follows from Lemma 2 that, near ρ_k,

$$
\frac{\partial}{\partial y} U^{(k)}(z,y)\Big|_{y=1} = \frac{\beta_k(\tau_k - \rho_k)}{2\rho_k(1-z/\rho_k)^{1/2}} + o\left(\frac{1}{(1-z/\rho_k)^{1/2}} \right).
$$

Combining these asymptotic estimates gives, near ρ_k,

$$
\frac{\partial}{\partial y} P^{(k)}(z,y)\Big|_{y=1} = \frac{\beta_k(\tau_k - \rho_k)}{2\rho_k(1-\tau_k)^2} \frac{1}{(1-z/\rho_k)^{1/2}} + o\left(\frac{1}{(1-z/\rho_k)^{1/2}} \right).
$$

Recalling the identity $\gamma_k = \frac{\beta_k}{2\sqrt{\pi}}$ and the asymptotic behaviour of $[z^n]P^{(k)}(z,1) = P_n^{(k)}$ given in Theorem 5, we deduce that the average number of internal nodes in $\mathcal{P}^{(k)}$ trees is

$$
\frac{[z^n]\frac{\partial}{\partial y} P^{(k)}(z,y)\Big|_{y=1}}{[z^n]P^{(k)}(z,1)} \sim_{n\to\infty} \frac{\beta_k(\tau_k - \rho_k)}{2\rho_k(1-\tau_k)^2\sqrt{\pi n}} \rho_k^{-n} \cdot \frac{(1-\tau_k)^2}{\gamma_k \rho_k^{-n}} n^{3/2} = \frac{(\tau_k - \rho_k)}{\rho_k} \cdot n.
$$

4.3.2 Number of prime nodes

Like before, let us denote by $U^{(k)}(z,y)$ (resp. $P^{(k)}(z,y)$) the bivariate generating function of $\mathcal{U}^{(k)}$ trees (resp. $\mathcal{P}^{(k)}$ trees), counted by size (for z) and number of prime nodes (for y). We know an asymptotic estimates of $U^{(k)}(z,1) = U^{(k)}(z)$ near ρ_k, and we now apply the method of Section 2 to compute one for $\frac{\partial}{\partial y} U^{(k)}(z,y)\Big|_{y=1}$.

For any $\mathcal{U}^{(k)}$ tree t, let $\sigma(t) = \xi(t)$ denote the number of prime nodes in t and let $\eta(t)$ be 1 if the root of t is a prime node, 0 otherwise. With the notations of Lemma 2, we have

$$
H(z) = \sum_{t \in \mathcal{U}^{(k)}} \eta(t) z^{|t|} = S^{\leq k}(U^{(k)}(z)) \quad \text{where } S^{\leq k}(u) = \sum_{j=4}^{k} s_j u^j
$$

and $\quad \frac{\partial}{\partial y} U^{(k)}(z,y)\Big|_{y=1} = \Xi(z) = H(z) \cdot \frac{\partial}{\partial z} U^{(k)}(z) = S^{\leq k}(U^{(k)}(z)) \cdot \frac{\partial}{\partial z} U^{(k)}(z).$

The asymptotic estimate of $U^{(k)}(z)$ near ρ_k is $U^{(k)}(z) = \tau_k - \beta_k\sqrt{1-z/\rho_k} + \mathcal{O}(1-z/\rho_k)$, from which we deduce $U^{(k)}(z)^j = \tau_k^j + o(1)$. Moreover, Singular Differentiation gives, near ρ_k,

$$
\frac{\partial}{\partial z} U^{(k)}(z) = \frac{\beta_k}{2\rho_k(1-z/\rho_k)^{1/2}} + o\left(\frac{1}{(1-z/\rho_k)^{1/2}} \right).
$$

14

Consequently, we obtain that near ρ_k,

$$\frac{\partial}{\partial y} U^{(k)}(z, y)\Big|_{y=1} = S^{\leq k}(\tau_k) \cdot \frac{\beta_k}{2\rho_k} \cdot \frac{1}{(1 - z/\rho_k)^{1/2}} + o\left(\frac{1}{(1 - z/\rho_k)^{1/2}}\right).$$

Now turning to $\mathcal{P}^{(k)}$ trees, Eq. (7) implies that

$$P^{(k)}(z, y) = U^{(k)}(z, y) + \frac{U^{(k)}(z, y)^2}{1 - U^{(k)}(z, y)}.$$

Differentiation gives

$$\frac{\partial}{\partial y} P^{(k)}(z, y)\Big|_{y=1} = \left(1 + \frac{2U^{(k)}(z, 1)}{1 - U^{(k)}(z, 1)} + \frac{U^{(k)}(z, 1)^2}{(1 - U^{(k)}(z, 1))^2}\right) \frac{\partial}{\partial y} U^{(k)}(z, y)\Big|_{y=1}.$$

The asymptotic estimates obtained above give that, near ρ_k,

$$\frac{\partial}{\partial y} P^{(k)}(z, y)\Big|_{y=1} = S^{\leq k}(\tau_k) \cdot \frac{\beta_k}{2\rho_k(1 - \tau_k)^2} \cdot \frac{1}{(1 - z/\rho_k)^{1/2}} + o\left(\frac{1}{(1 - z/\rho_k)^{1/2}}\right).$$

Finally, we deduce that the average number of prime nodes in $\mathcal{P}^{(k)}$ trees is

$$\frac{[z^n] \frac{\partial}{\partial y} P^{(k)}(z, y)\Big|_{y=1}}{[z^n] P^{(k)}(z, 1)} \sim_{n \to \infty} \frac{S^{\leq k}(\tau_k) \cdot \beta_k}{2\rho_k(1 - \tau_k)^2 \sqrt{\pi n}} \rho_k^{-n} \cdot \frac{(1 - \tau_k)^2}{\gamma_k \rho_k^{-n}} n^{3/2} = \frac{S^{\leq k}(\tau_k)}{\rho_k} \cdot n.$$

4.3.3 Subtree size sum

Again, we denote by $U^{(k)}(z, y)$ (resp. $P^{(k)}(z, y)$) the bivariate generating function of $\mathcal{U}^{(k)}$ trees (resp. $\mathcal{P}^{(k)}$ trees), counted by size (for z) and number of prime nodes (for y). In this case, Eq. (7) gives

$$P^{(k)}(z, y) = U^{(k)}(z, y) + \frac{U^{(k)}(zy, y)^2}{1 - U^{(k)}(zy, y)}.$$

As before, we have $U^{(k)}(z, 1) = U^{(k)}(z)$. Note also that $\frac{\partial}{\partial z} U^{(k)}(z, y)\Big|_{y=1} = \frac{\partial}{\partial z} U^{(k)}(z)$. It follows that

$$\frac{\partial}{\partial y} P^{(k)}(z, y)\Big|_{y=1} = \frac{\partial}{\partial y} U^{(k)}(z, y)\Big|_{y=1}$$
$$+ \left(\frac{2U^{(k)}(z, 1)}{1 - U^{(k)}(z, 1)} + \frac{U^{(k)}(z, 1)^2}{(1 - U^{(k)}(z, 1))^2}\right)\left(z \frac{\partial}{\partial z} U^{(k)}(z) + \frac{\partial}{\partial y} U^{(k)}(z, y)\Big|_{y=1}\right)$$

and we proceed like in the previous cases. Near ρ_k, the asymptotic estimate of $\frac{\partial}{\partial z} U^{(k)}(z)$ is

$$\frac{\partial}{\partial z} U^{(k)}(z) = \frac{\beta_k}{2\rho_k(1 - z/\rho_k)^{1/2}} + o\left(\frac{1}{(1 - z/\rho_k)^{1/2}}\right),$$

and we have seen in Section 2 that

$$\frac{\partial}{\partial y} U^{(k)}(z, y)\Big|_{y=1} = \frac{\beta_k^2}{4\rho_k(1 - z/\rho_k)} + o\left(\frac{1}{1 - z/\rho_k}\right),$$

15

since this function counts $\mathcal{U}^{(k)}$ trees weighted by their substree size sum. Consequently, the asymptotic estimate of $\frac{\partial}{\partial y}P^{(k)}(z,y)\big|_{y=1}$ near ρ_k is

$$\frac{\partial}{\partial y}P^{(k)}(z,y)\bigg|_{y=1} = \frac{\beta_k^2}{4\rho_k(1-\tau_k)^2(1-z/\rho_k)} + o\left(\frac{1}{1-z/\rho_k}\right).$$

We conclude that the average value of the subtree size sum in $\mathcal{P}^{(k)}$ trees is

$$\frac{[z^n]\frac{\partial}{\partial y}P^{(k)}(z,y)\big|_{y=1}}{[z^n]P^{(k)}(z,1)} \sim_{n\to\infty} \frac{\beta_k^2}{4\rho_k(1-\tau_k)^2}\rho_k^{-n} \cdot \frac{(1-\tau_k)^2}{\gamma_k\rho_k^{-n}}n^{3/2} = \frac{\beta_k^2}{4\rho_k\gamma_k} \cdot n^{3/2}.$$

4.4 Random generation

Equation (5) gives immediate access to random sampling of trees in $\mathcal{P}^{(k)}$. Thinking of the classes $\mathcal{P}^{(k)}$ as possible models for the biological data collected in [11], it is interesting to generate random trees in $\mathcal{P}^{(k)}$, to compare them with the trees obtained from the data. In this context, our interest is the global shape of the trees, and not the particulars of the internal nodes. We have produced a Boltzmann generator which generates trees in $\mathcal{P}^{(k)}$ of size approximately 10000 for k up to 800 without generating the simple permutation labels (prime and linear nodes are however distinguished). Figure 2 illustrates a randomly generated tree from $\mathcal{P}^{(7)}$ with approximately 1000 leaves. Remark that the structure is dominated by prime nodes of arity 7.

Figure 2: A tree from $\mathcal{P}^{(7)}$ generated uniformly at random

The results of this random generation experiment are somehow disappointing, because the trees generated do not look like the trees obtained from the biological data. These have for instance significantly fewer prime nodes and are flatter. A careful statistical analysis would however be necessary to properly invalidate our proposed model. It would also set a solid basis for the comparison of other proposed models with the data, since this statistical analysis could then be reproduced for other subclasses of strong interval trees defined by finer restrictions.

One of our long term goals on the biological side is to identify the very specific traits which arise in permutations which encode mammalian genome comparisons, and to provide more adequate models. Chauve, McCloskey and Mishna [11] have taken some preliminary steps in this direction, and a reasonable model might use $\mathcal{P}^{(k)}$ trees as components to build realistic trees. Note that permutations are very often used to model real-world problems, not only in

biology: for instance also in sorting problems in algorithmic. We can therefore view this goal as part of a larger project: that of defining subclasses of permutations modeling "well" the permutations occurring in these real-world contexts (using for instance strong interval trees), and of proving statistically that these models indeed represent well the data.

5 Studying a combinatorial class *via* its filtration

We now turn to the second aspect of the study of the classes $\mathcal{P}^{(k)}$: understanding the convergence towards the full class $\mathcal{P}$, in particular at the level of the asymptotic number of trees in the class. The example of $\mathcal{P}$ we have in hand is a particularly instructive one, since the limit is known by other means, namely from the correspondence between $\mathcal{P}$ and permutations.

This example is also meant to illustrate a more general goal, discussed further in Subsection 5.2: that of analyzing classes of trees $\mathcal{C}$ via a filtration $\mathcal{C}^{(k)}$ similar to $\mathcal{P}^{(k)}$, especially when $\mathcal{C}$ fail to be a simple variety of trees because the series governing the number of children available (our Λ) is not analytic.

5.1 From the asymptotic estimate of $P_n^{(k)}$ to the factorial

Recall that $P_n^{(k)}$ denotes the number of strong interval trees with n leaves and arity of prime nodes at most k. For any fixed k, the asymptotic behavior of $P_n^{(k)}$ is given in Equation (6), and is of the form $\gamma \cdot \rho^{-n} \cdot n^{-3/2}$, which is typical for trees. However, taking the limit as k tends to infinity, we recover the class of all strong interval trees, or equivalently of permutations, and hence an asymptotic behavior in $n! \sim \sqrt{2\pi} e^{-n} n^{n+1/2}$. Our goal is to reconcile those estimates.

Most of this section aims at producing an upper bound for the asymptotic estimate of $P_n^{(k)}$ given in Equation (6). This is obtained by bounding ρ_k and $\Lambda_k''(\tau_k)$. The first ingredient is a more explicit bound for s_n, the number of simple permutations of size n.

Lemma 6. *For every $n \geq 4$, $s_n \leq \sqrt{2\pi}\, n^{n+1/2}\, e^{-n-2}$.*

Proof. This inequality follows from Equation (4), stating that $s_n \leq \frac{n!}{e^2}\left(1 - \frac{4}{n} + \frac{2}{n(n-1)}\right)$, and the following upper bound on $n!$: $n! \leq \sqrt{2\pi} n^{n+\frac{1}{2}} e^{-n}\, e^{\frac{1}{12n}}$. Combining these two, our claim will follow if we prove that $(1 - \frac{4}{n} + \frac{2}{n(n-1)})e^{\frac{1}{12n}} \leq 1$ for $n \geq 4$. This is equivalent to $(1 - \frac{4}{n} + \frac{2}{n(n-1)}) \leq e^{-\frac{1}{12n}}$. And since $1 - x \leq e^{-x}$, it is sufficient to prove that $1 - \frac{4}{n} + \frac{2}{n(n-1)} \leq 1 - \frac{1}{12n}$, *i.e.*, that $4 - \frac{2}{n-1} \geq \frac{1}{12}$. This obviously holds for $n \geq 4$, concluding the proof. $\square$

From this estimate, the derivations of the bounds on τ_k and ρ_k are relatively straightforward, but technical. Working with the value $\tilde{\tau}_k = \frac{\tau_k}{1-\tau_k}$ simplifies the expressions. To derive those bounds, it is essential to keep in mind this sequence of inequalities, which follow from $\tau_k < 1$ and $\rho_k = \tau_k - \Lambda_k(\tau_k)$:

$$0 < \rho_k < \tau_k < \tilde{\tau}_k < 1.$$

Proposition 7 (Bounds for $\tilde{\tau}_k$)**.** *For any $\alpha < \frac{e-2}{e-1}$, there exists $k(\alpha)$ such that for $k > k(\alpha)$*

$$\left(\frac{\alpha}{ks_k}\right)^{\frac{1}{k-1}} < \tilde{\tau}_k < \left(\frac{1}{ks_k}\right)^{\frac{1}{k-1}}.$$

Consequently,

$$\frac{e}{k}\left(\frac{\alpha e^3}{\sqrt{2\pi}\,k^{5/2}}\right)^{\frac{1}{k-1}} < \tilde{\tau}_k < \frac{e}{k}\left(\frac{e^3}{\sqrt{2\pi}\,k^{3/2}(k-4)}\right)^{\frac{1}{k-1}} < \frac{e}{k}.$$

Computational evidence suggests that $k(\alpha) = 4$, for all α near $\frac{e-2}{e-1}$.

Proof. The starting point is the equation $\Lambda'_k(x) = 1$, satisfied by τ_k. Because $\Lambda_k(x) = \frac{x^2}{1-x} + \sum_{j=4}^{k} s_j\left(\frac{x}{1-x}\right)^j$, it is convenient to consider this equation under the change of variables $y = \frac{x}{1-x}$, i.e., $x = \frac{y}{1+y}$. Notice that it implies $\frac{1}{(1-x)^2} = (1+y)^2$.

Derivation gives $\Lambda'_k(x) = \frac{1}{(1-x)^2} - 1 + \frac{1}{(1-x)^2}\sum_{j=4}^{k} js_j\left(\frac{x}{1-x}\right)^{j-1}$, so that the equation $\Lambda'_k(x) = 1$ can be rewritten as

$$(1+y)^2 - 1 + (1+y)^2\sum_{j=4}^{k} js_j y^{j-1} = 1 \quad \text{which implies} \quad \frac{2-(1+y)^2}{(1+y)^2} = \sum_{j=4}^{k} js_j y^{j-1}. \quad (9)$$

The next step towards proving the stated inequalities is the fact that for $0 < y < 1$, $1 - 5y < \frac{2-(1+y)^2}{(1+y)^2} < 1$, which is immediately proved by simple manipulations of inequalities. Indeed, we now observe that (by definition of $\tilde{\tau}_k$), Equation (9) is satisfied at $y = \tilde{\tau}_k$. Consequently, these inequalities yield an upper and a lower bound for $\sum_{j=4}^{k} js_j \tilde{\tau}_k^{j-1}$:

$$1 - 5\tilde{\tau}_k < \sum_{j=4}^{k} js_j \tilde{\tau}_k^{j-1} < 1. \quad (10)$$

From Equation (10), we get $ks_k\tilde{\tau}_k^{k-1} \le \sum_{j=4}^{k} js_j\tilde{\tau}_k^{j-1} < 1$, from which the upper bound $\tilde{\tau}_k < \left(\frac{1}{ks_k}\right)^{\frac{1}{k-1}}$ follows. From there, deriving $\tilde{\tau}_k < \frac{e}{k}\left(\frac{e^3}{\sqrt{2\pi}\,k^{3/2}(k-4)}\right)^{\frac{1}{k-1}}$ is then a routine exercise using $\frac{k!}{e^2}\left(1 - \frac{4}{k}\right) \le s_k$ (see Equation (4)) and Stirling's inequality $\left(\frac{k}{e}\right)^k\sqrt{2\pi k} \le k!$. This quantity is no larger than $\frac{e}{k}$ as soon as $k \ge 5$. This concludes the part of the proof about upper bounds.

For the lower bounds, we start again from Equation (10) above. We use the inequality $1 - 5\tilde{\tau}_k - \sum_{j=4}^{k-1} js_j\tilde{\tau}_k^{j-1} < ks_k\tilde{\tau}_k^{k-1}$, and combine it with the bound $0 < \tilde{\tau}_k \le e/k = o(1)$, and an upper bound on $\sum_{j=4}^{k-1} js_j\tilde{\tau}_k^{j-1}$ obtained below. We split this sum as

$$\sum_{j=4}^{k-1} j\,s_j\,\tilde{\tau}_k^{j-1} = \underbrace{\sum_{j=4}^{k-\iota_k-1} j\,s_j\,\tilde{\tau}_k^{j-1}}_{A(k)} + \underbrace{\sum_{j=k-\iota_k}^{k-1} j\,s_j\,\tilde{\tau}_k^{j-1}}_{B(k)}.$$

where $\iota_k = \lfloor k^{\frac{1}{3}}\rfloor$. Note that ι_k an non-decreasing integer function of k that tends to infinity and such that $\iota_k = o(\sqrt{k})$. Lemmas 8 and 9 below prove that

$$A(k) = \sum_{j=4}^{k-\iota_k-1} js_j\tilde{\tau}_k^{j-1} = \mathcal{O}\left(\frac{1}{k^3}\right) \qquad \text{and that} \qquad B(k) = \sum_{k-\iota_k}^{k-1} js_j\tilde{\tau}_k^{j-1} = \frac{1}{e-1} + o(1).$$

It follows that

$$ks_k\tilde{\tau}_k^{k-1} > 1 - 5\tilde{\tau}_k - \sum_{j=4}^{k-1} js_j\tilde{\tau}_k^{j-1} = 1 - \frac{1}{e-1} + o(1) = \frac{e-2}{e-1} + o(1).$$

Hence for any $\alpha < \frac{e-2}{e-1}$, there exists $k(\alpha)$ such that for any $k \geq k(\alpha)$, we have $k\,s_k\,\tilde{\tau}_k^{k-1} > \alpha$, and therefore $\tilde{\tau}_k > \left(\frac{\alpha}{k\,s_k}\right)^{\frac{1}{k-1}}$. To conclude the proof, we plug in the upper bound on s_k from Lemma 6. $\qquad\square$

Lemma 8. *The quantity $A(k) = \sum_{j=4}^{k-\iota_k-1} js_j\tilde{\tau}_k^{j-1}$ defined in the proof of Proposition 7 satisfies $A(k) = \mathcal{O}\left(\frac{1}{k^3}\right)$.*

Proof. It is convenient to define $b_j = j\,s_j$. For any k, since $\tilde{\tau}_k < e/k$, $a_j = b_j\,e^{j-1}\,k^{1-j}$ is an upper bound on $j\,s_j\,\tilde{\tau}_k^{j-1}$, so that $A(k) \leq \sum_{j=4}^{k-\iota_k-1} a_j$. In what follows, we prove that $\sum_{j=4}^{k-\iota_k-1} a_j = \mathcal{O}\left(\frac{1}{k^3}\right)$ (which is enough to conclude, since $A(k) > 0$).

We claim that for some integer j_0, the sequence $(b_j)_{j\geq j_0}$ is log-convex. Indeed, for any $j \geq 6$, $\frac{b_j^2}{b_{j-1}b_{j+1}} = \frac{j^2}{(j-1)(j+1)}\frac{s_j^2}{s_{j+1}s_{j-1}}$, and Equation (4) then gives

$$\frac{b_j^2}{b_{j-1}b_{j+1}} \leq \frac{j^2}{(j-1)(j+1)}\frac{j!^2\left(1 - \frac{4}{j} + \frac{2}{j(j-1)}\right)^2}{(j-1)!(j+1)!\left(1 - \frac{4}{j+1}\right)\left(1 - \frac{4}{j-1}\right)} = 1 - \frac{1}{j} + \mathcal{O}\left(\frac{1}{j^2}\right).$$

In particular, there exists an integer $j_0 \geq 6$ such that for any $j \geq j_0$, $\frac{b_j^2}{b_{j-1}b_{j+1}} < 1$ and therefore the sequence $(b_j)_{j\geq j_0}$ is log-convex.

Now, note that for any k, $(a_j)_{j\geq j_0}$ is also log-convex, since $\frac{a_j^2}{a_{j-1}a_{j+1}} = \frac{b_j^2}{b_{j-1}b_{j+1}}$ for all j. The reason for considering the sequence (b_j) instead of (a_j) in the first place is to ensure that j_0 does not depend on k, although the definition of $a_j = j\,s_j\,e^{j-1}\,k^{1-j}$ depends on k.

Log-convex sequences are decreasing down to a given minimum then increasing, and therefore are bounded from above by the values reached at the extremities. Thus for all $j \in \{j_0, \ldots, k - \iota_k - 1\}$, $a_j \leq \max\{a_{j_0}, a_{k-\iota_k-1}\} \leq a_{j_0} + a_{k-\iota_k-1}$. Consequently,

$$\sum_{j=4}^{k-\iota_k-1} a_j = \sum_{j=4}^{j_0-1} a_j + \sum_{j=j_0}^{k-\iota_k-1} a_j \leq \sum_{j=4}^{j_0-1} a_j + k\,a_{j_0} + k\,a_{k-\iota_k-1},$$

and the result will follow if we find adequate upper bounds on each on these three terms, which we now do.

For any $j \in \{4, \ldots j_0 - 1\}$, we have $a_j = j\,s_j\,e^{j-1}\,k^{1-j} \leq jj!\,e^{j-1}\,k^{1-j} \leq j_0j_0!\,e^{j_0-1}\,k^{-3}$ so that $\sum_{j=4}^{j_0-1} a_j \leq j_0^2 j_0!\,e^{j_0-1}\,k^{-3} = \mathcal{O}(k^{-3})$.

For the term $k\,a_{j_0}$, we have $k\,a_{j_0} = j_0\,s_{j_0}\,e^{j_0-1}\,k^{2-j_0} = \mathcal{O}(k^{-3})$ since $j_0 \geq 6$. Using Lemma 6 and the fact that for all $x \in (0,1)$, $\log(1-x) < -x$, we obtain the bound for the

last term. More precisely, we have:

$$
\begin{aligned}
k\,a_{k-\iota_k-1} &\le k^2 \cdot s_{k-\iota_k-1} \cdot e^{k-\iota_k-2} \cdot k^{2-k+\iota_k} \\
&\le k^2 \cdot \sqrt{2\pi} \cdot (k-\iota_k-1)^{k-\iota_k-1/2} \cdot e^{-k+\iota_k-1} \cdot e^{k-\iota_k-2} \cdot k^{2-k+\iota_k} \\
&\le \frac{\sqrt{2\pi}}{e^3} k^{7/2} \cdot \left(1 - \frac{\iota_k+1}{k}\right)^{k-\iota_k-1/2} \\
&\le \frac{\sqrt{2\pi}}{e^3} k^{7/2} \cdot \exp\left((k-\iota_k-1/2)\log\left(1 - \frac{\iota_k+1}{k}\right)\right) \\
&\le \frac{\sqrt{2\pi}}{e^3} k^{7/2} \cdot \exp\left(-\frac{(k-\iota_k-1/2)(\iota_k+1)}{k}\right).
\end{aligned}
$$

The quantity in the exponential is asymptotically equivalent to $-\iota_k = -\lfloor k^{\frac{1}{3}} \rfloor$. Hence $k\,a_{k-\iota_k-1}$ decreases super-polynomially fast toward 0, and is therefore a $\mathcal{O}(k^{-3})$ too. $\qquad\square$

Lemma 9. *The quantity $B(k) = \sum_{k-\iota_k}^{k-1} j s_j \tilde{\tau}_k^{j-1}$ defined in the proof of Proposition 7 satisfies $B(k) = \frac{1}{e-1} + o(1)$.*

Proof. With the change of variable $i = k - j$, we can write $B(k) = \sum_{i=1}^{\iota_k}(k-i)\,s_{k-i}\,\tilde{\tau}_k^{k-i-1}$. By Lemma 6 and the upper bound on $\tilde{\tau}_k$ proved in Proposition 7, we have

$$
(k-i)\,s_{k-i} \le \frac{\sqrt{2\pi}(k-i)^{k-i+3/2}}{e^{k-i+2}},
$$

$$
\tilde{\tau}_k^{k-i-1} \le \frac{e^{k-i-1}}{k^{k-i-1}}\left(\frac{e^3}{\sqrt{2\pi}\,k^{3/2}\,(k-4)}\right)\cdot\left(\frac{e^3}{\sqrt{2\pi}\,k^{3/2}\,(k-4)}\right)^{\frac{-i}{k-1}}.
$$

Therefore $(k-i)\,s_{k-i}\,\tilde{\tau}_k^{k-i-1} \le \left(1-\frac{i}{k}\right)^{k-i+3/2}\left(e^{-3}\sqrt{2\pi}\,k^{3/2}\,(k-4)\right)^{\frac{i}{k-1}} \cdot \frac{1}{1-\frac{4}{k}}$. Since $i \le \iota_k$ and $e^{-3}\sqrt{2\pi}\,k^{3/2}\,(k-4) \ge 1$ as soon as $k \ge 5$, we obtain that for $k \ge 5$,

$$
(k-i)\,s_{k-i}\,\tilde{\tau}_k^{k-i-1} \le \left(1-\frac{i}{k}\right)^{k-i+3/2}\left(e^{-3}\sqrt{2\pi}\,k^{3/2}\,(k-4)\right)^{\frac{\iota_k}{k-1}} \cdot \underbrace{\frac{1}{1-\frac{4}{k}}}_{1+\mathcal{O}(\frac{1}{k})}.
$$

Using again that $\log(1-x) < -x$ for $x \in (0,1)$, we have

$$
(1-i/k)^{k-i+3/2} = e^{(k-i+3/2)\log\left(1-\frac{i}{k}\right)} \le e^{-\frac{(k-i+3/2)i}{k}} = e^{-i+\frac{i^2}{k}-\frac{3i}{2k}}.
$$

Recalling that $i \le \iota_k = \lfloor k^{\frac{1}{3}} \rfloor$, this gives $(1-i/k)^{k-i+3/2} \le e^{-i}\exp(k^{-1/3}) = e^{-i}(1+o(1))$. Proceeding similarly, the middle term satisfies

$$
\left(e^{-3}\sqrt{2\pi}\,k^{3/2}\,(k-4)\right)^{\frac{\iota_k}{k-1}} = 1 + o(1).
$$

Therefore, we obtain $(k-i)\,s_{k-i}\,\tilde{\tau}_k^{k-i-1} \le e^{-i}(1+o(1))$, where the function hidden in the $o(1)$ notation depends on k but not on i. Consequently, summing over i, we obtain

$$
B(k) \le \left(\sum_{i=1}^{\lambda_k} e^{-i}\right)(1+o(1)) \le \left(\sum_{i=1}^{\infty} e^{-i}\right)(1+o(1)) = \frac{1+o(1)}{e-1} \quad \text{as claimed.} \qquad\square
$$

Theorem 10 (Bounds for ρ_k). *There exists a constant β such that for any $\alpha < \frac{e-2}{e-1}$, there exist $k(\alpha, \beta)$ such that for any $k \geq k(\alpha, \beta)$,*

$$\frac{e}{k} \left(\frac{\alpha e^3}{\sqrt{2\pi}\, k^{5/2}} \right)^{\frac{1}{k-1}} \left(1 - \frac{\beta}{k} \right) < \rho_k < \frac{e}{k} \left(\frac{e^3}{\sqrt{2\pi}\, k^{3/2}(k-4)} \right)^{\frac{1}{k-1}}.$$

Consequently, $\rho_k = \frac{e}{k} \left(1 - \frac{5}{2} \frac{\log k}{k} + \mathcal{O}(\frac{1}{k}) \right)$.

Proof. The upper bound is immediate from the bound $\rho_k < \tilde{\tau}_k$ and Proposition 7.

For the lower bound, we start from $\rho_k = \tau_k - \Lambda_k(\tau_k)$. The definitions of $\tilde{\tau}_k$ and Λ_k give $\rho_k = \tilde{\tau}_k \left(1 - \frac{2\tilde{\tau}_k}{1+\tilde{\tau}_k} - \sum_{j=4}^{k} s_j \tilde{\tau}_k^{j-1} \right)$. Our main step is to deduce from this equality that $\rho_k \geq \tilde{\tau}_k(1 - \beta/k)$ for some constant β. The lower bound will then follow from Proposition 7.

As in the proof of Proposition 7, we leverage upper bounds on $\tilde{\tau}_k$ to build a lower bound on $1 - \frac{2\tilde{\tau}_k}{1+\tilde{\tau}_k} - \sum_{j=4}^{k} s_j \tilde{\tau}_k^{j-1}$. In this case, we use $\frac{2\tilde{\tau}_k}{1+\tilde{\tau}_k} \leq 2\tilde{\tau}_k \leq 2\frac{e}{k}$, and we will bound the summation by splitting the sum at the same place:

$$\sum_{j=4}^{k} s_j\, \tilde{\tau}_k^{j-1} = \sum_{j=4}^{k-\iota_k-1} s_j\, \tilde{\tau}_k^{j-1} + \sum_{j=k-\iota_k}^{k-1} s_j\, \tilde{\tau}_k^{j-1} + s_k\, \tilde{\tau}_k^{k-1}.$$

Even though it is not the same summation, we can re-use the bounds from Lemmas 8 and 9. Indeed,

$$\sum_{j=4}^{k-\iota_k-1} s_j\, \tilde{\tau}_k^{j-1} \leq \sum_{j=4}^{k-\iota_k-1} j\, s_j\, \tilde{\tau}_k^{j-1} = A(k) = \mathcal{O}\left(\frac{1}{k^3} \right)$$

$$\text{and} \quad \sum_{j=k-\iota_k}^{k-1} s_j\, \tilde{\tau}_k^{j-1} \leq \sum_{j=k-\iota_k}^{k-1} \frac{j}{k-\iota_k} s_j\, \tilde{\tau}_k^{j-1} = \frac{B(k)}{k-\iota_k} = \mathcal{O}\left(\frac{1}{k} \right).$$

Finally, Proposition 7 ensures that $k\, s_k\, \tilde{\tau}_k^{k-1} \leq 1$, and we obtain $\frac{2\tilde{\tau}_k}{1+\tilde{\tau}_k} + \sum_{j=4}^{k} s_j \tilde{\tau}_k^{j-1} = \mathcal{O}\left(\frac{1}{k} \right)$. It follows that for some β, there exists $k(\beta)$ such that when $k \geq k(\beta)$ we have:

$$\frac{2\tilde{\tau}_k}{1+\tilde{\tau}_k} + \sum_{j=4}^{k} s_j \tilde{\tau}_k^{j-1} \leq \frac{\beta}{k} \quad \text{and hence} \quad \rho_k \geq \tilde{\tau}_k \left(1 - \frac{\beta}{k} \right),$$

which together with Proposition 7 proves the lower bound.

To obtain the claimed asymptotic estimate of ρ_k, it is enough to observe that both the

upper and the lower bound behave like $\frac{e}{k}\left(1 - \frac{5}{2}\frac{\log k}{k} + \mathcal{O}(\frac{1}{k})\right)$. More precisely,

$$\left(\frac{\alpha e^3}{\sqrt{2\pi}\,k^{5/2}}\right)^{\frac{1}{k-1}} = \exp\left(\frac{\log(k^{-5/2}) + cst}{k-1}\right) = \exp\left(-\frac{5}{2}\frac{\log k}{k-1} + \frac{cst}{k-1}\right)$$

$$= 1 - \frac{5}{2}\frac{\log k}{k} + \mathcal{O}\left(\frac{1}{k}\right)$$

so that $\left(\frac{\alpha e^3}{\sqrt{2\pi}\,k^{5/2}}\right)^{\frac{1}{k-1}}\left(1 - \frac{\beta}{k}\right) = 1 - \frac{5}{2}\frac{\log k}{k} + \mathcal{O}\left(\frac{1}{k}\right)$

and $\left(\frac{e^3}{\sqrt{2\pi}\,k^{3/2}(k-4)}\right)^{\frac{1}{k-1}} = \exp\left(\frac{\log(k^{-5/2}) + \log(\frac{1}{1-4/k}) + cst}{k-1}\right)$

$$= 1 - \frac{5}{2}\frac{\log k}{k} + \mathcal{O}\left(\frac{1}{k}\right). \qquad \square$$

It was known in [10] that $\rho_k = \frac{e}{k}(1 + o(1))$, but we are able to produce a more precise estimate. We require this precision when we consider the limit as $k \to \infty$.

Looking at the asymptotic estimate of $P_n^{(k)}$ provided by Theorem 5, and aiming at obtaining an upper bound on this estimates, the only missing piece is a lower bound on $\Lambda_k''(\tau_k)$. The definition of Λ_k (see Theorem 5) gives

$$\Lambda_k''(x) = \frac{2}{(1-x)^3}\left(1 + \sum_{j=4}^{k} j s_j \left(\frac{x}{1-x}\right)^{j-1} + \frac{1}{2(1-x)}\sum_{j=4}^{k} j(j-1)s_j\left(\frac{x}{1-x}\right)^{j-2}\right)$$

$$\geq \frac{2}{(1-x)^3} \text{ for all } x \in (0,1),$$

and therefore the series expansion of $(1-x)^{-3}$ ensures that $\Lambda_k''(\tau_k) \geq 2 + 6\tilde{\tau}_k$. We could expand this expression further, and use lower bounds on $\tilde{\tau}_k$, but it turns out that for our purposes, the bound $\Lambda_k''(\tau_k) \geq 2$ is sufficient.

Finally, we have all of the elements to find an upper bound for the asymptotic estimate of $P_n^{(k)}$.

Theorem 11. *For any fixed k, as n tends to infinity, $P_n^{(k)}$ behaves like $\frac{\gamma_k}{(1-\tau_k)^2}\rho_k^{-n}n^{-3/2}$, where where $\gamma_k = \sqrt{\frac{\rho_k}{2\pi\Lambda_k''(\tau_k)}}$. And when k grows to infinity, this estimates is no larger than*

$$\frac{1}{(1 - \frac{e}{k})^2}\sqrt{\frac{e}{4k\pi}}\left(\frac{k}{e}\right)^n\left(1 + \frac{5}{2}\frac{\log k}{k} + \mathcal{O}\left(\frac{1}{k}\right)\right)^n n^{-3/2} \qquad (11)$$

Proof. Theorem 1 ensures that $P_n^{(k)} \sim \frac{\gamma_k}{(1-\tau_k)^2}\rho_k^{-n}n^{-3/2}$ as $n \to \infty$. From Proposition 7 and Theorem 10, assuming now that k is large enough, we have:

- $\tau_k \leq \tilde{\tau}_k \leq \frac{e}{k}$, hence $\frac{1}{(1-\tau_k)^2} \leq \frac{1}{(1-\frac{e}{k})^2}$;

- $\rho_k \leq \frac{e}{k}$ and $\Lambda_k''(\tau_k) \geq 2$, hence $\gamma_k \leq \sqrt{\frac{e}{4k\pi}}$;

- and $\rho_k^{-n} = \left(\frac{e}{k}\right)^{-n}\left(1 - \frac{5}{2}\frac{\log k}{k} + \mathcal{O}\left(\frac{1}{k}\right)\right)^{-n} = \left(\frac{k}{e}\right)^n\left(1 + \frac{5}{2}\frac{\log k}{k} + \mathcal{O}\left(\frac{1}{k}\right)\right)^n$. $\qquad \square$

In the limit, Stirling's approximation. Our analysis of $\mathcal{P}$ has brought together two classic asymptotic facts. The asymptotic growth of each $\mathcal{P}^{(k)}$ is of the form $P_n^{(k)} \sim \gamma \rho^{-n} n^{-3/2}$ for some real valued ρ and γ. (Note that although $\mathcal{P}^{(k)}$ is not a simple variety of trees, the asymptotic behaviour of $P_n^{(k)}$ is of the same form as for such families.) But for the full class $\mathcal{P}$, the classical Stirling's approximation of $n!$ gives $P_n \sim \left(\frac{n}{e}\right)^n \sqrt{2\pi n}$. Subtle analysis is required to reconcile these two estimates, and our upper bound on the asymptotic estimate of $P_n^{(k)}$ allows us to take a first step in this direction.

For any n, the strong interval tree of a permutation of size n contains no prime node of arity larger than n. Thus, if $k \geq n$, $\mathcal{P}_n^{(k)}$ contains all trees corresponding to permutations of size n, and hence $P_n^{(k)} = n!$ for $k \geq n$. Now, forget for a moment that the estimates for $\mathcal{P}_n^{(k)}$ as $n \to \infty$ is valid only for fixed k, and consider the expression in (11) with $k = n$. It simplifies as follows:

$$\frac{1}{(1 - \frac{e}{n})^2} \sqrt{\frac{e}{4n\pi}} \left(\frac{n}{e}\right)^n \left(1 + \frac{5}{2}\frac{\log n}{n} + \mathcal{O}\left(\frac{1}{n}\right)\right)^n n^{-3/2} = \sqrt{\frac{e}{4\pi}} \left(\frac{n}{e}\right)^n \sqrt{n} \cdot (1 + o(1)).$$

This is a constant times Stirling's formula (the constant being $\sqrt{\frac{e}{8\pi^2}}$). And this is encouraging: indeed, even though setting $k = n$ was not justified, these purely formal manipulations do reconcile the two asymptotics, up to a constant factor.

However, if we follow the same route for $P_n^{(2n)}$, which is also $n!$, the quantity in (11) gains an unwanted factor of 2^n. This does not contradict the correctness of our asymptotic form for fixed k. It rather emphasizes that it is an open problem to develop asymptotic formulas when k is a function of n, and they go to infinity together. This will require a very delicate treatment of the bounds, a much stronger understanding of how to take the limit as $k \to \infty$, and a return to the analytic inversion and transfer theorems to study how the error terms depend on k.

5.2 A simpler case: when Λ is analytic

The example developed above is meant to illustrate a strategy to enumerate classes $\mathcal{C}$ of trees whose generating functions satisfy $C(z) = z + \Lambda(C(z))$, in particular in the case where Λ is not analytic.

The method we proposed is to consider a sequence of analytic Λ_k (obtained for instance by truncations at order k) such that as formal power series, $\lim_{k \to \infty} \Lambda_k = \Lambda$, and to study first the sets $\mathcal{C}^{(k)}$ of Λ_k-trees.

The next step, which is for the moment not accessible to us, is to obtain results about $\mathcal{C}$ from what is known on the classes $\mathcal{C}^{(k)}$. We view the following questions as particularly interesting in this regard: Can we describe conditions so that the limit of the asymptotics of the subclasses tends to the asymptotics of the whole class? To which extent are the parameter formulas valid under the limit? We hope that our work will help developing techniques to obtain information on $\mathcal{C}$ by letting k go to infinity.

The difficulty here lies in Λ being not analytic. Notice however that the same filtration by truncations at order k may also be defined when Λ is analytic. Next, we show that in this case, we obtain the correct asymptotic formula when taking the limit as k tends to infinity, *i.e.* that limits in n and k commute.

Consider a series $\Lambda(x) = \sum_{i \geq 2} \lambda_i x^i$ with non-negative coefficients. And for all $k \geq 2$, define $\Lambda_k(x) = \sum_{i=2}^{k} \lambda_i x^i$. We denote respectively by $\mathcal{C}$ and $\mathcal{C}^{(k)}$ the classes of trees whose generating functions satisfy

$$C(z) = z + \Lambda(C(z)) \qquad \text{and} \qquad C^{(k)}(z) = z + \Lambda_k(C^{(k)}(z)).$$

We make the following assumptions: Λ is analytic at 0, and denoting R the radius of convergence of Λ, there is a unique solution $\tau \in (0, R)$ to the equation $\Lambda'(x) = 1$. Then, it follows from Theorem 1 that $C(z)$ is analytic at 0, has a unique dominant singularity $\rho = \tau - \Lambda(\tau)$, and, assuming further that $C(z)$ is aperiodic, that the coefficients of this series behave asymptotically like $[z^n] C(z) \sim \sqrt{\frac{\rho}{2\pi \Lambda''(\tau)}} \cdot \frac{\rho^{-n}}{n^{3/2}}$.

Lemma 12. *For all $k \geq 2$, there exists a unique $\tau_k \in (0, +\infty)$ such that $\Lambda_k'(\tau_k) = 1$. Moreover, the sequence $(\tau_k)_{k \geq 2}$ is decreasing and converges to τ as k goes to infinity.*

Proof. Fix some $k \geq 2$. From the definition of $\Lambda_k(x) = \sum_{i=2}^{k} \lambda_i x^i$, it follows that $\Lambda_k'(x)$ is a polynomial with non-negative coefficients, increasing from 0 to $+\infty$ when x varies from 0 to $+\infty$. Moreover, its derivative Λ_k'' being nowhere zero on $(0, +\infty)$, Λ_k' is strictly increasing. Therefore, there is a unique positive solution to $\Lambda_k'(x) = 1$, that we denote τ_k.

The fact that the sequence $(\tau_k)_{k \geq 2}$ is decreasing is immediate from

$$1 = \Lambda_k'(\tau_k) = \sum_{i=2}^{k} i \lambda_i \tau_k^{i-1} \leq \sum_{i=2}^{k+1} i \lambda_i \tau_k^{i-1} = \Lambda_{k+1}'(\tau_k)$$

and the fact that Λ_{k+1}' is increasing.

The sequence $(\tau_k)_{k \geq 2}$ being decreasing and non-negative, it admits a limit, that we denote ℓ. We want to prove that $\ell = \tau$, *i.e.*, that $\Lambda'(\ell) = 1$. First, for all k, $\ell \leq \tau_k$, so that $\Lambda_k'(\ell) \leq 1$. Moreover, the sequence $(\Lambda_k'(\ell))$ is increasing (we keep adding non-negative terms), and thus converges towards a limit that is no larger than 1. This limit being $\Lambda'(\ell)$, we obtain that $\Lambda'(\ell) \leq 1$. Second, since $(\tau_k)_{k \geq 2}$ is decreasing towards $\tau < R$, we get that for k large enough, Λ' is defined in τ_k. For any such large k, we have

$$1 = \Lambda_k'(\tau_k) = \sum_{i=2}^{k} i \lambda_i \tau_k^{i-1} \leq \sum_{i \geq 2} i \lambda_i \tau_k^{i-1} = \Lambda'(\tau_k),$$

and taking the limit in k gives $\Lambda'(\ell) \geq 1$. $\qquad \square$

Lemma 13. *For all $k \geq 2$, define $\rho_k = \tau_k - \Lambda_k(\tau_k)$. The sequence $(\rho_k)_{k \geq 2}$ converges to ρ as k goes to infinity.*

Proof. It is enough to prove that $(\Lambda_k(\tau_k))$ converges to $\Lambda(\tau)$. Like in the previous proof, since $(\tau_k)_{k \geq 2}$ is decreasing towards $\tau < R$, we get that for k large enough, Λ is defined in τ_k. For such large k, we have

$$\sum_{j=2}^{k} \lambda_k \tau^k \leq \sum_{j=2}^{k} \lambda_k \tau_k^k \leq \sum_{j \geq 2} \lambda_k \tau_k^k \quad \text{that is to say } \Lambda_k(\tau) \leq \Lambda_k(\tau_k) \leq \Lambda(\tau_k).$$

Because $(\Lambda_k(\tau))$ and $(\Lambda(\tau_k))$ share the same limit $\Lambda(\tau)$ as k goes to infinity, we obtain that $\lim_{k \to +\infty} \Lambda_k(\tau_k) = \Lambda(\tau)$. $\qquad \square$

From Theorem 1, we obtain $[z^n]C^{(k)}(z) \sim \sqrt{\frac{\rho_k}{2\pi\Lambda_k''(\tau_k)}} \cdot \frac{\rho_k^{-n}}{n^{3/2}}$, and the two lemmas above ensure that taking the limit in k in this estimates give $\sqrt{\frac{\rho}{2\pi\Lambda''(\tau)}} \cdot \frac{\rho^{-n}}{n^{3/2}}$. In addition, $\lim_{k\to+\infty} C^{(k)}(z) = C(z)$ from which we get $[z^n]\lim_{k\to+\infty} C^{(k)}(z) \sim \sqrt{\frac{\rho}{2\pi\Lambda''(\tau)}} \cdot \frac{\rho^{-n}}{n^{3/2}}$. In other words, taking the limit in k in the estimate of the number of trees of size n in $\mathcal{C}^{(k)}$ gives the estimates of the number of trees of size n in $\mathcal{C}$.
