Employing lattice theory, I examine in greater detail the structure of the space of assertions and questions demonstrating that the symmetries between the logical relations in each of the spaces derive directly from the lattice structure. Furthermore, I show that while symmetries between the spaces exist, the two lattices are not isomorphic. The lattice of assertions is described by a Boolean lattice $\mathbf{2}^N$, whereas the lattice of assuredly real questions is shown to be a sublattice of the free distributive lattice $\mathbf{FD}(N) = \mathbf{2}^{\mathbf{2}^N}$. Thus there does not exist a one-to-one mapping of assertions to questions, there is no reflection symmetry between the two spaces, and questions in general do not possess complements. Last, with these lattice structures in mind, I discuss the relationship between probability, relevance, and entropy.

"*Man has made some machines that can answer questions provided the facts are profusely stored in them, but we will never be able to make a machine that will ask questions. The ability to ask the right question is more than half the battle of finding the answer.*"

- Thomas J. Watson (1874-1956)

INTRODUCTION

It was demonstrated by Richard T. Cox [1, 2] that probability theory represents a generalization of Boolean implication to a degree of implication represented by a real number. This insight has placed probability theory on solid ground as a calculus for conducting inductive inference. While at this stage this work is undoubtedly his greatest contribution, his ultimate paper, which takes steps to derive the logic of questions in terms of the set of assertions that answer them, may prove yet to be the most revolutionary. While much work has been done extending and applying Cox's results [3-12], the mathematical structure of the space of questions remains poorly understood. In this paper I employ lattice theory to describe the structure of the space

of assertions and demonstrate how logical implication on the Boolean lattice provides the framework on which the calculus of inductive inference is constructed. I then introduce questions by following Cox [13] who defined a question in terms of the set of assertions that can answer it. The lattice structure of questions is then explored and the calculus for manipulating the relevance of a question to an unresolved issue is examined.

The first section is devoted to the formalism behind the concepts of partially ordered sets and lattices. The second section deals with the logic of assertions and introduces Boolean lattices. In the third section, I introduce the definition of a question and introduce the concept of an ideal question. From the set of ideal questions I construct the entire question lattice identifying it as a free distributive lattice. Assuredly real questions are then shown to comprise a sublattice of the entire lattice of questions. In the last section I discuss the relationship between probability, relevance, and entropy in the context of the lattice structure of these spaces.

FORMALISM

Partially Ordered Sets

In this section I begin with the concept of a partially ordered set, called a *poset*, which is defined as a set with a binary ordering relation denoted by $a \le b$, which satisfies for all a, b, c [14]:

P1.	For all a, $a \le a$.	(Reflexive)
P2.	If $a \le b$ and $b \le a$, then $a = b$	(Antisymmetry)
P3.	If $a \le b$ and $b \le c$, then $a \le c$	(Transitivity)

Alternatively one can write $a \le b$ as $b \ge a$ and read "b contains a" or "b includes a". If $a \le b$ and $a \ne b$ one can write $a < b$ and read "a is less than b" or "a is properly contained in b". Furthermore, if $a < b$, but $a < x < b$ is not true for any x in the poset P, then we say that "b *covers* a", written $a \prec b$. In this case b can be considered an immediate superior to a in a hierarchy. The set of natural numbers {1, 2, 3, 4, 5} along with the binary relation "less than or equal to" $\le$ is an example of a poset. In this poset, the number 3 covers the number 2 as $2 < 3$, but there is no number x in the set where $2 < x < 3$. This covering relation is useful in constructing diagrams to visualize the structure imposed on these sets by the binary relation.

To demonstrate the construction of these diagrams, consider the poset defined by the powerset of $\{a,b,c\}$ with the binary relation $\subseteq$ read "is a subset of", $P = \left(\left\{\varnothing, \{a\}, \{b\}, \{c\}, \{a,b\}, \{b,c\}, \{a,c\}, \{a,b,c\}\right\}, \subseteq\right)$ where the powerset $\wp(X)$ of a set X is the set of all possible subsets of X. As an example, it is true that $\{a\} \subseteq \{a,b,c\}$, read "$\{a\}$ is included in $\{a,b,c\}$". Furthermore, it is true that $\{a\} \subset \{a,b,c\}$, read "$\{a\}$ is properly contained in $\{a,b,c\}$" as $\{a\} \subseteq \{a,b,c\}$, but

$\{a\} \neq \{a,b,c\}$. However, $\{a,b,c\}$ does not cover $\{a\}$ as $\{a\} \subset \{a, b\} \subset \{a,b,c\}$. We can construct a diagram (Figure 1) by choosing two elements *x* and *y* from the set, and writing *y* above *x* when $x \subset y$. In addition, we connect two elements *x* and *y* with a line when *y* covers *x*, $x \prec y$.

Posets also possess a duality in the sense that the converse of any partial ordering is itself a partial ordering [14]. This is known as the *duality principle* and can be understood by changing the ordering relation "is included in" to "includes" which equates graphically to flipping the poset diagram upside-down.

With these examples of posets in mind, I must briefly describe a few more concepts. If one considers a subset *X* of a poset *P*, we can talk about an element $a \in P$ that contains every element $x \in X$; such an element is called an *upper bound* of the subset *X*. The *least upper bound*, or l.u.b., is an element in *P*, which is an upper bound of *X* and is contained in every other upper bound of *X*. Thus the l.u.b. can be thought of as the immediate successor to the subset *X* as one moves up the hierarchy. Dually we can define the *greatest lower bound*, or g.l.b. The *least element* of a subset *X* is an element $a \in X$ such that $a \leq x$ for all $x \in X$. The *greatest element* is defined dually.

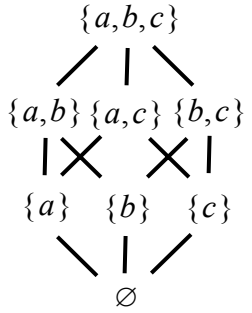

FIGURE 1. The poset $P = \left(\{\varnothing, \{a\}, \{b\}, \{c\}, \{a,b\}, \{b,c\}, \{a,c\}, \{a,b,c\}\}, \subseteq\right)$ results in the diagram shown here. The binary relation $\subseteq$ dictates the height of an element in the diagram. The concept of covering allows us to draw lines between a pair of elements signifying that the higher element in the pair is an immediate successor in the hierarchy. Note that $\{a\}$ is covered by two elements. These diagrams nicely illustrate the structural properties of the poset. The element $\{a,b,c\}$ is the greatest element of *P* and $\varnothing$ is the least element of *P*.

Lattices

The next important concept is the *lattice*. A lattice is a poset *P* where every pair of elements *x* and *y* has a least upper bound called the *join*, denoted as $x \vee y$, and a greatest lower bound called the *meet*, denoted by $x \wedge y$. The meet and join obey the following relations [14]:

L1.	$x \wedge x = x, \quad x \vee x = x$	(Idempotent)
L2.	$x \wedge y = y \wedge x, \quad x \vee y = y \vee x$	(Commutative)
L3.	$x \wedge (y \wedge z) = (x \wedge y) \wedge z, \quad x \vee (y \vee z) = (x \vee y) \vee z$	(Associative)
L4.	$x \wedge (x \vee y) = x \vee (x \wedge y) = x$	(Absorption)

In addition, for elements x and y that satisfy $x \le y$ their meet and join satisfy *the consistency relations*

C1. $x \wedge y = x$ (x is the greatest lower bound of x and y)
C2. $x \vee y = y$ (y is the least upper bound of x and y).

The relations L1-4 above come in pairs related by the duality principle; as they hold equally for a lattice L and its dual lattice (denoted L^{∂}), which is obtained by reversing the ordering relation thus exchanging upper bounds for lower bounds and hence exchanging joins and meets. Note that the meet and join are generally defined for all posets satisfying the definition of a lattice; even though the notation is the same they should not be confused with the logical conjunction and disjunction, which refer to a specific ordering relation. I will get to how they are related and we will see that lattice theory provides a general framework that clears up some mysteries surrounding the space of assertions and the space of questions.

THE LOGIC OF ASSERTIONS

Boolean Lattices

I introduce the concept of a Boolean lattice, which possesses structure in addition to L1-4. A Boolean lattice is a *distributive lattice* satisfying the following identities for all x, y, z:

B1. $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$
$x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z)$ (Distributive)

Again the two identities are related by the duality principle. Last the Boolean lattice is a *complemented lattice*, such that each element x has one and only one *complement* $\sim x$ that satisfies [14]:

B2. $x \wedge \sim x = O \qquad x \vee \sim x = I$
B3. $\sim (\sim x) = x$
B4. $\sim (x \wedge y) = \sim x \vee \sim y \qquad \sim (x \vee y) = \sim x \wedge \sim y$

where O and I are the least and greatest elements, respectively, of the lattice. Thus a Boolean lattice is a *complemented distributive lattice*.

We now consider a specific application where the elements a and b are logical assertions and the ordering relation is $x \le y \equiv x \rightarrow y$, read "$x$ implies y". The logical operations of conjunction and disjunction can be used to generate a set of four logical statements, which with the binary relation "implies" forms a Boolean lattice displayed in Figure 2. It can be shown that the meet of a and b, written $a \wedge b$, is identified with

the logical conjunction of *a* and *b*, and the join of *a* and *b*, written $a \vee b$, is identified with the logical disjunction of *a* and *b*. I will require that the lattice be complemented, which means that the complement of *a* must be *b*, $\sim a = b$, and vice versa. If we require the assertions to be exhaustive, then either *a* or *b* are true, and their join, the disjunction $a \vee b$, must always be true. By B2 $a \vee b$ must be the greatest element and is thus *I*, which in logic is called *the truism*, as it is always true. Similarly their meet, the conjunction $a \wedge b$, is the least element *O* and when *a* and *b* are mutually exclusive *O* must always be false, earning it the name *the absurdity*.

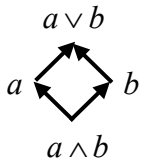

FIGURE 2. The lattice diagram formed from two assertions a and b. In this diagram I chose to use arrows to emphasize the direction of implication among the assertions in the lattice.

The symbol for the truism I mirrors the I used by Jaynes to symbolize "one's prior information" [15]. In fact, in an inference problem, if one believes that one of a set of assertions is true then one's prior knowledge consists, in part, of the fact that the disjunction of the entire set of assertions is true. By fortuitous circumstance the notation of lattice theory agrees quite nicely with the notation used by Jaynes.

Deductive inference refers to the process where one knows that an assertion a is true, and deduces that any assertion reached by a chain of arrows must also be true. If for two assertions *x* and *y* elements of a lattice *L*, *x* is included in *y*, $x \leq y$, we say that *x* implies *y*, denoted $x \rightarrow y$.

If a set of assertions used to generate the lattice is a mutually exclusive set then all possible conjunctions of these assertions are equal to the absurdity,

$$x \wedge y = O \quad \textit{for all } x, y \in \quad : x \neq y .$$

These elements that cover O are called *atoms* or *points*. As all other elements are formed from joins of these atoms, they are called generators or generating elements and the lattice is called an *atomic lattice*. The total number of assertions in the atomic Boolean lattice is 2^N, where N is the number of atoms. These Boolean lattices can be named according to the number of atoms, $\mathbf{2}^N$. The first three atomic Boolean lattices are shown in Figure 3. In these figures one can visualize the curious fact of logic: the absurdity O implies everything. Also, it is instructive to identify and verify the complements of the generators (eg. in $\mathbf{2}^2$, $\sim a = b$, and in $\mathbf{2}^3$, $\sim a = b \vee c$). These lattices are self-dual as the same lattice structure results by reversing the ordering relation (turning the diagram upside-down) and interchanging meets and joins ($x \vee y$ and $x \wedge y$).

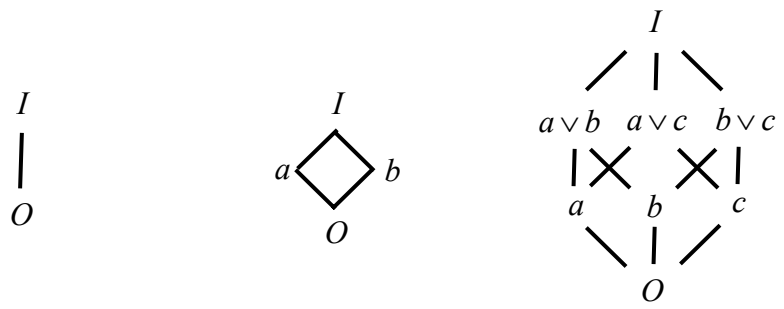

FIGURE 3. Here are the first three atomic Boolean lattices where the upward pointing arrows denoting the property "*is included in*" or "implies" have been omitted. Left: The lattice $\mathbf{2}^1$ where $I = a$. Center: The lattice $\mathbf{2}^2$ generated from two assertions (same as Fig. 2) where $O = a \wedge b$ and $I = a \vee b$. Right: The lattice $\mathbf{2}^3$ generated from three atomic assertions where the conjunction of all three assertions is represented by the absurdity O, and the disjunction of all three assertions is represented by the truism I.

For fun we could consider creating another lattice $\boldsymbol{\Lambda}^N$ where we define each atom λ_i in $\boldsymbol{\Lambda}^N$ from the mapping $\Lambda : b_i \rightarrow \lambda_i = \{b_i\}$ as a set containing a single atomic assertion b_i from $\mathbf{2}^N$. In addition, we map the operations of logical conjunction and disjunction to set intersection and union respectively, that is $(\mathbf{2}^3, \wedge, \vee) \rightarrow (\boldsymbol{\Lambda}^3, \cap, \cup)$. Figure 4 shows $\boldsymbol{\Lambda}^3$ generated from $\mathbf{2}^3$. As we can define a one-to-one and onto mapping (an *isomorphism*) from $\mathbf{2}^3$ to $\boldsymbol{\Lambda}^3$, the lattices $\boldsymbol{\Lambda}^3$ and $\mathbf{2}^3$ are said to be *isomorphic*, which I shall write as $\boldsymbol{\Lambda}^3 = \mathbf{2}^3$. The Boolean nature of the lattice $\boldsymbol{\Lambda}^3$ can be related to a base-2 number system by visualizing each element in the lattice as being labeled with a set of three numbers, each either a one or zero, denoting whether the set contains (1) or does not contain (0) each of the three atoms. $\{a, b, c\}$

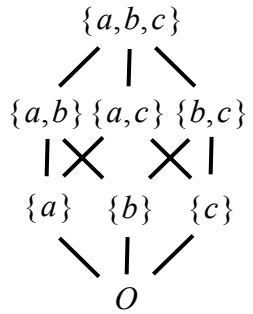

FIGURE 4. The lattice $\boldsymbol{\Lambda}^3$ was generated from $\mathbf{2}^3$ by defining each atom as a set containing a single atomic assertion from $\mathbf{2}^3$, and by replacing the operations of logical conjunction and disjunction with set intersection and union, respectively as in $(\mathbf{2}^3, \wedge, \vee) \rightarrow (\boldsymbol{\Lambda}^3, \cap, \cup)$. Note that in this lattice $I = \{a, b, c\}$ and $O = \varnothing$ (the empty set). As there is a one-to-one and onto mapping of this lattice to the lattice in Fig. 3 (right), they are isomorphic.

Inductive Inference guided by Lattices

Inductive inference derives from deductive inference as a generalization of Boolean implication to a relative degree of implication. In the lattice formalism that this is equivalent to a generalization from inclusion as defined by the binary ordering relation of the poset to a relative degree of inclusion. The degree of implication can be represented as a *real number* [1, 2] denoted $(x \to y)$ defined within a closed interval. Contrast this notation with $x \to y$, which represents the binary ordering relation $x \le y$, "x is included in y". For convenience we choose $(x \to y) \in [0,1]$, where $(x \to y) = 1$ represents the maximal degree of implication with $x \wedge y = x$, which is consistent with $x \to y$, and $(x \to y) = 0$ represents the minimal degree of implication, which is consistent with $x \wedge y = O$. Intermediate values of degree of implication arise from cases where $x \wedge y = z$ with $z \neq x$, $z \neq y$ and $z \neq O$. Thus relative degree of implication is a measure relating arbitrary pairs of assertions in the lattice. Since the binary ordering relation of the poset is all that is needed to define the lattice, there does not exist sufficient structure in the lattice framework to define such a measure. Thus we should expect some form of indeterminacy that will require us to impose additional structure on the space. This manifests itself in the fact that the prior probabilities must be externally defined.

Cox derived relations that the relative degree of implication should follow in order to be consistent with the rules of Boolean logic, i.e. the structure of the Boolean lattice. I will briefly mention the origin of these relations; the original work can be found in [1, 2, 13]. From the associativity of the conjunction of assertions, $(a \to (b \wedge c) \wedge d) = (a \to b \wedge (c \wedge d))$, Cox derived a functional equation, which has as a general solution

$$(a \to b \wedge c)^r = (a \to b)^r \, (a \wedge b \to c)^r , \tag{1}$$

where r is an arbitrary constant. The special relationship between an assertion and its complement results in a relationship between the degree to which a premise a implies b and the degree to which a implies $\sim b$

$$(a \to b)^r + (a \to \sim b)^r = C , \tag{2}$$

where r is the same arbitrary constant in (1) and C as another arbitrary constant. Setting $r = C = 1$ and changing notation so that $p(b \mid a) \equiv (a \to b)$ one sees that (1) and (2) are analogous to the familiar product and sum rules of probability.

$$p(b \wedge c \mid a) = p(b \mid a)\, p(c \mid a \wedge b) \tag{3}$$

$$p(b \mid a) + p(\sim b \mid a) = 1 \tag{4}$$

Furthermore, commutativity of the conjunction with (3) leads to Bayes' Theorem

$$p(b \mid a \wedge c) = p(b \mid a) \frac{p(c \mid a \wedge b)}{p(c \mid a)} \tag{5}$$

These three equations (3)-(5) form the foundation of inductive inference.

THE LOGIC OF QUESTIONS

"*It is not the answer that enlightens, but the question.*"
-Eugene Ionesco (1912-1994)

"*To be, or not to be: that is the question.*"
-William Shakespeare, Hamlet, Act 3 scene 1, (1579)

Defining a Question

Richard Cox [13] defines *a system of assertions* as a set of assertions, which includes every assertion implying any assertion of the set. The *irreducible set* is a subset of the system, which contains every assertion that implies no assertion other than itself. Finally, a *defining set* of a system is a subset of the system, which includes the irreducible set. As an example, consider the lattice $\mathbf{2}^3$ in Figure 3 right. To generate a system of assertions, we will start with the set $\{a,b\}$. The system must also contain all the assertions in the lattice which imply both assertion *a* and assertion *b*. These are all the assertions that can be reached by climbing down the lattice from these two elements. In this case, the lattice is rather small and the only assertion that implies the assertions in this set is *O*, the absurdity. Thus $\{a,b,O\}$ is a system of assertions. The irreducible set is simply the set $\{a,b\}$. Last, there are two defining sets for this system: $\{a,b,O\}$ and $\{a,b\}$. Note that in general there are many defining sets. Given a defining set, one can reduce it to the irreducible set by removing assertions that are implied by another assertion in the defining set, or expand it by including implicants of assertions in the defining set, to the point of including the entire system.

Cox defines a question as the system of assertions that answer that question. Why the system of assertions? The reason is that any assertion that implies another assertion that answers a question is itself an answer to the same question. Thus the system of assertions represents an exhaustive set of possible answers to a given question. Two questions are then equivalent if they are answered by the same system of assertions. This can be easily demonstrated with the questions "*Is it raining?*" and "*Is it not raining?*" Both questions are answered by the statements "*It is raining!*" and "*It is not raining!*", and thus they are equivalent in the sense that they ask the same thing. Furthermore, one can now impose an ordering relation on questions, as some questions may include other questions in the sense that one system of assertions contains another system of assertions as a subset.

Consider the following question: T = "*Who stole the tarts made by the Queen of Hearts all on a summer day?*" This question can be written as a set of all possible statements that answer it. Here I contrive a simple defining set for *T*, which I claim is an exhaustive, irreducible set

$$T \equiv \{a = \text{"}\textit{Alice stole the tarts!}\text{"},\ k = \text{"}\textit{The Knave of Hearts stole the tarts!}\text{"},$$
$$m = \text{"}\textit{The Mad Hatter stole the tarts!}\text{"},\ w = \text{"}\textit{The White Rabbit stole the tarts!}\text{"}\}.$$

This is a fun example as it is not clear from the story[1] that the tarts were even stolen. In the event that no one stole the tarts, the question is answered by no true statement and is called a *vain question* [13]. If there exists a true statement that answers the question, that question is called a *real question*. For the sake of this example, we assume that the question T is real, and consider an alternate question A = "*Did or did not Alice steal the tarts?*" A defining set for this question is

$$A \equiv \{\ a = \text{"}\textit{Alice stole the tarts!}\text{"}\ ,\ \sim a = \text{"}\textit{Alice did not steal the tarts!}\text{"}\ \}.$$

As the defining set of T is exhaustive, the statement $\sim a$ above, which is the complement of a, is equivalent to the disjunction of all the statements in the irreducible set of T except for a, that is $\sim a = k \vee m \vee w$. As the question A is a system of assertions, which includes all the assertions that imply any assertion in its defining set, the system of assertions A must also contain k, m and w as each implies $\sim a$. Thus system of assertions T is a subset of the system of assertions A, and so by answering T, one will have answered A. Of course, the converse is not generally true. In the past has been said [11] that the question A *includes* the question T, but it may be more obvious to see that the question T *answers* the question A. As I will demonstrate, identifying the conjunction of questions with the meet and the disjunction of questions with the join is consistent with the ordering relation "*is a subset of*". This however is dual to the ordering relation intuitively adopted by Cox, "*includes as a subset*", which alone is the source of the interchange between conjunction and disjunction in identifying relations among assertions with relations among questions in Cox's formalism.

With the ordering relation "*is a subset of*" the meet or conjunction of two questions, called the *joint question*, can be shown to be the intersection of the sets of assertions answering each question.

$$A \wedge B \quad \equiv \quad A \cap B\,. \tag{6}$$

It should be noted that Cox's treatment dealt with the case where there the system was not built on an exhaustive set of mutually exclusive atomic assertions. This leads to a more general definition of the joint question [13], which reduces to set intersection in the case of an exhaustive set of mutually exclusive atomic assertions. Similarly, the join or disjunction of two questions, called the *common question*, is defined as the question that the two questions ask in common. It can be shown to be the union of the sets of assertions answering each question

$$A \vee B \quad \equiv \quad A \cup B\,. \tag{7}$$

According to the definitions laid out in the section on posets, the consistency relation states that B includes A, written $A \le B$ (or $A \to B$) if $A \wedge B = A$ and $A \vee B = B$. This is entirely consistent where the ordering relation is "*is a subset of*", and is dual to the convention chosen by Cox[2] where $B \to^{\partial} A$ is equated with $A \le B$ and thus consistent with $A \wedge B = A$ and $A \vee B = B$. As the relation "*is a subset of*" is more

[1] Chapters XI and XII of Alice's Adventures in Wonderland, Lewis Carroll, 1865.

[2] Highlighting the arrow with a ∂ indicates that it is the dual relation, which will be read conveniently as "*B includes A*".

conventional, I will deviate here from Cox's convention and say that "*answering A answers B*" or "*B includes A*", written $A \le B$, or $A \to B$, when $A \wedge B = A$ and $A \vee B = B$. Although the way in which this relation is expressed is contrary to the handful of published works on inductive logic I make this suggestion to assure that this burgeoning field of inductive logic is notationally and conceptually consistent with the more mature field of lattice theory on which it is undoubtedly based.

Notation aside, the concepts I have been discussing are unaltered and can be more easily visualized by considering questions *A* and *T* above. The questions "*Who stole the tarts made by the Queen of Hearts all on a summer day?*" and "*Did or did not Alice steal the tarts?*" jointly ask "*Who stole the tarts made by the Queen of Hearts all on a summer day?*" Whereas they ask, "*Did or did not Alice steal the tarts?*" in common. Therefore $T \subseteq A$, which is $T \le A$, written also as $T \to A$, read either as "*T answers A*" or "*A includes T*". Dually, *A* includes *T* as a subset, written $A \supseteq T$, which is $A \le^{\partial} T$, written also as $A \to^{\partial} T$, and read "*A includes T*".

Next I construct the lattice of questions.

Ideals and Ideal Questions

An *ideal* is a nonvoid subset *J* of a lattice *A* with the properties [14]

I1. $a \in J, \quad x \in A \quad$ where $\quad x \le a \quad$ then $\quad x \in J$

I2. $a \in J, \quad b \in J \quad$ then $\quad a \vee b \in J$

In the case that the lattice A is a lattice of assertions, property I1 above is a necessary and sufficient condition for the set *J* to be a system of assertions. Thus each ideal of a lattice of assertions represents a unique system of assertions, or equivalently a question. For this reason, I call these systems of assertions, which are also ideals, *ideal systems* or *ideal questions*.

Given any assertion *x* in the lattice *A*, one can construct the set q(*x*) of all assertions *y* such that $x \le y$. Thus the function $\mathrm{q}(\bullet)$ takes an assertion to a question. Furthermore, one can show ([14], Theorem 3.3) that the set of all ideals of any lattice *L* ordered by set inclusion forms a lattice $\hat{L}$, and that for a finite lattice $\hat{L}$ is isomorphic to *L*. This is significant, as the space of ideal questions possesses a structure isomorphic to the space of assertions (Figure 5). An inverse mapping can be defined as a function $\mathrm{a}(\bullet)$ that takes an ideal question to an assertion by selecting the greatest element from its system of assertions, so that $\mathrm{a}(\mathrm{q}(x)) = x$. By virtue of this isomorphism, we know that any identities that hold for the lattice *A* shall also hold for the lattice $\hat{Q}$.

At this point the space of assertions looks isomorphic to the space of questions. However, recall that the ideal questions satisfy an additional property I2, which requires that there be a single greatest element in the set. This is not a property required of questions in general by the definition put forward by Cox. Thus there exist additional questions not represented in the lattice $\hat{Q}$. One such question is the binary

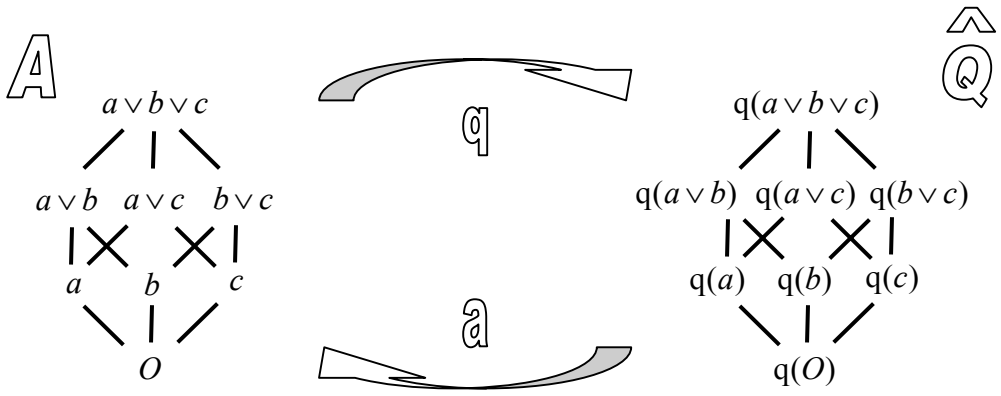

FIGURE 5. The lattice of assertions $A \sim \mathbf{2}^3$ (left) and the lattice $\hat{Q}$ (right) obtained by mapping each element *x* of *A* to the set q(*x*) of all assertions $y \geq x$ and ordering by set inclusion. Note that $\hat{Q}$ and *A* are isomorphic, written as $\hat{Q} = A = \mathbf{2}^3$.

question represented by the defining set $\{a, \sim a\}$. If the space of assertions is again $A = \mathbf{2}^3$ then $\sim a = b \vee c$ and the defining set is equivalently $\{a, b \vee c\}$. However, by property I2, the ideal containing the elements in the defining set must also include $a \vee (b \vee c) = a \vee b \vee c$, which is not contained in the system of assertions. Thus the system $\{a, \sim a\}$ is not an ideal question and is not represented in the lattice $\hat{Q}$.

I now examine the full space of questions in greater detail. As the assertion lattices are $\mathbf{2}^N$, I shall also denote the question lattices according to the cardinality of the atomic assertions N by $\mathbf{Q}(N)$, and the lattice of ideal questions is denoted $\hat{\mathbf{Q}}(N) = \mathbf{2}^N$. If a system of assertions defining a question contains an assertion *a*, then the system must contain all the elements of the ideal of *a*, which we have denoted $\mathrm{q}(a)$. Thus any question in the lattice $\mathbf{Q}(N)$ can be constructed from a finite set union of ideal questions from the lattice $\hat{\mathbf{Q}}(N)$. This finite set union can be constructed by using a vector of Boolean values denoting whether or not each of the 2^N ideal questions is included in a particular union. The resulting lattice $\mathbf{Q}^N$ is thus the power set $\mathbf{Q}(N) = \wp(\hat{\mathbf{Q}}(N)) = \mathbf{2}^{\mathbf{2}^N}$ of $\hat{\mathbf{Q}}(N)$, which is known as the *free distributive lattice* $\mathbf{FD}(N)$ [14, 16]. The lattices $\mathbf{Q}(1)$, $\mathbf{Q}(2)$, and $\mathbf{Q}(3)$ are shown in Figure 6, with notation where $A \equiv q(a)$, $AB \equiv q(a \vee b)$, $ABC \equiv q(a \vee b \vee c)$, and $A \cup BC$ is the set union of the sets *A* and *BC*. Recall that the natural ordering relation $\subseteq$ of the sets is used.

The number of possible questions grows rapidly with the number of atomic assertions for $N = 1$ through 8: 2, 5, 19, 167, 7 580, 7 828 353, 2 414 682 040 997, 56 130 437 228 687 557 907 787 [16, 17]. The numbers are known as Dedekind's numbers and their determination is known as Dedekind's problem [18]. This is related to the number of monotonic increasing Boolean functions of N variables and to the number of antichains (also called Sperner systems) on the *N*-set [19]. The lattice

$\mathbf{Q}(3) = \mathbf{FD}(3)$ with *I* added, (Figure 6, right) is better visualized in three dimensions, and is nicely displayed as an example (FD3) in Ralph Freese's java-based Lattice Drawing Program [20].

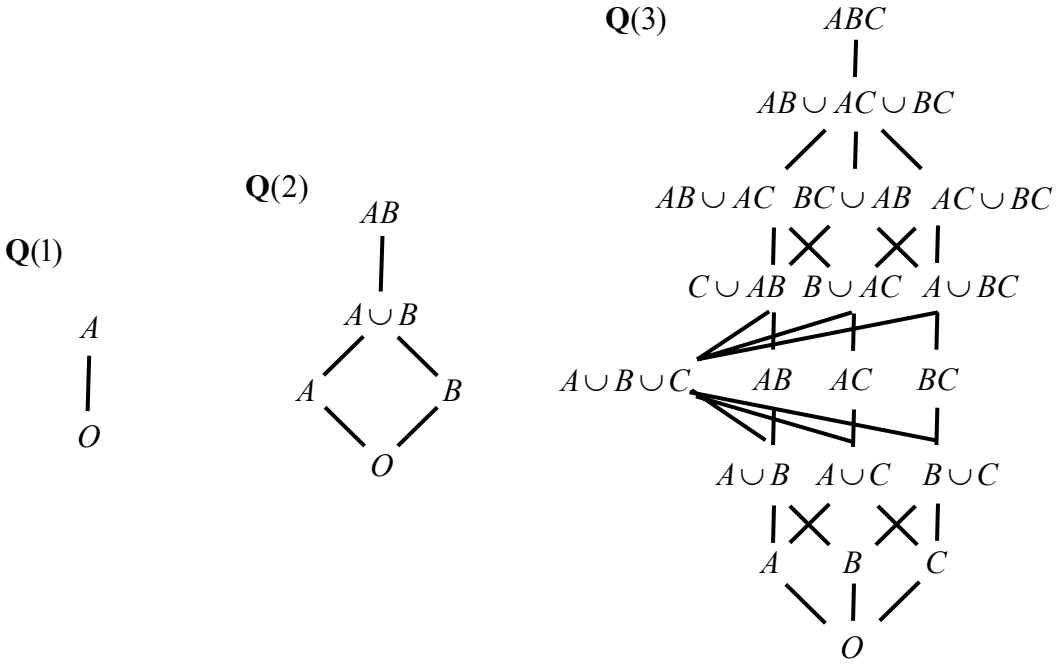

FIGURE 6. The question lattices $\mathbf{Q}(1)$ (left), $\mathbf{Q}(2)$ (center), and $\mathbf{Q}(3)$ (right). These lattices are the free distributive lattices with 1, 2, and 3 generators respectively. Note that $A \equiv q(a)$, $AB \equiv q(a \vee b)$, $ABC \equiv q(a \vee b \vee c)$, and $A \cup BC$ is the set union of the system of assertions for questions *A* and *BC*.

Real Questions

Thus far in these examinations one important point has been neglected; I have not stipulated that the assertions defining a question be exhaustive. That is, there is no assurance that all of the questions in the lattice $\mathbf{Q}(N)$ are *real questions* answerable by a true assertion. As the atoms of the lattice of assertions $\mathbf{2}^N$ are an exhaustive set, then only questions containing the set of atoms as a subset are assured to be real questions. There of course may be questions that do not contain this entire set, that for a given situation may be answerable by a true assertion, but this in general is not guaranteed *a priori*. The least element that contains the set of atoms as a subset is given by $R_\perp = \bigvee_{i=1}^{N} q(a_i)$, where $\bigvee_{i=1}^{N} q(a_i) = q(a_1) \vee q(a_2) \vee \ldots \vee q(a_N)$, which is the disjunction of all the ideals formed from the *N* atomic assertions. This is A, $A \cup B$, $A \cup B \cup C$ for lattices $\mathbf{Q}(1)$, $\mathbf{Q}(2)$, and $\mathbf{Q}(3)$ respectively. Thus all the lattice elements that are greater than this question $R_\perp$ are all assured to be real questions that can be answered by every atomic assertion in the exhaustive set. These *assuredly real questions* are bounded above by the question at the top of the lattice, *I*, which I will

instead denote as $R_\top = q(\bigvee_{i=1}^{N} a_i)$, where $\bigvee_{i=1}^{N} a_i = a_1 \vee a_2 \vee \ldots \vee a_N$. It can be easily shown that these assuredly real questions bounded by $R_\perp$ and $R_\top$ form a sublattice $\mathbf{R}(N)$ where all joins and meets of elements of $\mathbf{R}(N)$ are also elements of $\mathbf{R}(N)$.

Looking at the lattices in Figure 6, it appears in each case that the sublattice $\mathbf{R}(N)$ (excluding $R_\top$) is Boolean (compare to the lattice structures in Figure 3). However, this pattern does not hold in general and in fact fails for $\mathbf{Q}(4)$. This can be demonstrated by looking at what are called the join-irreducible elements of $\mathbf{R}(N)$. In short these are the elements of a lattice that cannot be written as a join of elements of the lattice, excluding O. In any finite Boolean lattice, the join-irreducible elements are its atoms (see $\mathbf{2}^3$ in Figure 3) [21, 22]. The poset formed by these atoms alone consists only of these elements side-by-side, and is called an antichain (Figure 7a). Thus the join-irreducible elements of a Boolean lattice form an antichain, written symbolically as $J(\mathbf{2}^N) = \overline{\mathbf{N}}$. A proof that $\mathbf{R}(N)$ is not Boolean, which will be published by in a future paper, relies on the observation that the join-irreducible elements of $\mathbf{R}(N)$ are of the form $\bigvee_{i=1}^{M} q(a_{b_i}) \vee q(\bigvee_{j=M+1}^{N} a_{b_j})$ where a_k represents the k^{th} atom of $\mathbf{2}^N$ from which $\mathbf{R}(N)$ is formed and b is some permuted sequence of the set of natural numbers from 1 to N, and $1 \le M < N$. In $\mathbf{R}(3)$ there are three join-irreducible elements $\{A \cup BC, B \cup AC, C \cup AB\}$, which form an antichain and hence $\mathbf{R}(3)$ (excluding $R_\top$) is a Boolean lattice. In $\mathbf{R}(4)$ there are a total of 10 join-irreducible elements: 4 of $\{A \cup BCD, \cdots, D \cup ABC\}$ and 6 of $\{A \cup B \cup CD, A \cup C \cup BD, \cdots, C \cup D \cup AB\}$. However, these 10 elements do not form an antichain since $A \cup B \cup CD \le A \cup BCD$, and so on. Figure 7 shows the forms of $J(\mathbf{R}(3))$, $J(\mathbf{R}(4))$ and $J(\mathbf{R}(5))$. The fact that $\mathbf{R}(N)$ is not in general a Boolean lattice has a very important implication – its elements are not complemented. Therefore, assuredly real questions, like questions in general, do not possess complements.

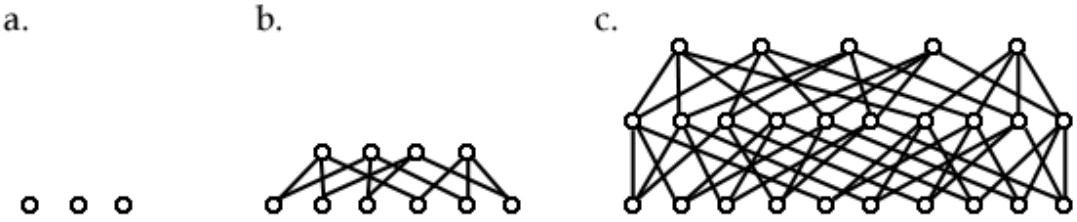

FIGURE 7. The join-irreducible elements of the sublattice of real questions (excluding $R_\top$), (a.) $J(\mathbf{R}(3)) = \overline{\mathbf{3}}$ is an antichain, thus $\mathbf{R}(3)$ excluding $R_\top$ is a Boolean lattice, whereas (b.) $J(\mathbf{R}(4))$, and (c.) $J(\mathbf{R}(5))$ are not antichains indicating that $\mathbf{R}(4)$, $\mathbf{R}(5)$ and in general $\mathbf{R}(N)$ are not Boolean lattices. Drawing these structures in a tidy way is quite a challenge. Note that I have not labeled the elements (described in the text for $\mathbf{R}(3)$ and $\mathbf{R}(4)$) and that their ordering in the diagram is not necessarily the order of the listing the text.

Inductive Inquiry on Lattices

As briefly described earlier, the sum rule of probability (2) derives from the fact that Boolean lattices are uniquely complemented. In Cox's earlier work, he described how there could be no complete analog in the algebra of systems (questions) to the complement in the algebra of assertions ([2], pp. 52-3). In a footnote Cox describes how Boole [23] applied his algebra to classes of objects in addition to propositions (see Figure 1). He notes that one might be inclined to think of a system as a class as defined by Boole, however the set of assertions not included in a system, while forming a class, do not itself form a system. For this reason the algebra of systems cannot possibly be Boolean.

In Cox' paper on inquiry [13] he defines a mutually contradictory pair of questions "as a pair whose conjunction is equal to the conjunction of all questions, and whose disjunction is equal to the disjunction of all questions." While this definition is acceptable, he does not prove their existence. While my discussion on join-irreducible elements may convincingly prove to a mathematician familiar with the theory that complements to questions do not exist, those less-familiar may require more tangible evidence. Consider the question $A \cup B$ in the lattice **Q**(3), (Figure 6c). Its hypothetical complement must satisfy two relations $(A \cup B) \vee \sim (A \cup B) = I$ and $(A \cup B) \wedge \sim (A \cup B) = O$. Consider the first relation $(A \cup B) \vee \sim (A \cup B) = I$. If its complement $\sim (A \cup B) > (A \cup B \cup C)$ then $\sim (A \cup B) > (A \cup B \cup C) > (A \cup B)$, which by the consistency relation gives $\sim (A \cup B) \vee (A \cup B) = \sim (A \cup B)$. This implies that its complement is *I*, which is a contradiction. Now $(A \cup B \cup C)$ cannot be its complement as $(A \cup B \cup C) > (A \cup B)$. So its complement must satisfy $(A \cup B \cup C) > \sim (A \cup B)$. However, $\sim (A \cup B) \vee (A \cup B) \leq (A \cup B \cup C)$ as both $(A \cup B \cup C) > (A \cup B)$ and $(A \cup B \cup C) > \sim (A \cup B)$, which is again a contradiction. Thus there does not exist a complement to the question $A \cup B$ in the lattice **Q**(3).

Last, distributive lattices share the associative and commutative properties of the Boolean lattice. For this reason, one can fully expect that generalizations of the binary ordering relation to measures of degree of inclusion will result in a calculus possessing a product rule as well as a rule analogous to Bayes' Theorem.

RELEVANCE AND PROBABILITY

There is a deep relationship between the Boolean lattice and the free distributive lattice generated from it. Looking at the lattices **Q**(1), **Q**(2), and **Q**(3), one can see that the join-irreducible elements are precisely the ideal questions, which have a lattice structure isomorphic to the original Boolean lattice from which the questions were generated. This is the map[3] $Q \mapsto J(Q)$, whereas the process of generating the question lattice is a map from the Boolean lattice of assertions to the question lattice, which I write as $A \mapsto O(A)$. We thus have an isomorphic correspondence between

[3] Note that these are maps from one lattice structure to another, and are not maps from an element in one lattice to an element in another.

the lattice structures where $Q = O(A)$ and $A = J(Q)$. This is true in general for all finite distributive lattices Q and all finite ordered sets A and is known as Birkhoff's Representation Theorem [16]. The lattice Q is called the *dual* of $J(A)$ and A is called the *dual* of $O(Q)$, however this duality should not be confused with the duality induced by the ordering relation discussed earlier. Furthermore, it can be shown that the join-irreducible map takes products of lattices to sums of lattices, so that one can think of $Q \mapsto J(Q)$ and $A \mapsto O(A)$ as being the logarithm and exponential functions, respectively, for lattices [16]. This is quite enticing in that it further supports our expectations that the relevance of a question on an issue can be represented in terms of the logarithms of the probabilities of the assertions involved, and that entropy may play the same role with distributive lattices as probability does with Boolean lattices.

THE ROLE OF ORDER

The lattice structure of the space of assertions and the space of questions has provided great insights into their structures, symmetries, and relationships. In addition, the associative and commutative properties of lattices suggest that analogies to the familiar product rule of probability and Bayes' Theorem may appear in the calculi of other fields where ordering relations play an important role. This in fact may have already been recognized with the realization that the cross-ratio in projective geometry has the same form as the odds ratio from Bayes' Theorem [24]. Considering the findings in this paper, such a relationship may no longer be such a mystery as the notion of closeness in a projective space provides such an ordering relation. In fact, we might now not be surprised to see forms identical to probability and perhaps entropy appearing in seemingly unrelated fields. In such cases, it is not geometry that underlies these theories – but order.

"*The important thing is not to stop questioning.*"
-Albert Einstein (1879-1955)

ACKNOWLEDGEMENTS

I would like to thank Jeffrey Jewell for noting at MaxEnt 2001 that my work reminded him of lattice theory, and Ralph Freese, David Clark, and Mick Adams for their correspondences, which have helped me to better understand the ins-and-outs of this theoretical framework. I would also like to extend a special thank you to my friend and colleague Domhnull Granquist-Fraser who inspired me to keep my focus during this effort. Last, I would like to thank Bob Fry for introducing me to this fascinating area of study and for his continued friendship.

The Future of Mathematical Software

Ulrich H. Kortenkamp

Institut für Informatik
Freie Universität Berlin
Takustr. 9
D-14195 Berlin

1 Introduction

This article gives my very personal view of the development of (mathematical) software in the past and in the future. It is based both on my experiences as a *user* and as an *author* of math software [1], and also as a non-software-using mathematician.

This is not a real mathematical article. Probably the conclusions of this article could also be applied to completely different types of software, not even necessarily scientific software. Try it.

Nevertheless, it *is* a mathematical article, since I would like to call mathematicians all over the world to participate in the process of creating better tools for communicating mathematics. It is our chance to change the way mathematics is perceived by non-mathematicians or early students, it is the chance to *teach* more and *understand* more.

Instead of filling this article with lots of figures and pictures I decided to add links to many relevant web sites. This gives all the necessary illustrations without having to worry about copyright issues. You should consider reading the online version with clickable hyperlinks.

I will start by trying to identify what I call the "Ten Year Cycle of Software Innovation," which will almost automatically ask for the next innovations that will come. Then I try to spot at least a few requirements that I consider essential for the future. For the rest of this article, "ten years" almost always means "more or less ten years."

2 The Ten Year Cycle

Let us look back in the development of mathematical software. Moores' Law tells us, that every 18 months processing speed doubles. This law has held a long time now, and despite the predictions that it cannot go on any longer, there is currently no end within sight[1]. But what happens with all the computing power?

Instead of using the processor speed increase only for rushing through the same calculations that had been done a few years ago using the same

[1] Physically, there must be an end, and right now it is expected around 2030. But still, it might happen that there will be some other technical breakthrough, maybe another processor technology, maybe quantum computing, that will make Moores' Law continue.

software, much of it is spend for new software elements, like user interfaces, desktop environments, inter-process/inter-network communications, and so on. Many people complain about the fact, that new versions of a software package seem to be slower, even if run on a faster machine. This is annnoying, but most of the times it is not recognized that the new version indeed delivers enhanced user interaction. I do not consider it bad spending computing resources for making computing resources more accessible.

Let us turn to the timeline of computing history and try to find the milestones in math software evolution.

2.1 More Than 30 Years Ago

Let me just pick a few events in the "stone ages" of computing to get started. Many computing timelines can be found on the internet, I used (among others) the Computing History of Hofstra University [2]

It was 60 years ago, in January 1940, when the first Bell Labs relay computer was operational, the *Complex Number Calculator* [3]. This was hardware, not software, but nevertheless very "mathematical hardware." It was demonstrated in September 1940 at the American Mathematical Association meeting via a remote terminal. Also in 1940, Konrad Zuse [4] completes the first fully functioning electro-mechanical computer of the world, the Z2.

5 years later, John von Neumann introduces the concept of a stored-program computer, and Konrad Zuse develops the first programming language, Plankalkül. Also in 1945, the concept of a "bug" is introduced, although at that time it was a hardware[2] bug: A moth caused a relay failure in a prototype of the Mark II computer at Harvard.

Zuses' Z4 survives World War II and is reinstalled at ETH Zürich in 1950, where it continues to work until 1954 [5]. This decision was made by Eduard Stiefel, who initiated the Institute for Applied Mathematics at ETH. This move made the institute at that time the one with the most available computing power on the European continent.

From 1954 on FORTRAN (FORmula TRANSlation) is invented by John Backus [6] and others at IBM, with a compiler following in 1957. Being the first scientific computer programming language, it has had a strong influence on mathematical software, and it is still popular for numerical calculations that depend on raw processing power.

Another important language was and is LISP, introduced by John McCarthy [7] in 1959. In fact, the creation of new programming languages is the main software development during the following years.

In 1967, the first hand-held calculator was invented by Jack Kilby, Jerry Merryman, and James van Tassel at Texas Instruments [8]. Finally, simple calculations could be done without having to reserve a special room for the computer.

[2] At that time there was no and could not be a real distinction between hardware and software, even the terms were not introduced at that time

As of 1969, IBM started to unbundle hardware and software[3]. This is a good point to start looking at the mathematical software development.

2.2 30 Years Ago: Before Visualization

It was around thirty years ago that computing power became broadly accessible for non-military scientific research[4]. The automatization of computations, the incredible speed and exactness offered new possibilities in mathematics. At the same time, new research branches had to be explored – numerical stability, generation of random numbers, or algorithms and their complexity, just to name a few. The famous books of Knuth [10] reflect most of these trends, and at the same time they show that it was then necessary to have computer and mathematics experts to do not only the programming, but also feed the input into the software and to interpret the output. The concept of a user interface was almost unknown, except for the visionary work of Xerox Palo Alto Research Center [11], where the Alto mini-computer was built as early as in 1972 [12].

A very short characterization of mathematical software in the 1970s could be that *computing power can be used as an aid for expert mathematicians.*

2.3 20 Years Ago: Computer Graphics

The commercial successor of the Alto, the Xerox Star [13], in 1981 marked the beginning of a decade that changed a lot[5]. Computers in general became cheaper, i.e. affordable, even for home use – the "home computer" was a concept of the 80s, which was superceded by the "personal computer." Bit-mapped computer graphics became affordable, with more pixels in more colors every year. The output channel of mathematical software could be and was improved, and a lot of work was done in visualization techniques. This lead to an easier way to access mathematics. Still expert knowledge was necessary to change which mathematical facts should be shown: Although the now popular software package Maple [15] had been around since 1980, there were only 300 users in 1987, the year before Waterloo Maple. In the same year 1988 another software was introduced that helped to change the situation, Mathematica [16].

The eighties could be summarized by saying that *mathematics is done traditionally, but can be shown* to a wide audience.

---

[3] It is interesting that companies like Microsoft try and succeed to bundle them again

[4] There is probably no better event to characterize the "going public" of computing resources than the first email by Ray Tomlinson in 1971 [9].

[5] The Star took a lot of its user interface design concepts from Ivan Sutherlands' [14] Sketchpad, the first interactive graphics software, developed in the early sixties.

2.4 10 Years Ago: Interactive Visualization

Not only Mathematica was introduced in the late eighties, there was also a now famous conference in Grenoble in 1989 that could be claimed as the birth of modern dynamic geometry software. After some time these packages, Cabri Géomètre [17] and Geometers' Sketchpad [18], became available commercially. There is no doubt that these software packages had some, significant impact on mathematics education, since for the first time true interaction with mathematical objects in a mathematical way was possible (though there is still a need for expert guidance). Of course, this never would have been possible without fast computer graphics and mice becoming standard output and input devices.

The nineties really introduced *new ways to do mathematics for everybody.*

2.5 The Millenium?

Extrapolating from this ten year cycle of software innovation we should expect a new quantum leap for the millenium. This quantum leap is not just faster software caused by new hardware. We can be sure that hardware will become better and better as it always did, we just have to find the applications to exploit the new possibibilities.

A rough analysis of the history of (math) software evolution actually shows two interwoven development processes: On the one hand, every ten years "something really great" is introduced to the public and changes the way how we use computers. On the other hand, most of the novelties existed before they became widespread: First as a dream of some scientist, then as a scientific prototype, then as a first – commercially not always successful – product. And, these stages seem to be reached in a similar ten-year cycle. To support this theory at least a little think of the Desktop metaphor: it was initiated as a user interface in the 60s, the first scientific prototypes came in the early 70s, in the 80s you could buy software for it, in the 90s it was well established (and nowadays most people cannot live without it).

So, where is the next generation? We have ultrafast high resolution 3d computer graphics, high-bandwidth cheap networking, even at home, it seems that we do not have to care about hardware[6]. What can we do with it? What do we want to do with it? And: How can we do it?

[6] Jon Borwein points out that we *should* care about hardware in an international context. He is right, but from the software engineering point of view we should care less. It would be better, if it were possible to close the gaps between the technological equipments of different countries, which can only mean to raise everybody to the current standard in North America and Western Europe.

3 Better Software for Better Mathematics

Three key ingredients will help to build these better tools for doing mathematics: Ease of use, software intelligence, and software interoperability.

3.1 Easy Software

The first important step seems to be a commonplace not very special to math software. But it cannot be stressed enough that software must be easy to use and easy to install. Good software should render system administrators obsolete – how often did you wait for some software to be installed or fixed? Software manufacturers should spend some time to create install processes that care just about everything: Why should I as a mathematician have to know what a "CLASSPATH" is?

Another important part of mathematical software is the user interface. Most often mathematical software comes with a barely understandable user interface. Actually, most user interfaces differ from punchcard readers just by using a keyboard to type directly into the computer. Many mathematicians do not think that this is a major drawback – "this software is for specialists who know what to do!" or "we had to take care with the computations and did not have the time to create a nice GUI" are common justifications for this lack of comfort. But it is not just a lack of comfort, it is a real barrier for the rest of the world to use the software – and to work with the mathematical content provided by it. It is like publishing a notepad with some scribbling on it instead of typing a paper. Much of the work of software development is trashcan-ready just because of omitting the step of creating a (good) user interface[7].

I want to finish each issue identified with a good example or two that show that we have left the stage of just dreaming a scientists' dream, that there are products available, and it will be feasible to expect the widespread adoption within a few years.

For the ease of use part, both of the software and the installation, there are two examples, that could eventually merge to a single one. The Mac OS of Apple Computer [19] has always been famous for its consistent and facile handling, which was also fostered by the rigid application development guidelines for third-party software. I for myself had to learn that Mac OS is even easier to use than I expected it, and most problems I had with it came from thinking too complexly, like I was used to from working with other operating systems.

[7] This is also a drawback of free software (despite all the good things about it): Without the pressure of a *final version*, that is put on CD and which must be accounted for by the developers, important parts are sometimes unfinished for years. It is like the difference between a technical report and a paper submitted to a conference: the deadline forces the authors to rethink and formulate their ideas to make them accessible to the rest of the community.

The other example is the metamorphosis of Unix, which is close to become an operating system for any user due to the advent of Linux. Some parts still need to be improved, but for instance the installation procedure of the Mandrake distribution [20] is faster and easier than the installation of Microsoft Windows.

3.2 Intelligent Software

Many mathematical problems that are tackled using the help of a computer, especially in teaching and learning mathematics, are easy with respect to the computational requirements. Differentiation of functions and even solving most integrals that appear in calculus courses do not take more than a few milliseconds. How can we then spend all the available CPU power?

The answer is *intelligent software*. Despite being an important vision of the early years of scientific computation, Artificial Intelligence (AI) never became a serious application. Most expert systems are based on database queries together with good ranking functions for the results. Most questions are not answered by automatic deduction, but can be solved by googling [21] them – type them into the search field of your browser and the most relevant web sites will be shown in a few seconds.

But when it comes to mathematics we cannot expect to find the answers to the problems on the internet. In fact, it is not easy at all to formulate mathematical questions in a way to make standard queries to databases[8]. Only for special purposes the problem is solved, see for example the great database of integer sequences by Neil Sloane [23].

So here is a proposition for the unused CPU cycles: Let the software *understand* what the user is doing. *Guide* him (or her), point out what next operation is promising, which simplification leads to a nicer formula, which known results have a similar structure. Try to find *alternate ways* of doing it, that lead to more insight, give additional evidence or even proofs of facts. Discover repetitive patterns in the work, offer *shortcuts* that avoid theses error-prone repetitions.

This goes far beyond visualization: computer aided research where the computer is more like a good scientific assistent who knows enough mathematics to make good suggestions and to quickly check conjectures, though the final work of creating a good proof remains for the professor.

On a lower level this goal is achieved by Cinderella [1], which can be used as an authoring tool for students' exercises. Here one complete solution of a construction exercise must be given by the author (the teacher or educational software designer), together with intermediate solutions (subgoals) that lead to the final construction. The automatic theorem checking engine of Cinderella tries to identify whether the student has reached one of these subgoals and is able to trigger certain actions – like writing out a text or jumping to a URL – in that case. This definition

[8] The OpenMath initiative tries to find such standards, but it looks like we are still far away from a real solution to this problem, see also [22].

of subgoals detaches the solution from the actual construction sequence the teacher used, and thus also unfamiliar or even unknown solutions to an exercise are still accepted. Many examples can be found at Mathsnet UK [24].

The weak part here is that we still need an author for these computer guided exercises. It is not necessary to have an expert to create these, but still the author needs some knowledge – actually, one solution must be known, which is a problem if we would try to guide mathematicians working on problems for which no answer is known. Two strategies in conjunction could be used in the future to address this issue: First, whenever a user does something which can be verified as being meaningful in some sense, the software could request a justification for that step: Why did he do it? Why is it a valid transformation? What did the user expect from that transformation? With the networking capabilities of today such information can be gathered and re-used with other users.

A possible scenario: Mathematician A is trying to find an answer to some question and types in a formula in a computer algebra system. After some work he finds another representation of the formula and is able to proceed with it on his original problem. The computer algebra system asks for the motivation and the success of his software use, records it and stores it in a database. A few weeks later, mathematician B uses the same formula, with the same or another problem in mind. After he types it in his computer algebra system, he is prompted with the information and the solution of mathematician A, and – in the best case – is able to quickly proceed with it. Other continuations would be that he can contact A and talk with him, or he could provide more information that is related to the formula.

On the educational geometry software level a similar goal is even easier to achieve (and will probably be implemented within the next few years): If Cinderella detects a correct solution that is not the same solution as the one of the teacher, it could request additional information that will be reused for other students that follow the same new construction sequence. This does not create more work than the usual classroom situation: A new solution presented by a student usually requires an explanation by the student and a review by the teacher.

The second strategy extends this first concept by letting the computer create the alternate solutions, either by random or by search algorithms. The justification of necessary steps in a proof are then still left to the expert mathematician, but the proof may be found much easier and faster than by ordinary methods. Here I want to point out that techniques like randomized checking (as used in Cinderella) are probably best suited for the fast rejection of dead ends in proving.

3.3 Software Interoperability

The last point which is important in my eyes is *software interoperability*. It is the key to better, more versatile software without introducing new

huge systems that cannot be handled anymore. *Every math software author should be able to concentrate on the things he can do best and using the components other can do better.* Make it easy to link to other software packages! Possible ways are easy scripting interfaces, plug-in specifications, or open source code. As a last resort, there is your ability to provide a certain functionality via a small application programming interface on request.

There are three premier examples I want to discuss: Javaview, JDvi and JLink. All three appeared at the MTCM 2000 conference [25], and are good indicators of the upcoming software interoperability trend.

Javaview [26] is a software package for online visualization of 3D geometry and numerical experiments. Students can use it to view their numerical algorithms online and to interact with them. With Javaview we have the situation that it is easy to contact the programmers and to request new interoperability features. Also, it is possible to connect Javaview, even without the JLink package discussed below. The modular design of Javaview makes it possible to use only parts of it (for instance the 3D renderer) for other packages or to extend it for teaching purposes. A good example for all these aspects is JavaviewLIB [27].

At first sight, JDvi [28] does not seem to be a drastic improvement in math software development – after all, it is just another viewer for DVI files produced by the TeX system of Knuth[29]. But there are "next generation" features: JDvi extends the concept of a DVI viewer to an interactive and extendable DVI viewer: Java applets, for example Javaview, can be integrated into TeX documents and behave as if they were used within a web browser.

The third example is the JLink package [30] of Mathematica. It is a good sign to see that also commercial software producers are aware of the necessity to make it easy to let other software communicate with their software. JLink is a Java-based version of the mathlink-interface, that creates two way communication between a Mathematica kernel and custom software packages. So also here there is no real innovation – the mathlink interface has been present in Mathematica since the release of Mathematica 2.0 in 1991 (ten years ago!). But: it has never been so easy to link Mathematica with other software packages – we were able to set up a working Cinderella–Mathematica link within a few minutes, and we could create the first version of the once popular game *Pong* (see the color table) using Mathematica for the game programming (ball movement) and Cinderella as a front end within a few hours.

I think it is not just pure coincidence that all the examples above were done using the Java programming language [31]. Sun Microsystems did a good job when they decided to release a easy-to-learn programming language that supports modularization and messaging, remote invocation of methods and distribution. Java is not perfect, but it surely helps to achieve some of the goals mentioned above.

4 Conclusion

Let me repeat the most important statements of this article and add a few other observations:

The next revolution just began. It looks like there is a big step in software development every ten years, and there are indications that the next step must happen and is happening now.

(Math-)Software must be intelligent. A better way of spending all the CPU time which is currently used for waiting cycles is to understand what the user intends and to guide him or her to the next actions.

Focus on your strengths, and use those of others. We should not try to write a huge mathematics application that can do everything. Instead, everybody should concentrate on the own (mathematical) strengths, and enable others to use them.

(Math-)Software must be able to talk to each other. It must be very easy, at least for mathematically skilled programmers, to set up communication between different applications, either via application programming interfaces or via shared data formats. An excellent example is the JLink interface to Mathematica.

We do not need consortia (yet). Currently, there is no need for another consortium that specifies the exchange protocols used for math software. Since the mathematical software community is not that large to become unmanageable, we can instead rely on standard protocols like the ones that come with Java.

Pure academic software can be successful. It is a myth that scientific software is boring and that we need multimedia animations, cartoons, sound effects and other gimmicks to raise the curiosity of students. Make the scientific software easy to use and it will profit from the fact that science itself is interesting.

Do not underestimate the value of the user interface. It is not true that software that is for a very special purpose does not need a good user interface, since it is used by a maximum of two people. It is true, however, that software with a bad user interface is used by a maximum of two people.

Installation should never be a barrier. Software must be easy to install (and de-install). Everything that needs special libraries or configurations has to take care of that itself, without destroying other installed software. The optimal solution would be software that does not need any installation and just works.

5 Acknowledgements

I would like to thank Jürgen Richter-Gebert for the opportunity to join the Cinderella project, and all the work that resulted from that. Many thanks to the organizers of the MTCM conference [25] for the wonderful experience; I am quite sure that this conference was essential for the further development of mathematical software.

Advanced Determinant Calculus

(67 pages)

Abstract. The purpose of this article is threefold. First, it provides the reader with a few useful and efficient tools which should enable her/him to evaluate nontrivial determinants for the case such a determinant should appear in her/his research. Second, it lists a number of such determinants that have been already evaluated, together with explanations which tell in which contexts they have appeared. Third, it points out references where further such determinant evaluations can be found.

Asymptotic Redundancies for Universal Quantum Coding

(19 pages)

Abstract. Clarke and Barron have recently shown that the Jeffreys' invariant prior of Bayesian theory yields the common asymptotic (minimax and maximin) redundancy of universal data compression in a parametric setting. We seek a possible analogue of this result for the two-level *quantum* systems. We restrict our considerations to prior probability distributions belonging to a certain one-parameter family, q_u, $-\infty < u < 1$. Within this setting, we are able to compute exact redundancy formulas, for which we find the asymptotic limits. We compare our quantum asymptotic redundancy formulas to those derived by naively applying the (non-quantum) counterparts of Clarke and Barron, and find certain common features. Our results are based on formulas we obtain for the eigenvalues and eigenvectors of $2^n \times 2^n$ (Bayesian density) matrices, $\zeta_n(u)$. These matrices are the weighted averages (with respect to q_u) of all possible tensor products of n identical 2 x 2 density matrices, representing the two-level quantum systems. We propose a form of *universal* coding for the situation in which the density matrix describing an ensemble of quantum signal states is unknown. A sequence of n signals would be projected onto the dominant eigenspaces of $\zeta_n(u)$.

A classification of plane and planar 2-trees

Gilbert Labelle, Cédric Lamathe, Pierre Leroux*
LaCIM, Département de Mathématiques, UQÀM

January 31, 2002

Abstract

We present new functional equations for the species of plane and of planar (in the sense of Harary and Palmer, 1973) 2-trees and some associated pointed species. We then deduce the explicit molecular expansion of these species, *i.e.* a classification of their structures according to their stabilizers. There result explicit formulas in terms of Catalan numbers for their associated generating series, including the asymmetry index series. This work is closely related to the enumeration of polyene hydrocarbons of molecular formula C_nH_{n+2}.

1 Introduction

We define recursively the class $\mathcal{A}$ of *2-dimensional trees* (in brief 2-*trees*) as the smallest class of simple graphs such that

1. the single edge is in $\mathcal{A}$,
2. if a simple graph G has a vertex x of degree 2 whose neighbors are adjacent and such that $G \Leftrightarrow x$ is in $\mathcal{A}$, then G is in $\mathcal{A}$.

One can see that a 2-tree is essentially composed of triangles (complete graph on 3 vertices) glued together along edges in a tree-like fashion.

Note that all 2-trees are planar simple graphs. However, by a *planar* 2-*tree*, we mean here a 2-tree admitting an embedding in the plane in such a way that all faces (except possibly the outer face) are triangles, and we call *plane* 2-*tree* a 2-tree equipped with such an embedding. This terminology agrees with Harary and Palmer [8]. In Figure 3, we show a correspondence between plane 2-trees and (unrooted) triangulations of polygons in the plane which is also a correspondence between planar 2-trees and (unrooted) triangulations of polygons in space (no orientation), also known as triangulations of the disc, see [4] . Figure 1 gives an example of an unlabelled and a triangle-labelled planar 2-tree, Figure 2 shows two different plane 2-trees which are in fact the same planar 2-tree since they are isomorphic simple graphs. We point out the work of Palmer and Read, [15], who enumerate plane embeddings of 2-trees without any condition on the faces, and which they also call plane 2-trees. Planar 2-trees (in our sense) are closely related to acyclic polyene hydro-carbons of molecular formula C_nH_{n+2} (planar trees in the hexagonal lattice); see [5].

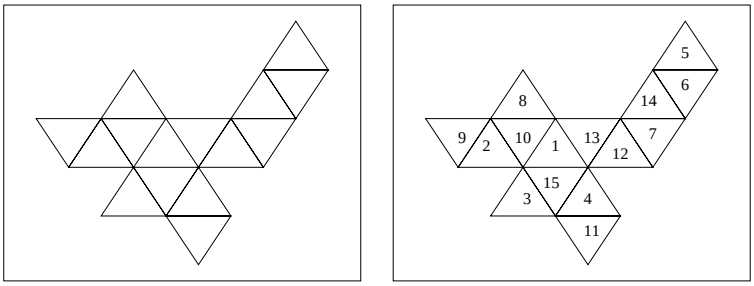

Figure 1: An unlabelled plane 2-tree and one of its labellings

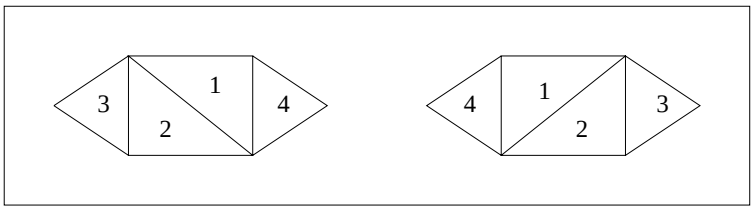

Figure 2: Two different plane 2-trees, one planar 2-tree

We follow the approach of Fowler and al. in [6, 7] for general 2-trees. However, we go further here, giving explicitly the molecular expansion of plane and planar 2-trees, which could not be done in the general case. This is a stronger result than simple labelled and unlabelled enumeration since it gives a classification of the different structures according to stabilizers. For instance, it permits us to have an explicit enumeration of the symmetric and asymmetric parts of these species. Moreover, we obtain closed formulas for all coefficients appearing in these expansions.

To derive these results we use functional equations in the context of the combinatorial theory of species and deduce the molecular expansions and all the associated series. In the following, we label 2-trees at triangles and we denote by X the species of singletons, *i.e.* of simple triangles. Recall that a combinatorial species is a class of finite labelled structures, closed under relabelling along bijections. To each species F we associate series : $F(x)$, the exponential generating series of labelled structures; $\widetilde{F}(x)$, the ordinary generating series of unlabelled structures; $\overline{F}(x)$, the generating series of unlabelled asymmetric structures; Z_F and $,_F$, the cycle and asymmetry index series. The usual shapes of these series for any species F are as follows

$$F(x) = \sum_{n\geq 0} f_n \frac{x^n}{n!}, \tag{1}$$

$$\widetilde{F}(x) = \sum_{n\geq 0} \widetilde{f}_n x^n, \quad \overline{F}(x) = \sum_{n\geq 0} \overline{f}_n x^n, \tag{2}$$

$$Z_F(x_1, x_2, \ldots) = \sum_{n_1,n_2,\ldots} f_{n_1,n_2,\ldots} \frac{x_1^{n_1} x_2^{n_2} \ldots}{1^{n_1} n_1! 2^{n_2} n_2! \ldots}, \tag{3}$$

$$,_F(x_1, x_2, \ldots) = \sum_{n_1,n_2,\ldots} f^*_{n_1,n_2,\ldots} \frac{x_1^{n_1} x_2^{n_2} \ldots}{1^{n_1} n_1! 2^{n_2} n_2! \ldots}, \tag{4}$$

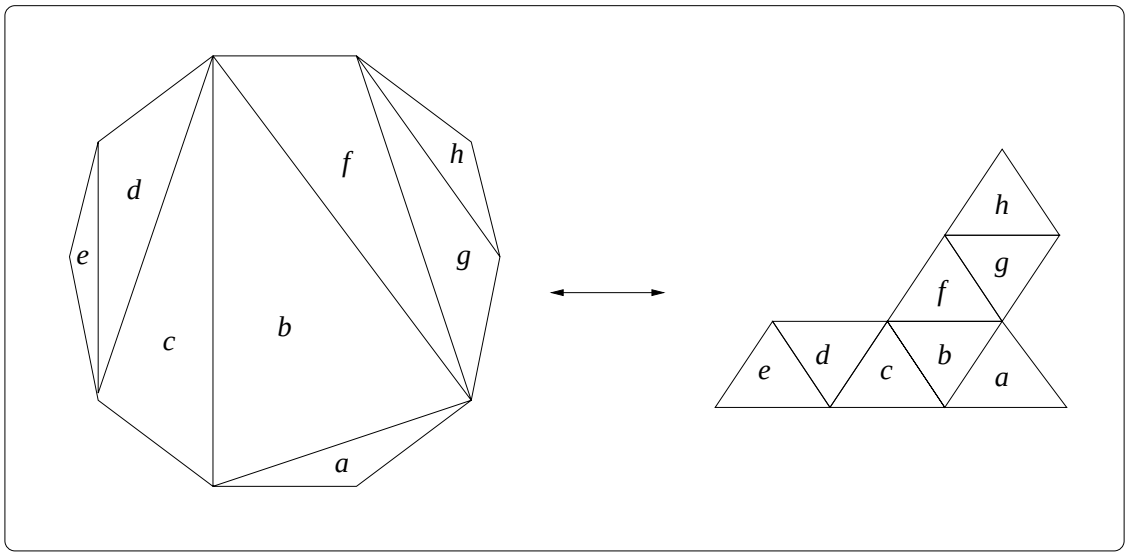

Figure 3: Correspondence between triangulations of a polygon and plane 2-trees

where f_n, $\widetilde{f}_n$ and $\overline{f}_n$ are the numbers of labelled, unlabelled and unlabelled asymmetric F-structures respectively, over an n-element set, and $f_{n_1,n_2,\ldots}$ is the number of F-structures left fixed under a given permutation of cycle type $1^{n_1}2^{n_2}\ldots$. For a definition of the asymmetry index series, see [3].

To illustrate the notion of molecular expansion, we give here the first few terms of this decomposition for the species a_π of plane 2-trees (Eq. (5) and Figure 4) and a_{p} of planar 2-trees (Eq. (6) and Figure 5). As usual, E_n denotes the species of n-element sets and C_3, of 3-element (oriented) cycles. For complete explicit expansions see Theorem 7 for plane 2-trees and Theorem 12 for planar 2-trees.

$$a_\pi = a_\pi(X) = 1 + X + E_2(X) + X^3 + XC_3(X) + 2E_2(X^2) + X^4 + 6X^5 + \cdots \qquad (5)$$

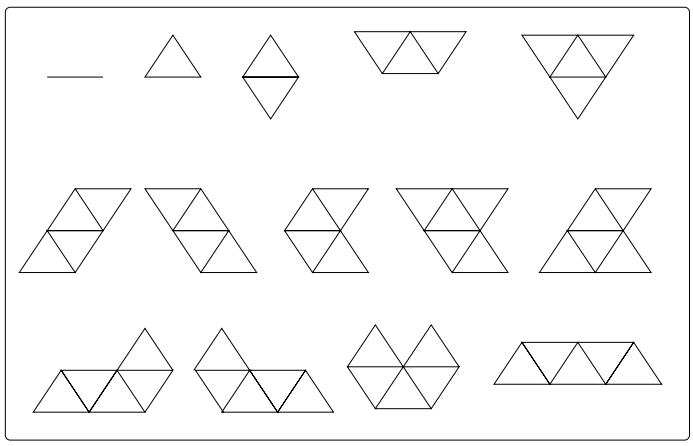

Figure 4: First terms of the molecular expansion of the species a_π of plane 2-trees

$$a_{\rm p} = a_{\rm p}(X) = 1 + X + E_2(X) + XE_2(X) + XE_3(X) + 2E_2(X^2) + 2X^5 + 2XE_2(X^2)$$
$$+X^2E_2(X^2) + \cdots + P_4^{bic}(X,X) + \cdots + XC_3(X^2) + \cdots + XP_6^{bic}(X,X) + \cdots . \qquad (6)$$

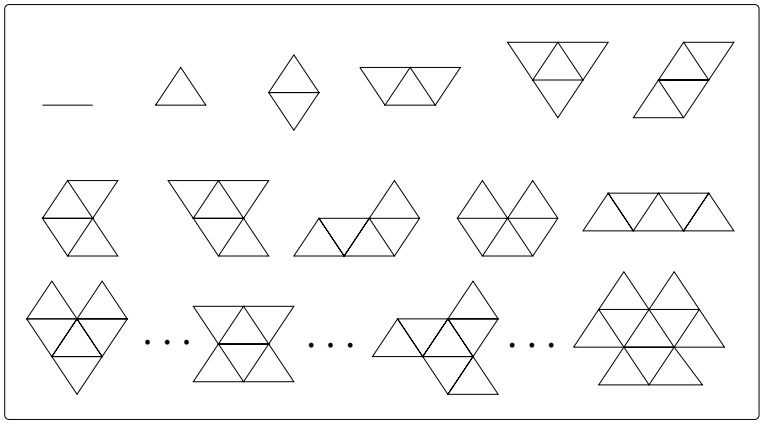

Figure 5: First terms of the molecular expansion of the species $a_{\rm p}$ of planar 2-trees

The expansion of $a_{\rm p}$ involves species $P_4^{bic}(X,Y)$ and $P_6^{bic}(X,Y)$ that are described in Section 2. They are two-sort variants of the species of P_{2n}^{bic} introduced by J. Labelle in [14].

In this paper, we call *degree* of an edge of a 2-tree, the number (less than or equal to 2) of triangles to which it belongs. Let us introduce the auxiliary species A which can be defined as follows:

- A represents the species of plane 2-trees pointed at an external edge, *i.e.* an edge of degree at most 1,
- A is isomorphic to the species of planar 2-trees pointed at an external edge equipped with an orientation,
- A is characterized by the functional equation

$$A = 1 + XA^2 , \qquad (7)$$

illustrated in Figure 6.

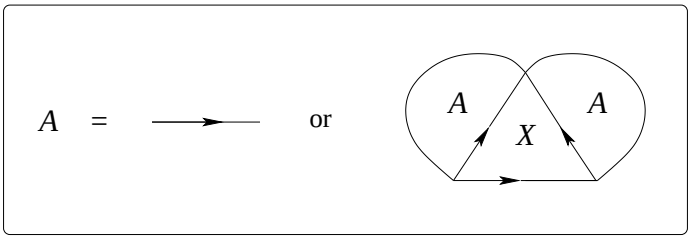

Figure 6: $A = 1 + XA^2$

Note that the species A can also be viewed as the species of rooted triangulations of polygons. This species is fundamental for the following and we will use it several times. We can see that it is asymmetric, *i.e.* the automorphism group of each of its structures is trivial; thus the molecular expansion and the associated series have the same coefficients in their expression. As expected, these coefficients are the Catalan numbers.

Proposition 1. The molecular expansion of the species $A = A(X)$ is

$$A(X) = \sum_{n\in\mathbb{N}} \mathbf{c}_n X^n, \tag{8}$$

where $\mathbf{c}_n = \frac{1}{n+1}\binom{2n}{n}$ (*Catalan numbers*). More generally, if $A^k(X) = \sum_{n\in\mathbb{N}} \mathbf{c}_n^{(k)} X^n$, $k \geq 1$, then

$$\begin{aligned} \mathbf{c}_n^{(k)} &= \sum_{i=0}^{\lfloor\frac{k-1}{2}\rfloor} (\Leftrightarrow 1)^i \binom{k-1-i}{i} \mathbf{c}_{n+k-1-i}, &(9)\\ &= \frac{k}{n}\binom{2n \Leftrightarrow 1+k}{n \Leftrightarrow 1}. &(10)\end{aligned}$$

Proof. The formula for $\mathbf{c}_n$ follows directly from a simple application of the Lagrange inversion on the relation (7). It can also be computed by expanding in series the algebraic solution $A(X) = (1 \Leftrightarrow \sqrt{1 \Leftrightarrow 4X})/2X$ of (7). For the $\mathbf{c}_n^{(k)}$, we work with the unlabelled generating series. First, we remark that

$$A^k(x) = \sum_{i=0}^{\lfloor\frac{k-1}{2}\rfloor} (\Leftrightarrow 1)^i \binom{k-1-i}{i} \frac{A(x)}{x^{k-1-i}} + \sum_{i=o}^{\lfloor\frac{k-2}{2}\rfloor} (\Leftrightarrow 1)^{i+1} \binom{k-2-i}{i} \frac{1}{x^{k-1-i}}, \tag{11}$$

where $\lfloor\cdot\rfloor$ represents the floor function. This formula is easily shown by recurrence on k distinguishing two cases depending on the parity of k and using the fact that $A^2(x) = \frac{1}{x}(A(x) \Leftrightarrow 1)$, which follows from (7). Next, extracting the coefficient of x^n in this expression gives the result. The second expression for $\mathbf{c}_n^{(k)}$ is obtained by a simple application of the composite Lagrange inversion formula on equation (7). ∎

For instance, for k from 1 up to 6, we have

$$\begin{aligned}
\mathbf{c}_n^{(1)} &= \mathbf{c}_n = \frac{1}{n}\binom{2n}{n \Leftrightarrow 1},\\
\mathbf{c}_n^{(2)} &= \mathbf{c}_{n+1} = \frac{2}{n}\binom{2n+1}{n \Leftrightarrow 1},\\
\mathbf{c}_n^{(3)} &= \mathbf{c}_{n+2} \Leftrightarrow \mathbf{c}_{n+1} = \frac{3}{n}\binom{2n+2}{n \Leftrightarrow 1}, &(12)\\
\mathbf{c}_n^{(4)} &= \mathbf{c}_{n+3} \Leftrightarrow 2\mathbf{c}_{n+2} = \frac{4}{n}\binom{2n+3}{n \Leftrightarrow 1},\\
\mathbf{c}_n^{(5)} &= \mathbf{c}_{n+4} \Leftrightarrow 3\mathbf{c}_{n+3} + \mathbf{c}_{n+2} = \frac{5}{n}\binom{2n+4}{n \Leftrightarrow 1},\\
\mathbf{c}_n^{(6)} &= \mathbf{c}_{n+5} \Leftrightarrow 4\mathbf{c}_{n+4} + 3\mathbf{c}_{n+3} = \frac{6}{n}\binom{2n+5}{n \Leftrightarrow 1}.
\end{aligned}$$

In order to lighten notations, we slighty extend the definition of the Catalan numbers as follows:

$$\mathbf{c}_n = \frac{1}{n+1}\binom{2n}{n}\chi(n \in \mathbb{N}). \tag{13}$$

In other words, $\mathbf{c}_n$ is the ususal Catalan number if n is a nonnegative integer, and 0 otherwise.

We will use two dissymmetry formulas, analogous to the case of classical 2-trees (see Fowler and al. in [6, 7]); the same proof applies in the case of plane and planar 2-trees and is omitted.

Theorem 1. DISSYMMETRY THEOREM FOR PLANE AND PLANAR 2-TREES. The species a_π of plane 2-trees and a_{p} of planar 2-trees satisfy the following isomorphisms of species

$$a_\pi^{-} + a_\pi^{\Delta} = a_\pi + a_\pi^{\underline{\Delta}}, \tag{14}$$

and

$$a_{\mathrm{p}}^{-} + a_{\mathrm{p}}^{\Delta} = a_{\mathrm{p}} + a_{\mathrm{p}}^{\underline{\Delta}}, \tag{15}$$

where the exponents $\Leftrightarrow$, Δ and $\underline{\Delta}$ represent the pointing of 2-trees at an edge (Figure 7a), at a triangle (Figure 7b) and at a triangle with one of its edges distinguished (Figure 7c).

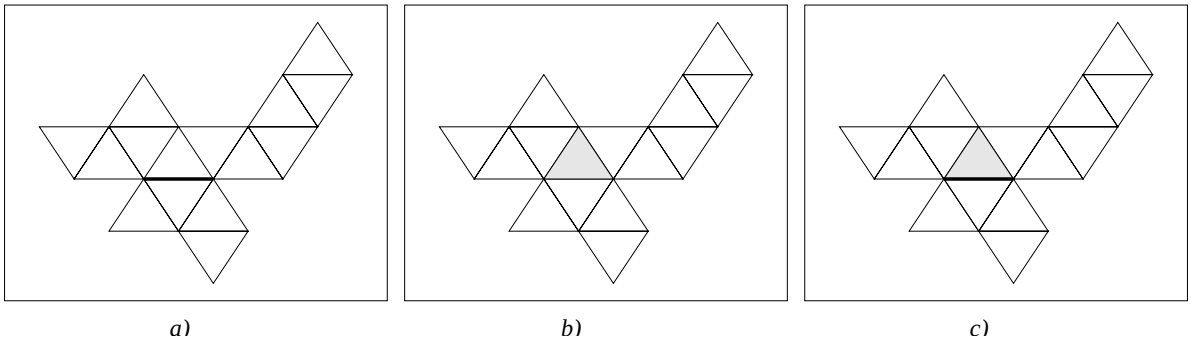

Figure 7: Examples of the exponents: a) $\Leftrightarrow$, b) Δ and c) $\underline{\Delta}$

The rest of the paper is organized as follows. In the next section, we introduce and study the auxiliary two-sort species $P_4^{\mathrm{bic}}(X,Y)$ and $P_6^{\mathrm{bic}}(X,Y)$ which are needed for the expression of the species a_{p}^{-} and a_{p}^{Δ} in terms of A. In Section 3, we give addition formulas for the substitution of an asymmetric species $Y = B(X)$ into the species $E_2(Y)$, $C_3(Y)$, $P_4^{\mathrm{bic}}(X,Y)$ and $P_6^{\mathrm{bic}}(X,Y)$. These results are put together in Section 4 to give the molecular expansion of the species a_π and a_{p}. All the coefficients that occur in the expressions are given explicitly in terms of Catalan numbers. Finally, the labelled, unlabelled and asymmetric enumeration of plane and planar 2-trees is carried out in Section 5.

2 The auxiliary molecular species $P_4^{\mathrm{bic}}(X,Y)$ and $P_6^{\mathrm{bic}}(X,Y)$

This section is devoted to the study of some particular molecular species. A *molecular species* M is a species having only one isomorphy type. In other words, any two M-structures are

isomorphic. A molecular species is characterized by the fact that it is indecomposable under the combinatorial sum :

$$M \text{ is molecular} \quad \Leftrightarrow \quad (M = F + G \Rightarrow F = 0 \text{ or } G = 0). \tag{16}$$

It is often very useful to write a molecular species in the form

$$M = \frac{X^n}{H}, \tag{17}$$

where X^n represents the species of lists of length n and H is a subgroup of the symmetric group $\mathbb{S}_n$. We write $H \leq \mathbb{S}_n$. In fact, H is the stabilizer of some M-structure on $[n] = \{1, 2 \ldots n\}$ and n is called the *degree* of the species M. Two molecular species of degree n, X^n/H and X^n/K, are equal (*i.e.* isomorphic as species) if and only if H and K are conjugate subgroups of $\mathbb{S}_n$.

Here are some examples of molecular species

- when $H = 1$, then $X^n/1 = X^n$,
- when $H = <\rho>$, where ρ is the circular permutation $\rho = (1, 2, \ldots n)$, then $X^n/<\rho> = C_n$, the species of oriented cycles of length n,
- if now the group H is $\mathbb{S}_n$, then we have $X^n/\mathbb{S}_n = E_n$, the species of sets of size n.

We denote by $\mathcal{M}$ the set of molecular species. We can see easily that the first elements of this set, up to degree 3, are

$$\mathcal{M} = \{1, X, X^2, E_2, X^3, XE_2, E_3, C_3(X), \ldots\}. \tag{18}$$

Moreover, each species F can be expressed as a (possibly infinite) linear combination with integer coefficients of molecular species as follows,

$$F = \sum_{M \in \mathcal{M}} f_M M, \tag{19}$$

where $f_M \in \mathbb{N}$ represents the number of subspecies of F isomorphic to M. This development is unique and it is called *molecular expansion* of the species F.

It is also possible to extend the notion of molecular species to the case of multi-sort species. For instance, for two-sort species, where X and Y represent the two sorts, any molecular species can be written as

$$M(X, Y) = \frac{X^n Y^m}{H}, \tag{20}$$

where $H \leq \mathbb{S}_n^X \times \mathbb{S}_m^Y$ is the stabilizer of an M-structure. Here, $\mathbb{S}_n^X$ represents the symmetric group of degree n for the points of sort X.

We can now introduce the auxiliary species $Q(X, Y)$ and $S(X, Y)$ which will be important in our analysis of planar 2-trees. They can be defined by Figures 8 a) and 8 b) respectively, where X stands for the sort of triangles and Y, of directed edges.

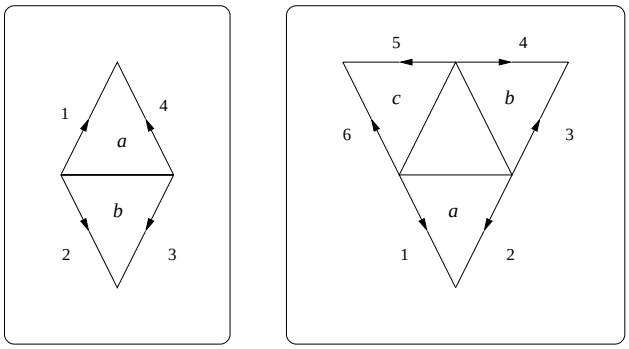

Figure 8: Structures belonging to the species $Q(X,Y)$ and $S(X,Y)$

These two molecular species are related to known species:

$$Q(X,Y) = P_4^{\text{bic}}(X,Y), \quad S(X,Y) = P_6^{\text{bic}}(X,Y), \tag{21}$$

where the species $P_n^{\text{bic}}(X)$, for n an even integer, represents the species of (vertex labelled) bicolored n-gons (see J. Labelle [14]). More precisely, the edges are colored with a set of two colors, $\{0,1\}$, in such a way that incident edges have different colors. We can then generalize to the two-sort species $P_n^{\text{bic}}(X,Y)$ where X represents the sort of edges of color 1 (dotted lines) and Y stands for the sort of vertices, as shown by Figure 9 for $n=4$ and $n=6$. This Figure also establishes (21).

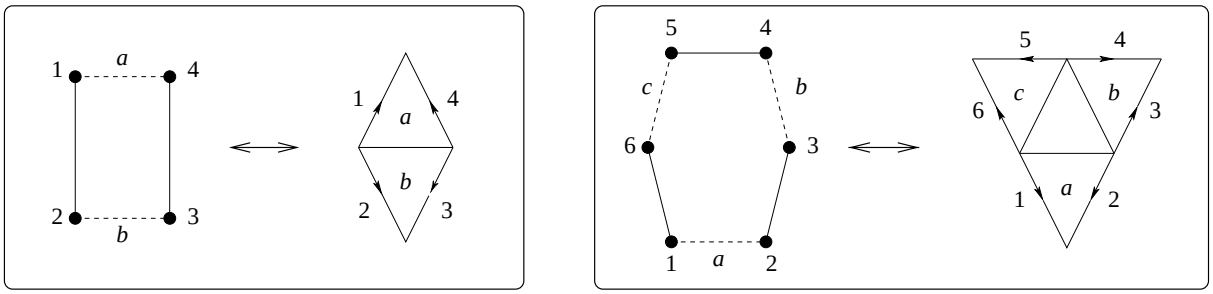

Figure 9: $P_4^{\text{bic}}(X,Y)$ and $P_6^{\text{bic}}(X,Y)$

In order to completly describe the species Q and S, we have to identify their stabilizers, and so we write them in the form (20). We have

$$P_4^{\text{bic}}(X,Y) = \frac{X^2Y^4}{D_2}, \quad P_6^{\text{bic}}(X,Y) = \frac{X^3Y^6}{S_3} \tag{22}$$

where the two groups D_2 and S_3 are characterized by their action on the labelled structures of Figure 9 :

1. $D_2 =< h, v > \leq \mathbb{S}_2^X \times \mathbb{S}_4^Y$, with

$$h = (a,b)(1,2)(3,4) \quad \text{and} \quad v = (a)(b)(1,4)(2,3).$$

Note that $h^2 = 1,\ v^2 = 1,\ hv = vh$, and $D_2 \cong \mathbb{Z}_2 \times \mathbb{Z}_2$.

2. $S_3 =< s, w > \leq \mathbb{S}_3^X \times \mathbb{S}_6^Y$, where

$$s = (a)(b,c)(1,2)(3,6)(4,5) \quad \text{and} \quad w = (a,b,c)(1,3,5)(2,4,6).$$

Note that $s^2 = 1,\ w^3 = 1,\ sws = w^2$, and $S_3 \tilde{=} \mathbb{S}_3$.

Here are the formulas giving the cycle index series and the asymmetry index series of a molecular two-sort species.

Theorem 2. [3, 10, 12] Let $M(X,Y) = X^n Y^m/H$ be a molecular species on two sorts, with $H \leq \mathbb{S}_n^X \times \mathbb{S}_m^Y$. Then, the cycle index series of M is given by

$$Z_M(x_1, x_2, \ldots; y_1, y_2, \ldots) = \frac{1}{|H|} \sum_{h \in H} x_1^{c_1(h)} x_2^{c_2(h)} \ldots y_1^{d_1(h)} y_2^{d_2(h)} \ldots, \tag{23}$$

where $c_i(h)$ (resp. $d_i(h)$), for $i \geq 1$, denotes the number of cycles of lenght i of the permutation on X-points (resp. Y-points) induced by the element $h \in H$. Furthermore, the asymmetry index series of M is given by

$$, _M(x_1, x_2, \ldots; y_1, y_2, \ldots) = \frac{1}{|H|} \sum_{V \leq H} \mu(\{1\}, V) x_1^{c_1(V)} x_2^{c_2(V)} \ldots y_1^{d_1(V)} y_2^{d_2(V)} \ldots, \tag{24}$$

where the sum is taken over all subgroups V of H, $\{1\}$ is the identity subgroup of H, $\mu(\{1\}, V)$ denotes the value of the Möbius function in the lattice of subgroup of H and $c_i(V)$ (resp. $d_i(V)$), represents the number of orbits with i elements of sort X (resp. Y) with respect to the natural action of V on $[n]$ (resp. $[m]$).

Proposition 2. The cycle index of the species $P_4^{\text{bic}}(X,Y)$ and $P_6^{\text{bic}}(X,Y)$ are given by

$$Z_{P_4^{\text{bic}}}(x_1, x_2, \ldots; y_1, y_2, \ldots) = \frac{1}{4}(x_1^2 y_1^4 + 2x_2 y_2^2 + x_1^2 y_2^2), \tag{25}$$

$$Z_{P_6^{\text{bic}}}(x_1, x_2, \ldots; y_1, y_2, \ldots) = \frac{1}{6}(x_1^3 y_1^6 + 2x_3 y_3^2 + 3x_1 x_2 y_2^3). \tag{26}$$

Proof. This is an easy exercise, using (23) and writing explicitly the elements of the group D_2 and S_3 : $D_2 = \{1, h, v, h \cdot v\}$ and $S_3 = \{1, s, \omega, \omega^2, s \cdot \omega, s \cdot \omega^2\}$. ∎

Proposition 3. The asymmetry index series of the two species $P_4^{\text{bic}}(X,Y)$ and $P_6^{\text{bic}}(X,Y)$ are given by

$$, _{P_4^{\text{bic}}}(x_1, x_2, \ldots; y_1, y_2, \ldots) = \frac{1}{4}(x_1^2 y_1^4 \Leftrightarrow x_1^2 y_2^2 \Leftrightarrow 2x_2 y_2^2 + 2x_2 y_4), \tag{27}$$

$$, _{P_6^{\text{bic}}}(x_1, x_2, \ldots; y_1, y_2, \ldots) = \frac{1}{6}(x_1^3 y_1^6 \Leftrightarrow x_3 y_3^2 \Leftrightarrow 3x_1 x_2 y_2^3 + 3x_3 y_6). \tag{28}$$

Proof. It suffices to determine the lattice of subgroups of D_2 and S_3 and to apply (24). Details are left to the reader. ∎

The cycle index series of a species encompasses the two other classical enumerative series, namely the exponential generating function of labelled structures and the ordinary generating function of unlabelled structures. In a similar way, the asymmetry index series contains other series as specializations, in particular the asymmetry generating series. For the two-sort case, these series are related as follows :

Theorem 3. ([3]). For any two-sort species F, we have

$$F(x,y) = Z_F(x,0,\ldots;y,0,\ldots) = {}_{,F}(x,0,\ldots;y,0,\ldots), \tag{29}$$
$$\widetilde{F}(x,y) = Z_F(x,x^2,\ldots;y,y^2,\ldots), \tag{30}$$
$$\overline{F}(x,y) = {}_{,F}(x,x^2,\ldots;y,y^2,\ldots). \tag{31}$$

We then confirm the expressions of the generating series of the species $P_4^{\mathrm{bic}}(X,Y)$ and $P_6^{\mathrm{bic}}(X,Y)$.

Remark 1. We have

$$P_4^{\mathrm{bic}}(x,y) = \frac{1}{4}x^2y^4, \quad \widetilde{P}_4^{\mathrm{bic}}(x,y) = x^2y^4, \quad \overline{P}_4^{\mathrm{bic}}(x,y) = 0, \tag{32}$$
$$P_6^{\mathrm{bic}}(x,y) = \frac{1}{6}x^3y^6, \quad \widetilde{P}_6^{\mathrm{bic}}(x,y) = x^3y^6, \quad \overline{P}_6^{\mathrm{bic}}(x,y) = 0. \tag{33}$$

The fact that $\overline{P}_4^{\mathrm{bic}}(x,y)$ and $\overline{P}_6^{\mathrm{bic}}(x,y)$ equals 0, means that these two species are purely symmetric, *i.e.* , their asymmetric part is reduced to the empty set.

Note that if we put $Y := X^k$, for $k \geq 1$, in the species $P_4^{\mathrm{bic}}(X,Y)$ and $P_6^{\mathrm{bic}}(X,Y)$, the resulting one-sort species are molecular. Indeed, the substitution of a molecular species in another one remains molecular. These two species $P_4^{\mathrm{bic}}(X,X^k)$ and $P_6^{\mathrm{bic}}(X,X^k)$, for $k \geq 1$, will be essential in order to obtain the molecular expansion of planar 2-trees. Besides, we remark the fact that

$$P_4^{\mathrm{bic}}(X,1) = E_2(X), \quad P_6^{\mathrm{bic}}(X,1) = E_3(X), \tag{34}$$

since, in Figure 8, setting $Y = 1$ corresponds to unlabelling the directed edges.

To end this section, let us give the derivative of the two-sort species $P_4^{\mathrm{bic}}(X,Y)$ and $P_6^{\mathrm{bic}}(X,Y)$.

Proposition 4. The partial derivatives of $P_4^{\mathrm{bic}}(X,Y)$ and $P_6^{\mathrm{bic}}(X,Y)$ are given by

$$\frac{\partial}{\partial X}P_4^{\mathrm{bic}}(X,Y) = XE_2(Y^2), \quad \frac{\partial}{\partial Y}P_4^{\mathrm{bic}}(X,Y) = X^2Y^3, \tag{35}$$
$$\frac{\partial}{\partial X}P_6^{\mathrm{bic}}(X,Y) = E_2(XY^3), \quad \frac{\partial}{\partial Y}P_6^{\mathrm{bic}}(X,Y) = X^3Y^5. \tag{36}$$

Proof. Let $F(X,Y)$ be a two-sort species and U and V be two sets representing the two sorts. Then, the partial derivatives, with respect to X and Y are defined by

$$\frac{\partial F}{\partial X}[U,V] = F[U+\{*\},V], \quad \frac{\partial F}{\partial Y}[U,V] = F[U,V+\{*\}],$$

where $*$ is a supplementary element which is used in the construction of the F-structures. From this definition, it is easy to obtain (35) et (36). ∎

3 Addition formulas

In this section, we prove some addition formulas which will be necessary to obtain the explicit molecular expansions for plane and planar 2-trees.

Proposition 5. Let B be an asymmetric species whose molecular expansion is given by

$$B(X) = \sum_{k\geq 0} b_k X^k \,.$$

Then, we have the following addition formulas relative to the species E_2 of two-element sets and C_3 of oriented 3-cycles :

$$E_2(B(X)) = \sum_{k\geq 1} b_k E_2(X^k) + \sum_{k\geq 0} \alpha_k X^k, \tag{37}$$

$$C_3(B(X)) = \sum_{k\geq 1} b_k C_3(X^k) + \sum_{k\geq 0} \beta_k X^k, \tag{38}$$

with

$$\alpha_0 = \frac{1}{2}(b_0^2 + b_0), \quad \beta_0 = \frac{1}{3}(b_0^3 + 2b_0)\,, \tag{39}$$

$$\alpha_k = \frac{1}{2}\sum_{i+j=k} b_i b_j \Leftrightarrow \frac{1}{2}\chi(2|k) b_{\frac{k}{2}}, \quad k \geq 1\,, \tag{40}$$

$$\beta_k = \frac{1}{3}\sum_{l+m+n=k} b_l b_m b_n \Leftrightarrow \frac{1}{3}\chi(3|k) b_{\frac{k}{3}}, \quad k \geq 1\,, \tag{41}$$

where, for $a, b \in \mathbb{N}$, $\chi(a|b) = 1$, if a divides b, and 0, otherwise.

Proof. First note that for any species F, the constant (*i.e.* of degree 0) term $F(b_0)$ of $F(B)$ is given by $Z_F(b_0, b_0, \ldots)$, in virtue of Polya's theorem. This yields (39). An analysis of the different shapes of molecular species which can arise in $E_2(B)$, permits us to write the following relation

$$E_2(B) = \sum_{k\geq 1} \gamma_k E_2(X^k) + \sum_{k\geq 0} \alpha_k X^k. \tag{42}$$

We now have to compute α_k and γ_k, for all $k \geq 1$. Note that we can order, in the species B, the b_k copies of the molecule X^k, for each $k \geq 1$. Then, to obtain an $E_2(X^k)$-structure from $E_2(B)$, we must take twice the same copy of X^k among the b_k available; otherwise the pair of B-structures will be asymmetric. Hence $\gamma_k = b_k$, for all $k \geq 1$. In order to compute α_k, we could perform a direct enumeration. However, we introduce a different method which will prove very useful in other situations. Differentiating the two members of (42), we get

$$BB' = \sum_{k\geq 1} k b_k X^{2k-1} + \sum_{k\geq 1} k\alpha_k X^{k-1}.$$

Integrating back this last relation, in the realm of formal power series in X, leads us to

$$\frac{1}{2}B^2 = \frac{1}{2}\sum_{k\geq 1} b_k X^{2k} + \sum_{k\geq 0} \alpha_k X^k + \text{const}\,.$$

Identifying coefficients of X^n in both sides of the last equality gives us the relation (40). To obtain (41), we first write

$$C_3(B) = \sum_{k\geq 1} \delta_k C_3(X^k) + \sum_{k\geq 0} \beta_k X^k. \tag{43}$$

The same argument as used above implies $\delta_k = b_k$, $k \geq 1$, and the same technique of differentiating-integrating equation (43) gives the announced formula for β_k. In the process, we use the fact that

$$(C_3(B))' = L_2(B)B' = B^2 B'$$

where L_2 represents the species of two-element lists. ∎

As a particular case, we have

$$E_2(1+X) = 1 + X + E_2(X), \tag{44}$$
$$C_3(1+X) = 1 + X + X^2 + C_3(X). \tag{45}$$

When $B = A$, formulas (39)–(41) take a simpler form because of the convolutive properties of Catalan numbers, as seen in Proposition 1. For this case, the coefficients α_k and β_k are given by $\alpha_0 = \beta_0 = 1$ and, for $k \geq 1$,

$$\alpha_k = \frac{1}{2}(\mathbf{c}_{k+1} \Leftrightarrow \mathbf{c}_{\frac{k}{2}}), \tag{46}$$
$$\beta_k = \frac{1}{3}(\mathbf{c}_{k+2} \Leftrightarrow \mathbf{c}_{k+1} \Leftrightarrow \mathbf{c}_{\frac{k}{3}}). \tag{47}$$

We now give the main result of this section, addition formulas for the species $P_4^{\mathrm{bic}}(X,Y)$ and $P_6^{\mathrm{bic}}(X,Y)$. Let $b_k^{(n)}$ denotes the coefficient of X^k in the species $B^n(X)$, with the convention that $b_x^{(n)} = 0$ if the index x is fractional, for all $n, k \geq 1$.

Theorem 4. Let B be an asymmetric species whose molecular expansion is given by

$$B(X) = \sum_{n\geq 0} b_k X^k.$$

Then,

$$P_4^{\mathrm{bic}}(X,B) = \sum_{k\geq 3} a_k^{'} X^k + \sum_{k\geq 2} a_k^{''} E_2(X^k) + \sum_{k\geq 1} a_k^{'''} X^2 E_2(X^k) + \sum_{k\geq 0} a_k^{iv} P_4^{\mathrm{bic}}(X, X^k), \tag{48}$$

where

$$a_k^{'} = \frac{1}{4} b_{k-2}^{(4)} \Leftrightarrow \frac{3}{4} b_{\frac{k-2}{2}}^{(2)} + \frac{1}{2} b_{\frac{k-2}{4}}, \tag{49}$$
$$a_k^{''} = b_{k-1}^{(2)} \Leftrightarrow b_{\frac{k-1}{2}}, \tag{50}$$
$$a_k^{'''} = \frac{1}{2}(b_k^{(2)} \Leftrightarrow b_{\frac{k}{2}}), \tag{51}$$
$$a_k^{iv} = b_k. \tag{52}$$

Proof. We proceed in a similar way as in Proposition 5, beginning with an analysis of the different symmetries which can appear in structures belonging to the species $P_4^{\mathrm{bic}}(X, B(X))$. This permits us to write (48) where all coefficients have to be determined. We first note that $a_k^{iv} = \mathbf{c}_k$ since the only way to build a $P_4^{\mathrm{bic}}(X, X^k)$-structure from the species $P_4^{\mathrm{bic}}(X, B)$ is to take four times the same copy of the molecule X^k among the b_k available copies. This gives (52). Next, we consider $E_2(X^k)$-structures. In order to obtain such a structure from the species $P_4^{\mathrm{bic}}(X, B)$, we can take two non isomorphic $X^{\frac{k-1}{2}}$-structures α and β from the species B, and put them in the two differents ways shown in Figure 10 a) and 10 b). This contributes for a term of

$$2\sum_l \binom{b_l}{2} E_2(X^{2l+1}),$$

remembering that the two internal triangles also contribute for one X each. We can also take an X^i-structure α and an X^j-structure β such that $i + j = k \Leftrightarrow 1$ and $i \neq j$, and put them in the two different configurations drawn in Figure 10 a) and b). In the molecular

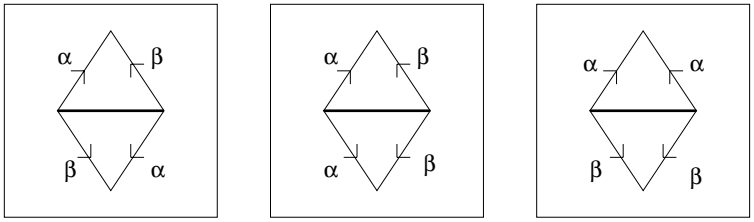

Figure 10: Symmetries of order 2 in $P_4^{\mathrm{bic}}(X, B)$

expansion of the species $Q(X, B)$ this stands for

$$2 \sum_{\substack{i+j=k-1 \\ i<j}} b_i b_j E_2(X^k).$$

It leads to (50), *i.e.*

$$a_k^{''} = 2 \sum_{\substack{i+j=k-1 \\ i<j}} b_i b_j + \binom{b_{\frac{k-1}{2}}}{2} = b_{k-1}^{(2)} \Leftrightarrow b_{\frac{k-1}{2}}.$$

Let us now turn to the coefficient $a_k^{'''}$ of $X^2 E_2(X^k)$ in the relation (48). The configurations belonging to an $X^2 E_2(X^k)$ are shown in Figure 10 c). We then have

$$a_k^{'''} = \sum_{\substack{i+j=k \\ i<j}} b_i b_j + \binom{b_{\frac{k}{2}}}{2} = \frac{1}{2}(b_k^{(2)} \Leftrightarrow b_{\frac{k}{2}})$$

types of $X^2 E_2(X^k)$-structures. It remains to determine the asymmetric part of the species $Q(X, B)$, *i.e.* the coefficient $a_k^{'}$ of X^k in the molecular expansion (48), for all k. To find it, we differentiate the relation (48) and we identify the coefficient of X^k in each side. It gives the expression (49), which completes the proof. Note that we use the combinatorial derivative of a composite species $F(X, B(X))$. As in calculus, we have

$$(F(X, B(X)))' = \frac{\partial F(X, Y)}{\partial X}|_{Y:=B} + \frac{\partial F(X, Y)}{\partial Y}|_{Y:=B} \cdot B', \tag{53}$$

and we can use Proposition 4. ∎

Remark 2. We can perform a precise classification separating rotational and reflectional symmetries. Indeed, the symmetries illustrated by Figure 10 are rotational for the case a), vertically reflectional for case b) and horizontally reflectional for c).

Remark also that we could obtain the expression of $a_k^{'''}$ by identifying the coefficient of $XE_2(X^k)$ after deriving (48).

Theorem 5. For all asymmetric species B whose molecular expansion is

$$B(X) = \sum_{k\geq 0} b_k X^k\,,$$

we have

$$P_6^{\mathrm{bic}}(X,B) = \sum_{k\geq 4} d_k^{'} X^k + \sum_{k\geq 2} d_k^{''} XE_2(X^k) + \sum_{k\geq 2} d_k^{'''} C_3(X^k) + \sum_{k\geq 0} d_k^{iv} P_6^{\mathrm{bic}}(X,X^k), \tag{54}$$

where

$$\begin{aligned}
d_k^{'} &= \frac{1}{6} b_{k-3}^{(6)} \Leftrightarrow \frac{1}{2} b_{\frac{k-3}{2}}^{(3)} + \frac{1}{3} b_{\frac{k-3}{3}}^{(2)} + \frac{2}{3} b_{\frac{k-3}{6}}, && (55)\\
d_k^{''} &= b_{k-1}^{(3)} \Leftrightarrow b_{\frac{k-1}{3}}, && (56)\\
d_k^{'''} &= \frac{1}{2}(b_{k-1}^{(2)} \Leftrightarrow b_{\frac{k-1}{2}}), && (57)\\
d_k^{iv} &= b_k, && (58)
\end{aligned}$$

where $b_k^{(n)}$ represents the coefficient of X^k in $B^n(X)$.

Proof. A precise analysis of the different symmetries arising in the species $P_6^{\mathrm{bic}}(X,B)$ permit us to write the expansion (54). We then compute all coefficients of this expression by the same method as for the species $P_4^{\mathrm{bic}}(X,B)$. ∎

When we put $B = A$ in the two previous theorems, the coefficients appearing in the molecular expansions of the species P_4^{bic} and P_6^{bic} are simpler. In fact, by Proposition 1 we get the following expressions for a_k^i and d_k^i, for $i \in \{\prime, \prime\prime, \prime\prime\prime, iv\}$

$$\begin{aligned}
a_k^{'} &= \frac{1}{4}\mathbf{c}_{k+1} \Leftrightarrow \frac{1}{2}\mathbf{c}_k \Leftrightarrow \frac{3}{4}\mathbf{c}_{\frac{k}{2}} + \frac{1}{2}\mathbf{c}_{\frac{k-2}{4}},\\
a_k^{''} &= \mathbf{c}_k \Leftrightarrow \mathbf{c}_{\frac{k-1}{2}}, && (59)\\
a_k^{'''} &= \frac{1}{2}(\mathbf{c}_{k+1} \Leftrightarrow \mathbf{c}_{\frac{k}{2}}),\\
a_k^{iv} &= \mathbf{c}_k,
\end{aligned}$$

$$\begin{aligned}
d_k^{'} &= \frac{1}{6}\mathbf{c}_{k+2} \Leftrightarrow \frac{2}{3}\mathbf{c}_{k+1} + \frac{1}{2}\mathbf{c}_k \Leftrightarrow \frac{1}{2}\mathbf{c}_{\frac{k+1}{2}} + \frac{1}{2}\mathbf{c}_{\frac{k-1}{2}} \Leftrightarrow \frac{1}{6}\mathbf{c}_{\frac{k}{3}} + \frac{1}{2}\mathbf{c}_{\frac{k-3}{6}},\\
d_k^{''} &= \mathbf{c}_{k+1} \Leftrightarrow \mathbf{c}_k \Leftrightarrow \mathbf{c}_{\frac{k-1}{3}}, && (60)\\
d_k^{'''} &= \frac{1}{2}(\mathbf{c}_k \Leftrightarrow \mathbf{c}_{\frac{k-1}{2}}),\\
d_k^{iv} &= \mathbf{c}_k.
\end{aligned}$$

4 Molecular expansion of plane and planar 2-trees

In this part, we use the dissymmetry theorem and the results of the previous section to obtain an explicit form for the molecular expansion of the species of plane 2-trees and of planar 2-trees.

4.1 Plane 2-trees

Recall that plane 2-trees are 2-trees that are embedded (drawn) in the plane in such a way that all internal faces are triangles. The dissymetry theorem gives an expression for the species a_π in terms of the pointed species a_π^-, a_π^Δ and $a_\pi^{\dot\Delta}$, namely

$$a = a_\pi^- + a_\pi^\Delta \Leftrightarrow a_\pi^{\dot\Delta}. \tag{61}$$

Here, we can use the orientation of the plane to obtain simple expressions for the pointed species as function of the species A defined in the introduction, as shown in Figure 11 :

Theorem 6. The species arising in the dissymmmetry theorem for plane 2-trees satisfy

$$a_\pi^- = E_2(A), \tag{62}$$
$$a_\pi^\Delta = XC_3(A), \tag{63}$$
$$a_\pi^{\dot\Delta} = A_+ \cdot A, \tag{64}$$

where $A_+ = A \Leftrightarrow 1$.

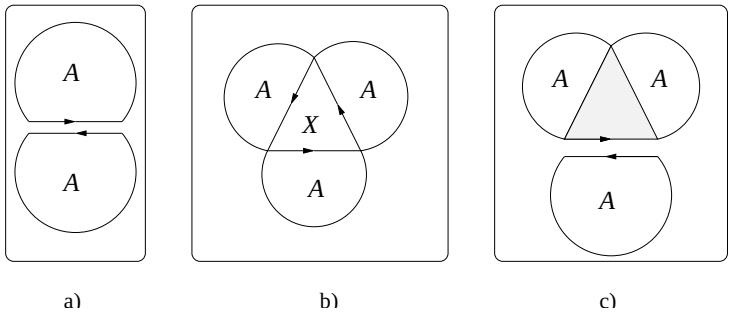

Figure 11: The species $E_2(A)$, $XC_3(A)$ and $A_+ \cdot A$

Using the expansion formulas for $E_2(A)$ and $C_3(A)$, given in Section 3, we can now compute the molecular expansion of the species a_π.

Theorem 7. The molecular expansion of the species a_π of plane 2-trees is given by

$$a_\pi = a_\pi(X) = 1 + X + \sum_{k\geq 2} b_k X^k + \sum_{k\geq 1} c_k E_2(X^k) + \sum_{k\geq 1} d_k XC_3(X^k), \tag{65}$$

where

$$b_k = \frac{2}{3}\mathbf{c}_k \Leftrightarrow \frac{1}{6}\mathbf{c}_{k+1} \Leftrightarrow \frac{1}{2}\mathbf{c}_{\frac{k}{2}} \Leftrightarrow \frac{1}{3}\mathbf{c}_{\frac{k-1}{3}}, \tag{66}$$
$$c_k = d_k = \mathbf{c}_k, \tag{67}$$

where X^k represents the species of k-lists of triangles and $\mathbf{c}_k$ are the usual Catalan numbers with the convention that $\mathbf{c}_r = 0$ if r is not an integer; see (13).

To conclude this section we write the asymmetric part, in the sense of G. Labelle [11], of the species of plane 2-trees :

$$\overline{a}_\pi(X) = 1 + X + \sum_{k\geq 2} b_k X^k, \tag{68}$$

where b_k, for $k \in \mathbb{N}$, is given by the formula (66). The species $\overline{a}_\pi$ is not to be confused with the pointed species a_π^-.

4.2 Planar 2-trees

This subsection is devoted to planar 2-trees, *i.e.* 2-trees admitting an embedding in the plane in such a way that all internal faces are triangles. The difference here is that the embedding is not explicitely given and that reflexive symmetries are possible. In other words, planar 2-trees are viewed as simple graphs. The dissymetry theorem for the species $a_{\rm p}$ of planar 2-trees yields

$$a_{\rm p} = a_{\rm p}^- + a_{\rm p}^\Delta \Leftrightarrow a_{\rm p}^{\underline{\Delta}}. \tag{69}$$

Moreover, we have the following expressions for the pointed species $a_{\rm p}^-$, $a_{\rm p}^\Delta$ and $a_{\rm p}^{\underline{\Delta}}$, in terms of the auxiliary species $P_4^{\rm bic}(X,Y)$ and $P_6^{\rm bic}(X,Y)$ introduced in Section 2.

Theorem 8. The species of pointed planar 2-trees $a_{\rm p}^-$, $a_{\rm p}^\Delta$ and $a_{\rm p}^{\underline{\Delta}}$ satisfy the following isomorphisms of species :

$$a_{\rm p}^-(X) = 1 + XE_2(A) + P_4^{\rm bic}(X,Y)|_{Y:=A}, \tag{70}$$

$$a_{\rm p}^\Delta(X) = X + X^2E_2(A) + XE_2(A_+) + XP_6^{\rm bic}(X,Y)|_{Y:=A}, \tag{71}$$

$$a_{\rm p}^{\underline{\Delta}}(X) = XE_2(A) + X^2E_2(A^2). \tag{72}$$

Proof. We obtain the functional equations (70) and (72) by analyzing the structures according to the degree of the distinguished edge. For example, the three terms on the right hand side of (70) correspond respectively to the degrees 0, 1 and 2 of the pointed edge. This isomorphism is described in Figure 12. In (71), the four terms correspond to the four possibilities for the number of edges of degree 2 in the pointed triangle, from 0 to 3; see Figure 13. For (72), see Figure 14. ∎

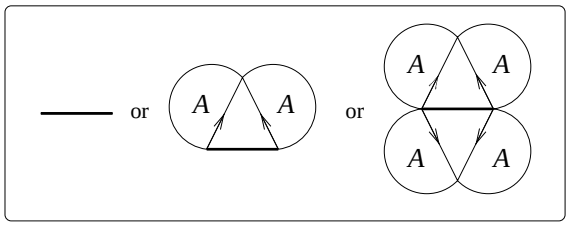

Figure 12: The species $a_{\rm p}^-$

Combining the molecular expansion of the quotient species $P_4^{\rm bic}(X,A)$ and $P_6^{\rm bic}(X,A)$ established in Section 3 with Proposition 1 and Proposition 5, gives the molecular expansion of the species $a_{\rm p}^-$ and $a_{\rm p}^\Delta$. Note that we use the same notation for the coefficients of the different molecular expansions in the four following theorems.

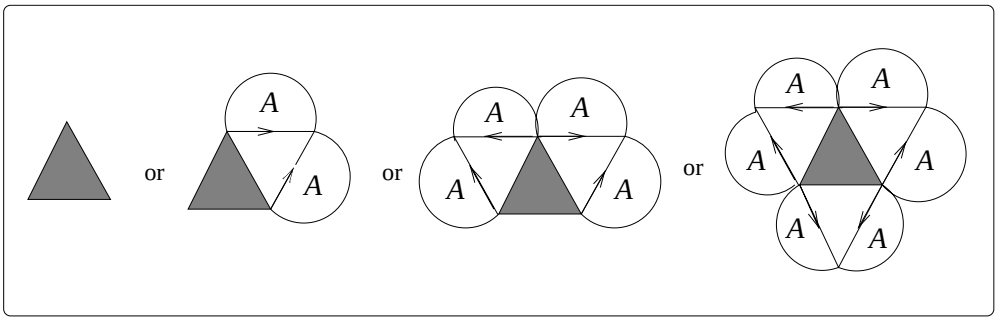

Figure 13: The species a_{p}^{Δ}

Theorem 9. The molecular expansion of the species a_{p}^{-} of edge pointed planar 2-trees is given by

$$\begin{aligned} a_{\mathrm{p}}^{-}(X) &= 1+\sum_{k\geq 0} a_k^1 X^k + \sum_{k\geq 1} a_k^2 E_2(X^k) + \sum_{k\geq 1} a_k^3 X E_2(X^k) \\ &\quad + \sum_{n\geq 1} a_k^4 X^2 E_2(X^k) + \sum_{k\geq 1} a_k^5 P_4^{\mathrm{bic}}(X, X^k), \end{aligned} \tag{73}$$

where

$$\begin{aligned} a_k^1 &= \frac{1}{4}\mathbf{c}_{k+1} \Leftrightarrow \frac{3}{4}\mathbf{c}_{\frac{k}{2}} \Leftrightarrow \frac{1}{2}\mathbf{c}_{\frac{k-1}{2}} + \frac{1}{2}\mathbf{c}_{\frac{k-2}{4}}, \\ a_k^2 &= \mathbf{c}_k \Leftrightarrow \mathbf{c}_{\frac{k-1}{2}}, \\ a_k^3 &= a_k^5 = \mathbf{c}_k, \\ a_k^4 &= \frac{1}{2}(\mathbf{c}_{k+1} \Leftrightarrow \mathbf{c}_{\frac{k}{2}}). \end{aligned} \tag{74}$$

Theorem 10. The molecular expansion of the species a_{p}^{Δ} is given by

$$\begin{aligned} a_{\mathrm{p}}^{\Delta}(X) &= 1+\sum_{k\geq 0} a_k^1 X^k + \sum_{k\geq 1} a_k^2 X\cdot E_2(X^k) + \sum_{k\geq 2} a_k^3 X^2 E_2(X^k) \\ &\quad + \sum_{k\geq 2} a_k^4 X C_3(X^k) + \sum_{k\geq 2} a_k^5 X P_6^{\mathrm{bic}}(X, X^k), \end{aligned} \tag{75}$$

where

$$\begin{aligned} a_k^1 &= \frac{1}{6}(\mathbf{c}_{k+1} \Leftrightarrow \mathbf{c}_k) \Leftrightarrow \frac{1}{2}\mathbf{c}_{\frac{k}{2}} \Leftrightarrow \mathbf{c}_{\frac{k-2}{2}} \Leftrightarrow \frac{1}{2}\mathbf{c}_{\frac{k-1}{2}} \Leftrightarrow \frac{1}{6}\mathbf{c}_{\frac{k-1}{3}} + \frac{1}{2}\mathbf{c}_{\frac{k-4}{6}}, \\ a_k^2 &= a_k^5 = \mathbf{c}_k, \\ a_k^3 &= \mathbf{c}_{k+1} \Leftrightarrow \mathbf{c}_{\frac{k-1}{3}}, \\ a_k^4 &= \frac{1}{2}(\mathbf{c}_k \Leftrightarrow \mathbf{c}_{\frac{k-1}{2}}). \end{aligned} \tag{76}$$

Proposition 1 and Proposition 5 also allow us to obtain the molecular expansion of the species $a_{\underline{\Delta}}$.

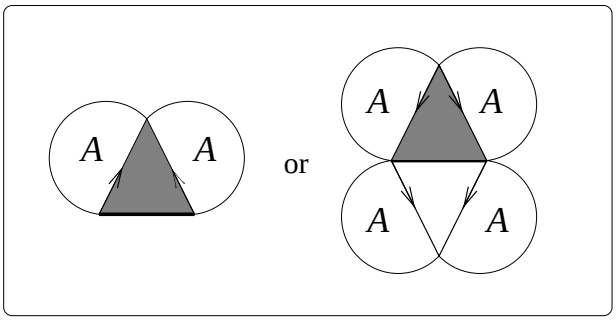

Figure 14: The species a_{p}^{Δ}

Theorem 11. The molecular expansion of the species a_{p}^{Δ} of planar 2-trees pointed at a triangle with a distinguished edge is given by

$$a_{\mathrm{p}}^{\Delta}(X) = \sum_{k\geq 0} a_k^1 X^k + \sum_{k\geq 1} a_k^2 X E_2(X^k) + \sum_{k\geq 1} a_k^3 X^2 E_2(X^k), \tag{77}$$

where

$$\begin{aligned} a_k^1 &= \frac{1}{2}\Big(\mathbf{c}_{k+1} \Leftrightarrow \mathbf{c}_k \Leftrightarrow \mathbf{c}_{\frac{k-1}{2}} \Leftrightarrow \mathbf{c}_{\frac{k}{2}}\Big), \\ a_k^2 &= \mathbf{c}_k, \\ a_k^3 &= \mathbf{c}_{k+1}. \end{aligned} \tag{78}$$

Using the dissymetry theorem, we are now able to put together relations (73)-(75)-(77) and give an explicit form of the molecular expansion of the species a_{p} of planar 2-trees.

Theorem 12. The molecular expansion of the species a_{p} of planar 2-trees is given by the following formula

$$\begin{aligned} a_{\mathrm{p}}(X) &= 1 + \sum_{k\geq 1} a_k^1 X^k + \sum_{k\geq 1} a_k^2 E_2(X^k) + \sum_{k\geq 1} a_k^3 X E_2(X^k) + \sum_{k\geq 2} a_k^4 X^2 E_2(X^k) \\ &\quad + \sum_{k\geq 2} a_k^5 X C_3(X^k) + \sum_{k\geq 0} a_k^6 P_4^{\mathrm{bic}}(X, X^k) + \sum_{k\geq 0} a_k^7 X P_6^{\mathrm{bic}}(X, X^k), \end{aligned} \tag{79}$$

where

$$\begin{aligned} a_k^1 &= \Leftrightarrow\frac{1}{12}\mathbf{c}_{k+1} + \frac{1}{3}\mathbf{c}_k \Leftrightarrow\frac{3}{4}\mathbf{c}_{\frac{k}{2}} \Leftrightarrow\frac{1}{2}\mathbf{c}_{\frac{k-1}{2}} \Leftrightarrow\frac{1}{6}\mathbf{c}_{\frac{k-1}{3}} + \frac{1}{2}\mathbf{c}_{\frac{k-2}{4}} + \frac{1}{2}\mathbf{c}_{\frac{k-4}{6}}, \\ a_k^2 &= \mathbf{c}_k \Leftrightarrow\mathbf{c}_{\frac{k-1}{2}}, \\ a_k^3 &= a_k^6 = a_k^7 = \mathbf{c}_k, \\ a_k^4 &= \frac{1}{2}(\mathbf{c}_{k+1} \Leftrightarrow\mathbf{c}_{\frac{k}{2}}) \Leftrightarrow\mathbf{c}_{\frac{k-1}{3}}, \\ a_k^5 &= \frac{1}{2}(\mathbf{c}_k \Leftrightarrow\mathbf{c}_{\frac{k-1}{2}}). \end{aligned} \tag{80}$$

5 Enumeration formulas

5.1 Enumeration of plane 2-trees

Before obtaining the explicit enumeration of plane 2-trees, we recall some basic formulas involving index series of the species of 2-element sets (E_2) and of oriented 3-cycles (C_3) :

$$Z_{E_2}(x_1,x_2,\ldots) = \frac{1}{2}(x_1^2+x_2), \quad ,_{E_2}(x_1,x_2,\ldots) = \frac{1}{2}(x_1^2 \Leftrightarrow x_2), \tag{81}$$

$$Z_{C_3}(x_1,x_2,\ldots) = \frac{1}{3}(x_1^3+2x_3), \quad ,_{C_3}(x_1,x_2,\ldots) = \frac{1}{3}(x_1^3 \Leftrightarrow x_3). \tag{82}$$

We will also use some substitutional laws of the theory of species : for any species F and G such that $G(0)=0$ (G has no structure on the empty set), we have

$$(F\circ G)(x) = F(G(x)), \tag{83}$$

$$(F\circ G)^{\sim}(x) = Z_F(\widetilde{G}(x),\widetilde{G}(x^2),\ldots)., \tag{84}$$

$$(\overline{F\circ G})(x) = ,_F(\bar{G}(x),\bar{G}(x^2),\ldots), \tag{85}$$

$$Z_{F\circ G} = Z_F\circ Z_G, \tag{86}$$

$$,_{F\circ G} = ,_F \circ ,_G, \tag{87}$$

where $\circ$ denotes the plethystic composition on the right hand side of (86) and (87).

If the species G has some structures on the empty set, *i.e.* $G(0)=g_0\neq 0$, formulas (84)–(86) remain valid. However, formula (83) should then be replaced by

$$(F\circ G)(x) = Z_F(G(x),g_0,g_0,\ldots), \tag{88}$$

and there is no known general formula for , . Here, we only need the following formulas

$$,_{E_2(G)}(x_1,x_2,\ldots) = g_0+\frac{1}{2}(,^2_G(x_1,x_2,\ldots)\Leftrightarrow,_G(x_2,x_4,\ldots)), \tag{89}$$

$$,_{C_3(G)}(x_1,x_2,\ldots) = g_0+\frac{1}{3}(,^3_G(x_1,x_2,\ldots)\Leftrightarrow,_G(x_3,x_6,\ldots)). \tag{90}$$

We now give the explicit enumerative formulas provided directly by the molecular expansion of the species of plane 2-trees.

Theorem 13. The numbers $a_{\pi,n}$, $\widetilde{a}_{\pi,n}$ and $\overline{a}_{\pi,n}$ of labelled, unlabelled and unlabelled asymmetric plane 2-trees on n triangles, $n\geq 2$, are given by

$$a_{\pi,n} = n!(\frac{2}{3}\mathbf{c}_n \Leftrightarrow \frac{1}{6}\mathbf{c}_{n+1}), \tag{91}$$

$$\widetilde{a}_{\pi,n} = \frac{2}{3}\mathbf{c}_n \Leftrightarrow \frac{1}{6}\mathbf{c}_{n+1}+\frac{1}{2}\mathbf{c}_{\frac{n}{2}}+\frac{2}{3}\mathbf{c}_{\frac{n-1}{3}}, \tag{92}$$

$$\overline{a}_{\pi,n} = \frac{2}{3}\mathbf{c}_n \Leftrightarrow \frac{1}{6}\mathbf{c}_{n+1} \Leftrightarrow \frac{1}{2}\mathbf{c}_{\frac{k}{3}} \Leftrightarrow \frac{1}{3}\mathbf{c}_{\frac{n-1}{3}}. \tag{93}$$

To obtain these enumerating formulas, we can also use the expressions (62)–(64) which lead to closed formulas for the associated series of the three pointed species : the exponential generating series of labelled structures,

$$\begin{aligned} a_{\pi}^{\bullet}(x) &= \frac{1}{2}(1+A^2(x)), \\ a_{\pi}^{\overset{\Delta}{\bullet}}(x) &= \frac{x}{3}(2+A^3(x)), \\ a_{\pi}^{\overset{\Delta}{\overset{\bullet}{\Delta}}}(x) &= A^2(x) \Leftrightarrow A(x), \end{aligned} \tag{94}$$

the ordinary generating series of unlabelled structures

$$\begin{aligned} \widetilde{a}_{\pi}^{\bullet}(x) &= \frac{1}{2}(A^2(x)+A(x^2)), \\ \widetilde{a}_{\pi}^{\overset{\Delta}{\bullet}}(x) &= \frac{x}{3}(A^3(x)+2A(x^3)), \\ \widetilde{a}_{\pi}^{\overset{\Delta}{\overset{\bullet}{\Delta}}}(x) &= A^2(x) \Leftrightarrow A(x), \end{aligned} \tag{95}$$

the cycle index series

$$\begin{aligned} Z_{a_{\pi}^{\bullet}}(x_1,x_2,\ldots) &= \frac{1}{2}\Big(A^2(x_1)+A(x_2)\Big), \\ Z_{a_{\pi}^{\overset{\Delta}{\bullet}}}(x_1,x_2,\ldots) &= \frac{x_1}{3}\Big(A^3(x_1)+2A(x_3)\Big), \\ Z_{a_{\pi}^{\overset{\Delta}{\overset{\bullet}{\Delta}}}}(x_1,x_2,\ldots) &= A^2(x_1) \Leftrightarrow A(x_1), \end{aligned} \tag{96}$$

the asymmetry cycle index series

$$\begin{aligned} \mathcal{A}_{a_{\pi}^{\bullet}}(x_1,x_2,\ldots) &= 1+\frac{1}{2}\Big(A^2(x_1) \Leftrightarrow A(x_2)\Big), \\ \mathcal{A}_{a_{\pi}^{\overset{\Delta}{\bullet}}}(x_1,x_2,\ldots) &= x_1+\frac{x_1}{3}\Big(A^3(x_1) \Leftrightarrow A(x_3)\Big), \\ \mathcal{A}_{a_{\pi}^{\overset{\Delta}{\overset{\bullet}{\Delta}}}}(x_1,x_2,\ldots) &= A^2(x_1) \Leftrightarrow A(x_1). \end{aligned} \tag{97}$$

We emphasize the fact, used above, that since the species A is asymmetric we have the following relations

$$A(x)=\widetilde{A}(x) = \overline{A}(x) \quad \text{and} \quad Z_A(x_1,x_2,\ldots)=A(x_1)=\mathcal{A}_A(x_1,x_2,\ldots). \tag{98}$$

We then deduce easily (thanks to the dissymmetry theorem) the expressions of the series associated with the species of plane 2-trees

Proposition 6. The series associated to the species a_{π} of plane 2-trees are given by

$$\begin{aligned} a_{\pi}(x) &= \frac{1}{2}+\frac{2}{3}x+A(x) \Leftrightarrow \frac{1}{2}A^2(x)+\frac{x}{3}A^3(x), \\ \widetilde{a}_{\pi}(x) &= 1+x+A(x)+\frac{x}{3}A^3(x) \Leftrightarrow \frac{1}{2}A(x^2) \Leftrightarrow \frac{x}{3}A(x^3) \Leftrightarrow \frac{1}{2}A^2(x), \\ \bar{a}_{\pi}(x) &= A(x)+\frac{x}{3}A^3(x) \Leftrightarrow A(x^2) \Leftrightarrow A(x^3) \Leftrightarrow \frac{1}{2}A^2(x), \\ Z_{a_{\pi}}(x_1,x_2,\ldots) &= A(x_1)+\frac{1}{2}A(x_2)+\frac{2}{3}x_1A(x_3) \Leftrightarrow \frac{1}{2}A^2(x_1)+\frac{x_1}{3}A^3(x_1), \\ \mathcal{A}_{a_{\pi}}(x_1,x_2,\ldots) &= 1+x_1+A(x_1)+\frac{x_1}{3}A^3(x_1) \Leftrightarrow \frac{1}{2}A(x_2) \Leftrightarrow \frac{x_1}{3}A(x_3) \Leftrightarrow \frac{1}{2}A^2(x_1). \end{aligned} \tag{99}$$

To recover the formulas (92), we can use the dissymmetry theorem and the next proposition giving the enumeration of the different pointed plane 2-trees.

Proposition 7. The coefficients $a^{-}_{\pi,n}$, $a^{\Delta}_{\pi,n}$, $a^{\underline{\Delta}}_{\pi,n}$ representing the numbers of labelled structures with n triangles for the different pointings, $\widetilde{a}^{-}_{\pi,n}$, $\widetilde{a}^{\Delta}_{\pi,n}$, $\widetilde{a}^{\underline{\Delta}}_{\pi,n}$ for the numbers of unlabelled structures, and $\overline{a}^{-}_{\pi,n}$, $\overline{a}^{\Delta}_{\pi,n}$, $\overline{a}^{\underline{\Delta}}_{\pi,n}$ for unlabelled asymmetric structures, are given, for $n \geq 2$, by

$$\begin{aligned} a^{-}_{\pi,n} &= \frac{n!}{2}\mathbf{c}_{n+1}, \\ a^{\Delta}_{\pi,n} &= \frac{n!}{3}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n), \\ a^{\underline{\Delta}}_{\pi,n} &= n!(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n), \end{aligned} \tag{100}$$

$$\begin{aligned} \widetilde{a}^{-}_{\pi,n} &= \frac{1}{2}(\mathbf{c}_{n+1} + \mathbf{c}_{\frac{n}{2}}), \\ \widetilde{a}^{\Delta}_{\pi,n} &= \frac{1}{3}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n + 2\mathbf{c}_{\frac{n-1}{3}}), \\ \widetilde{a}^{\underline{\Delta}}_{\pi,n} &= \mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n, \end{aligned} \tag{101}$$

and

$$\begin{aligned} \bar{a}^{-}_{\pi,n} &= \frac{1}{2}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_{\frac{n}{2}}), \\ \bar{a}^{\Delta}_{\pi,n} &= \frac{1}{3}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n \Leftrightarrow \mathbf{c}_{\frac{n-1}{3}}), \\ \bar{a}^{\underline{\Delta}}_{\pi,n} &= \mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n. \end{aligned} \tag{102}$$

Proof. To obtain these coefficients, we simply use relations (94), (95) and (97). ∎

We now give the explicit expressions for the cycle index series of the species of plane 2-trees.

Proposition 8. The cycle index series and the asymmetric index series of the species of plane 2-trees are

$$Z_{a_\pi}(x_1, x_2, \ldots) = 1 + \sum_{n\geq 1}(\frac{2}{3}\mathbf{c}_n \Leftrightarrow \frac{1}{6}\mathbf{c}_{n+1})x_1^n + \frac{1}{2}\sum_{n\geq 1}\mathbf{c}_n x_2^n + \frac{2}{3}x_1\sum_{n\geq 0}\mathbf{c}_n x_3^n, \tag{103}$$

$$, \; a_\pi(x_1, x_2, \ldots) = 1 + x_1 + \sum_{n\geq 1}(\frac{2}{3}\mathbf{c}_n \Leftrightarrow \frac{1}{6}\mathbf{c}_{n+1})x_1^n \Leftrightarrow \frac{1}{2}\sum_{n\geq 1}\mathbf{c}_n x_2^n \Leftrightarrow \frac{1}{3}x_1\sum_{n\geq 0}\mathbf{c}_n x_3^n. \tag{104}$$

Proof. We first express the cycle index series given by the relations (96) in powers of x_1, x_2, ...

$$\begin{aligned} Z_{a^{-}_\pi}(x_1, x_2, \ldots) &= \frac{1}{2}\sum_{n\geq 0}\mathbf{c}_{n+1}x_1^n + \frac{1}{2}\sum_{n\geq 0}\mathbf{c}_n x_2^n, \\ Z_{a^{\Delta}_\pi}(x_1, x_2, \ldots) &= \frac{1}{3}\sum_{n\geq 1}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n)x_1^n + \frac{2}{3}x_1\sum_{n\geq 0}\mathbf{c}_n x_3^n, \\ Z_{a^{\underline{\Delta}}_\pi}(x_1, x_2, \ldots) &= \sum_{n\geq 1}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n)x_1^n. \end{aligned} \tag{105}$$

We also have

$$\begin{aligned}
, \ a_{\pi}^{-}(x_1, x_2, \ldots) &= 1 + \frac{1}{2}\sum_{n\geq 0} \mathbf{c}_{n+1} x_1^n \Leftrightarrow \frac{1}{2}\sum_{n\geq 0} \mathbf{c}_n x_2^n, \\
, \ a_{\pi}^{\Delta}(x_1, x_2, \ldots) &= x_1 + \frac{1}{3}\sum_{n\geq 1} (\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n) x_1^n \Leftrightarrow \frac{1}{3} x_1 \sum_{n\geq 0} \mathbf{c}_n x_3^n, \\
, \ a_{\pi}^{\underline{\Delta}}(x_1, x_2, \ldots) &= \sum_{n\geq 1} (\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n) x_1^n.
\end{aligned} \tag{106}$$

It suffices then to use the dissymmetry theorem to obtain the stated result. ■

5.2 Enumeration of planar 2-trees

We now give all associated series of the species a_{p}^{-}, a_{p}^{Δ} and $a_{\mathrm{p}}^{\underline{\Delta}}$ using substitutionnal laws of the theory of species. After this, we will be able to give all coefficients arising in these differents series, and, with the dissymetry theorem, we obtain the number of labelled and unlabelled planar 2-trees on n triangles as well as the coefficients of its cycle and asymmetry index series.

Theorem 14. The exponential generating function of labelled stuctures for the species a_{p}^{-}, a_{p}^{Δ} and $a_{\mathrm{p}}^{\underline{\Delta}}$ of planar pointed 2-trees are given, in terms of the species A, by

$$\begin{aligned}
a_{\mathrm{p}}^{-}(x) &= 1 + \frac{x}{2}(1 + A^2(x)) + \frac{1}{4}x^2 A^4(x), \\
a_{\mathrm{p}}^{\Delta}(x) &= x + \frac{x^2}{2}(1 + A^2(x)) + \frac{x}{2}A_{+}^2(x) + \frac{x^4}{6}A^6(x), labelgf1 \\
a_{\mathrm{p}}^{\underline{\Delta}}(x) &= \frac{x}{2}(1 + A^2(x)) + \frac{x^2}{2}(1 + A^4(x)).
\end{aligned} \tag{107}$$

Moreover, the ordinary generating series of unlabelled structures of these species are given by

$$\begin{aligned}
\widetilde{a}_{\mathrm{p}}^{-}(x) &= 1 + xA(x) + \frac{x}{2}(A^2(x) + A(x^2)) + \frac{x^2}{4}(A^4(x) + 3A^2(x^2)), \\
\widetilde{a}_{\mathrm{p}}^{\Delta}(x) &= x + \frac{x^2}{2}(A^2(x) + A(x^2)) + \frac{x}{2}(A_{+}^2(x) + A_{+}(x^2)) \\
&\qquad + \frac{x^4}{6}(A^6(x) + 2A^2(x^3) + 3A^3(x^2)), \\
\widetilde{a}_{\mathrm{p}}^{\underline{\Delta}}(x) &= \frac{x}{2}(A^2(x) + A(x^2)) + \frac{x^2}{2}(A^4(x) + A^2(x^2)).
\end{aligned} \tag{108}$$

Corollary 1. The exponential and the ordinary generating functions of the species of planar 2-trees are given, in terms of A, by

$$\begin{aligned}
a_{\mathrm{p}}(x) &= 1 + x + \frac{x}{2}A_{+}^2(x) + \frac{x^2}{2}A^2(x) \Leftrightarrow \frac{x^2}{4}A^4(x) \Leftrightarrow \frac{x^4}{6}A^6(x), \\
\widetilde{a}_{\mathrm{p}}(x) &= 1 + x + \frac{x}{2}(A_{+}^2(x) + A_{+}(x^2)) + \frac{x^2}{2}A(x^2) + \frac{x^2}{2}(A^2(x) \Leftrightarrow A^2(x^2)) \\
&\qquad \Leftrightarrow \frac{x^2}{4}A^4(x) + \frac{x^4}{6}(A^6(x) + 2A^2(x^3) + 3A^3(x^2)).
\end{aligned} \tag{109}$$

A simple extraction of coefficients in Theorem 14, combined with Proposition 1, yields the following corollary.

Corollary 2. The numbers $a^{-}_{\mathrm{p},n}$, $a^{\Delta}_{\mathrm{p},n}$ and $a^{\underline{\Delta}}_{\mathrm{p},n}$ of labelled planar 2-trees on n triangles pointed respectively at an edge, at a triangle, and at a triangle pointed at one of its edges, are given by

$$\begin{aligned} a^{-}_{\mathrm{p},n} &= \frac{n!}{4}\mathbf{c}_{n+1}, \\ a^{\Delta}_{\mathrm{p},n} &= \frac{n!}{6}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n), \\ a^{\underline{\Delta}}_{\mathrm{p},n} &= \frac{n!}{2}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n). \end{aligned} \tag{110}$$

Moreover, for the same pointed series, the numbers of unlabelled structures on n triangles $\widetilde{a}^{-}_{\mathrm{p},n}$, $\widetilde{a}^{\Delta}_{\mathrm{p},n}$ and $\widetilde{a}^{\underline{\Delta}}_{\mathrm{p},n}$ have the following expressions :

$$\begin{aligned} \widetilde{a}^{-}_{\mathrm{p},n} &= \frac{1}{4}\mathbf{c}_{n+1} + \frac{1}{2}\mathbf{c}_{\frac{n-1}{2}} + \frac{3}{4}\mathbf{c}_{\frac{n}{2}}, \\ \widetilde{a}^{\Delta}_{\mathrm{p},1} &= 1,\ \widetilde{a}^{\Delta}_{\mathrm{p},2} = 1,\ \widetilde{a}^{\Delta}_{\mathrm{p},3} = 2,\ \widetilde{a}^{\Delta}_{\mathrm{p},4} = 6, \\ \widetilde{a}^{\Delta}_{\mathrm{p},n} &= \frac{1}{6}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n) + \frac{1}{2}\Big(\mathbf{c}_{\frac{n-1}{2}} + \mathbf{c}_{\frac{n}{2}}\Big) + \frac{1}{3}\mathbf{c}_{\frac{n-1}{3}}, \quad n \geq 5 \\ \widetilde{a}^{\underline{\Delta}}_{\mathrm{p},n} &= \frac{1}{2}(\mathbf{c}_{n+1} \Leftrightarrow \mathbf{c}_n) + \mathbf{c}_{\frac{n-1}{2}} + \mathbf{c}_{\frac{n}{2}}. \end{aligned} \tag{111}$$

Hence, the dissymmetry theorem leads us to enumeration formulas for labelled and unlabelled planar 2-trees as follows. For the unlabelled asymmetric enumeration, we use directly the molecular decomposition of the species a_{p}.

Theorem 15. The numbers $a_{\mathrm{p},n}$, $\widetilde{a}_{\mathrm{p},n}$ and $\bar{a}_{\mathrm{p},n}$ of labelled, unlabelled and unlabelled asymmetric planar 2-trees on n triangles, are given by the following formulas

$$a_{\mathrm{p},n} = n!(\frac{1}{3}\mathbf{c}_n \Leftrightarrow \frac{1}{12}\mathbf{c}_{n+1}), \tag{112}$$

$$\widetilde{a}_{\mathrm{p},n} = \frac{1}{3}\mathbf{c}_n \Leftrightarrow \frac{1}{12}\mathbf{c}_{n+1} + \frac{1}{2}\mathbf{c}_{\frac{n-1}{2}} + \frac{1}{3}\mathbf{c}_{\frac{n-1}{3}} + \frac{3}{4}\mathbf{c}_{\frac{n}{2}}, \tag{113}$$

$$\bar{a}_{\mathrm{p},n} = \Leftrightarrow\frac{1}{12}\mathbf{c}_{n+1} + \frac{1}{3}\mathbf{c}_n \Leftrightarrow \frac{3}{4}\mathbf{c}_{\frac{n}{2}} \Leftrightarrow \frac{1}{2}\mathbf{c}_{\frac{n-1}{2}} \Leftrightarrow \frac{1}{6}\mathbf{c}_{\frac{n-1}{3}} + \frac{1}{2}\mathbf{c}_{\frac{n-2}{4}} + \frac{1}{2}\mathbf{c}_{\frac{n-4}{6}}. \tag{114}$$

Finally, we give the expression of the asymmetry index series of the species a_{p} of planar 2-trees obtained directly from the molecular expansion of the species a_{p}.

Proposition 9. The asymmetry index series of the species of planar 2-trees is given by

$$\begin{aligned} ,\ a_{\mathrm{p}}(x_1, x_2, \ldots) = 1 + x_1 + \sum_n \gamma^1_n x_1^n + \sum_n \gamma^2_n x_2^n + \sum_n \gamma^3_n x_1 x_2^n + \sum_n \gamma^4_n x_1^2 x_2^n + \\ + \sum_n \gamma^5_n x_1 x_3^n + \sum_n \gamma^6_n x_2 x_4^n + \sum_n \gamma^7_n x_1 x_3 x_6^n, \end{aligned} \tag{115}$$

where

$$\begin{aligned}
\gamma_n^1 &= \Leftrightarrow\frac{1}{12}\mathbf{c}_{n+1} + \frac{1}{3}\mathbf{c}_n,\\
\gamma_n^2 &= \gamma_n^3 = \Leftrightarrow\frac{1}{2}\mathbf{c}_n,\\
\gamma_n^4 &= \Leftrightarrow\frac{1}{4}\mathbf{c}_{n+1},\\
\gamma_n^5 &= \Leftrightarrow\frac{1}{6}\mathbf{c}_n,\\
\gamma_n^6 &= \gamma_n^7 = \frac{1}{2}\mathbf{c}_n.
\end{aligned} \tag{116}$$

5.3 Another method for the unlabelled enumeration

In order to obtain the unlabelled enumeration of plane and planar 2-trees, we can also use the approach of Palmer and Read in [15]. Remark first that, for any species F, we can write

$$F = \sum_{k\geq 1} F_{(k)}, \tag{117}$$

where for $k \geq 1$, $F_{(k)}$ represents the symmetric part of F of order k, *i.e.* the subspecies consisting of F-structures whose stabilizer is of order k exactly. In particular, $F_{(1)} = \overline{F}$, the asymmetric part of F.

Also note that, for $G = F_{(k)}$, $k \geq 1$, we have $G(x) = \frac{1}{k}\widetilde{G}(x)$, since an unlabelled $F_{(k)}$-structure of degree n can be labelled in $n!/k$ ways. Hence

$$\widetilde{F}(x) = F(x) + \sum_{k\geq 2} \frac{k \Leftrightarrow 1}{k}\widetilde{F}_{(k)}(x). \tag{118}$$

For plane 2-trees, we have

$$a_\pi = \overline{a}_\pi + a_{\pi,(2)} + a_{\pi,(3)}, \tag{119}$$

and for planar 2-trees,

$$a_{\mathrm{p}} = \overline{a}_{\mathrm{p}} + a_{\mathrm{p},(2)} + a_{\mathrm{p},(3)} + a_{\mathrm{p},(4)} + a_{\mathrm{p},(6)}. \tag{120}$$

Hence, we can write

$$\widetilde{a}_\pi(x) = a_\pi(x) + \frac{1}{2}\widetilde{a}_{\pi,(2)}(x) + \frac{2}{3}\widetilde{a}_{\pi,(3)}(x), \tag{121}$$

and

$$\widetilde{a}_{\mathrm{p}}(x) = a_{\mathrm{p}}(x) + \frac{1}{2}\widetilde{a}_{\mathrm{p},(2)}(x) + \frac{2}{3}\widetilde{a}_{\mathrm{p},(3)}(x) + \frac{3}{4}\widetilde{a}_{\mathrm{p},(4)}(x) + \frac{5}{6}\widetilde{a}_{\mathrm{p},(6)}(x). \tag{122}$$

After identifying all terms appearing in (121), we then deduce

$$\widetilde{a}_\pi(x) = a_\pi(x) + \frac{1}{2}A(x^2) + \frac{2}{3}xA(x^3), \tag{123}$$

for the plane case. For planar 2-trees, we have

$$\begin{aligned}
\widetilde{a}_{\mathrm{p},(2)}(x) &= \frac{3}{2}(A(x^2) \Leftrightarrow x^2 A(x^4)) + xA(x^2) \Leftrightarrow x^4 A(x^6), \\
\widetilde{a}_{\mathrm{p},(3)}(x) &= \frac{1}{2}(xA(x^3) \Leftrightarrow x^4 A(x^6)), \\
\widetilde{a}_{\mathrm{p},(4)}(x) &= x^2 A(x^4), \quad \widetilde{a}_{\mathrm{p},(6)} = x^4 A(x^6),
\end{aligned} \tag{124}$$

which yields

$$\widetilde{a}_{\mathrm{p}}(x) = a_{\mathrm{p}}(x) + \frac{1}{2}xA(x^2) + \frac{1}{3}xA(x^3) + \frac{3}{4}A(x^2). \tag{125}$$

It remains to extract the coefficients of x^n in equations (123) and (125) to find the numbers of unlabelled plane and planar 2-trees over n triangles, given by (92) and (113).

Enumération des 2-arbres k-gonaux

Gilbert Labelle, Cédric Lamathe, Pierre Leroux

RÉSUMÉ : *Dans ce travail*[1]*, nous généralisons les 2-arbres en remplaçant les triangles par des quadrilatères, des pentagones ou des polygones à k côtés (k-gones), où $k \geq 3$ est fixe. Cette généralisation, aux 2-arbres k-gonaux, est naturelle et est étroitement liée dans le cas planaire aux arbres cellulaires. Notre objectif est le dénombrement, étiqueté et non étiqueté, des 2-arbres k-gonaux selon le nombre n de k-gones. Nous donnons des formules explicites dans le cas étiqueté, et, dans le cas non étiqueté, des formules de récurrence et des formules asymptotiques.*

ABSTRACT: *In this paper*[1]*, we generalize 2-trees by replacing triangles by quadrilaterals, pentagons or k-sided polygons (k-gons), where $k \geq 3$ is given. This generalization, to k-gonal 2-trees, is natural and is closely related, in the planar case, to some specializations of the cell-growth problem. Our goal is the enumeration, labelled and unlabelled, of k-gonal 2-trees according to the number n of k-gons. We give explicit formulas in the labelled case, and, in the unlabelled case, recursive and asymptotic formulas.*

1 Introduction

L'espèce des arbres bidimensionnels, ou 2-arbres, a été bien étudiée dans la littérature. Voir par exemple [4] et [2, 3]. Essentiellement, un 2-arbre est un graphe simple connexe constitué de triangles qui sont liés entre eux par les arêtes de manière arborescente, c'est-à-dire sans former de cycles (de triangles). Dans [5], Harary et al. ont énuméré une variante des arbres cellulaires (relié au "cell-growth problem"), à savoir des 2-arbres k-gonaux plans et planaires[2], dans lesquels les triangles ont été remplacés par des quadrilatères, des pentagones ou des polygones à k côtés (k-gones), où $k \geq 3$ est fixe. De tels 2-arbres, bâtis sur des k-gones, sont appelés 2-arbres k-gonaux. Cette généralisation apparaît naturellement et le but de ce travail est l'énumération des 2-arbres k-gonaux libres, c'est-à-dire vus comme graphes simples, sans question de planarité. La figure 1 a) propose un exemple de 2-arbres k-gonal, dans le cas où $k = 4$.

Nous disons qu'un 2-arbre k-gonal est *orienté* si ses arêtes sont orientées de façon telle que chaque k-gone forme un cycle orienté, voir la figure 1 b). Notons par $\mathcal{A}$ et par $\mathcal{A}_o$ les espèces des 2-arbres k-gonaux et des 2-arbres k-gonaux orientés respectivement. Pour ces deux espèces, nous utilisons les symboles $-$, $\diamond$ et $\underline{\diamond}$ en exposant pour indiquer que les structures ont été pointées en une arête, en un polygone, et en un polygone muni d'une arête distinguée, respectivement.

Notre objectif est le dénombrement, étiqueté et non étiqueté, des 2-arbres k-gonaux selon le nombre n de k-gones. Nous donnons des formules explicites dans le cas étiqueté, et dans le cas non étiqueté, des formules de récurrence et des formules asymptotiques. Pour cela, nous adaptons l'approche de Fowler et al. dans [2, 3] qui correspond au cas $k = 3$. En particulier, les 2-arbres sont étiquetés aux k-gones.

[1] Avec l'appui du FCAR (Québec) et du CRSNG (Canada)

[2] Au sens où toutes les faces, à part la face externe, sont des k-gones

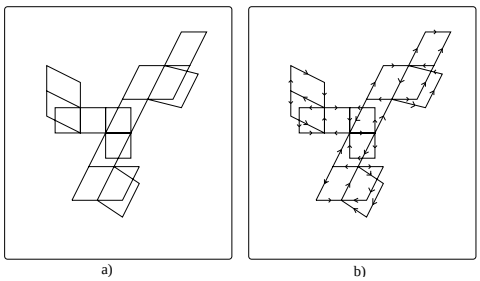

Figure 1: Un 2-arbre 4-gonal non orienté et orienté

La principale difficulté à cette extension vient, comme on le verra, du cas où k est pair.

Les deux premières étapes sont assez directes. Il s'agit d'étendre le théorème de dissymétrie au cas k-gonal et de caractériser l'espèce $B = \mathcal{A}^{\rightarrow}$ des 2-arbres k-gonaux munis d'une arête distinguée et orientée, à l'aide d'une équation fonctionnelle de type lagrangien. Le premier résultat est une extension immédiate du cas $k = 3$ et la démonstration est omise.

Théorème 1.1. THÉORÈME DE DISSYMÉTRIE. *Les espèces $\mathcal{A}$ et $\mathcal{A}_o$ des 2-arbres k-gonaux orientés et non orientés respectivement satisfont les isomorphismes d'espèces suivants :*

$$\mathcal{A}_o^{-} + \mathcal{A}_o^{\diamond} = \mathcal{A}_o + \mathcal{A}_o^{\underline{\diamond}}, \tag{1}$$

$$\mathcal{A}^{-} + \mathcal{A}^{\diamond} = \mathcal{A} + \mathcal{A}^{\underline{\diamond}}. \tag{2}$$

Dans la prochaine section, nous caractérisons l'espèce $B = \mathcal{A}^{\rightarrow}$ et nous en donnons ses propriétés. Par la suite, nous exprimons les diverses espèces pointées qui apparaissent dans le théorème de dissymétrie en fonction de l'espèce B et nous en déduisons les résultats énumératifs désirés pour les espèces $\mathcal{A}_o$ et $\mathcal{A}$. Le cas orienté, plus simple, est traité d'abord, dans la section 3. Le cas non orienté, suit, dans la section 4, en distinguant les deux cas de parité de k, pour le dénombrement non étiqueté. Enfin, les résultats asymptotiques sont présentés dans la section 5.

2 L'espèce $B = \mathcal{A}^{\rightarrow}$

L'espèce $B = \mathcal{A}^{\rightarrow}$ joue un rôle fondamental dans l'étude des 2-arbres k-gonaux.

Théorème 2.1. *L'espèce $B = \mathcal{A}^{\rightarrow}$ des 2-arbres k-gonaux pointés en une arête orientée satisfait l'équation (isomorphisme) fonctionnelle suivante :*

$$B = E(XB^{k-1}), \tag{3}$$

où E représente l'espèce des ensembles.

Preuve. On décompose une $\mathcal{A}^{\rightarrow}$-structure en un ensemble de *pages*, c'est-à-dire en sous-graphes maximaux qui partagent un seul k-gone avec l'arête distinguée. Pour chaque page, l'orientation de l'arête pointée permet alors de définir un ordre et une orientation sur les $k-1$ arêtes restantes du polygone possédant cette arête, selon la figure 2 a) pour le cas impair, et b) pour le cas pair. Ces arêtes étant orientées, on peut alors y accrocher des B-structures. On en déduit alors l'équation (3). ■

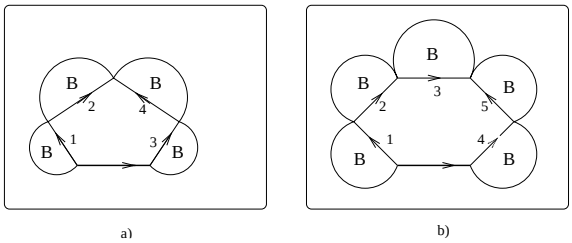

Figure 2: Une page orientée a) $k = 5$ b) $k = 6$

On peut relier simplement l'espèce $B = \mathcal{A}^{\rightarrow}$ à celle des arborescences (arbres enracinés), A, caractérisée par l'équation fonctionnelle $A = XE(A)$, où X est ici l'espèce des sommets. En effet de (3), on déduit successivement

$$(k-1)XB^{k-1} = (k-1)XE((k-1)XB^{k-1}), \tag{4}$$

sachant que $E^m(X) = E(mX)$, et, par unicité,

$$(k-1)XB^{k-1} = A((k-1)X). \tag{5}$$

Finalement, on obtient l'expression suivante pour l'espèce B en fonction de l'espèce des arborescences :

Proposition 2.2. *L'espèce $B = \mathcal{A}^{\rightarrow}$ des 2-arbres k-gonaux pointés en une arête orientée vérifie*

$$B = \sqrt[k-1]{\frac{A((k-1)X)}{(k-1)X}}. \tag{6}$$

Proposition 2.3. *Les nombres $a_n^{\rightarrow}$, $a_{n_1,n_2,\ldots}^{\rightarrow}$, et $b_n = \widetilde{a}_n^{\rightarrow}$ de 2-arbres k-gonaux pointés en une arête orientée et ayant n k-gones, respectivement étiquetés, laissés fixes par une permutation de $\mathbb{S}_n$ de type cyclique $1^{n_1}2^{n_2}\ldots$, et non étiquetés, satisfont les relations suivantes :*

$$a_n^{\rightarrow} = ((k-1)n+1)^{n-1} = m^{n-1}, \tag{7}$$

où $m = (k-1)n+1$ est le nombre d'arêtes,

$$a_{n_1,n_2,\ldots}^{\rightarrow} = \prod_{i=1}^{\infty}(1+(k-1)\sum_{d|i} dn_d)^{n_i-1}(1+(k-1)\sum_{\substack{d|i\\ d<i}} dn_d), \tag{8}$$

et

$$b_n = \frac{1}{n}\sum_{1\le j\le n}\sum_{\alpha}(|\alpha|+1)b_{\alpha_1}b_{\alpha_2}\ldots b_{\alpha_{k-1}}b_{n-j}, \qquad b_0 = 1, \tag{9}$$

la deuxième somme étant prise sur les $(k-1)$-uplets d'entiers $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_{k-1})$ tels que $|\alpha|+1$ divise l'entier j, où $|\alpha| = \alpha_1 + \alpha_2 + \cdots + \alpha_{k-1}$.

Preuve. Les formules (7) et (8) s'obtiennent en spécialisant avec $\mu = (k-1)^{-1}$ les formules suivantes, données par Fowler et al. dans [2, 3],

$$\left(\frac{A(x)}{x}\right)^{\mu} = \sum_{n\geq 0} \mu(\mu+n)^{n-1}\frac{x^n}{n!}, \tag{10}$$

$Z_{\left(\frac{A(X/\mu)}{X/\mu}\right)^{\mu}} =$

$$\sum_{n_1,n_2,\ldots} \frac{x_1^{n_1}x_2^{n_2}\ldots}{1^{n_1}n_1!2^{n_2}n_2!\ldots}\prod_{i=1}^{\infty}(1+\frac{1}{\mu}\sum_{d|i} dn_d)^{n_i-1}(1+\frac{1}{\mu}\sum_{d|i,d<i} dn_d). \tag{11}$$

La formule (7) peut également se voir directement par une adaptation de la bijection de Prüfer. Pour obtenir la récurrence (9), il suffit de prendre la dérivée logarithmique de l'équation

$$\widetilde{B}(x) = \exp\left(\sum_{i\geq 1}\frac{x^i\widetilde{B}^{k-1}(x^i)}{i}\right), \tag{12}$$

où $\widetilde{B}(x) = \sum_{n\geq 0} b_n x^n$, qui découle de la relation (3). ■

La suite des nombres $\{b_n\}$, pour $k = 2, 3, 4, 5$, est répertoriée dans l'encyclopédie des suites d'entiers [11] et l'équation (3), dans l'encyclopédie des structures combinatoires [6]. Le comportement asymptotique des nombres b_n est analysé, notamment en fonction de k, dans la section 5.

3 Cas orienté

Commençons par déterminer les espèces pointées qui apparaissent dans le théorème de dissymétrie. Ces relations sont assez immédiates et la démonstration est laissée au lecteur.

Proposition 3.1. *Les espèces $\mathcal{A}_o^-$, $\mathcal{A}_o^\diamond$, et $\mathcal{A}_o^{\underline{\diamond}}$ sont caractérisées par les isomorphismes suivants*

$$\mathcal{A}_o^- = B, \quad \mathcal{A}_o^\diamond = XC_k(B), \quad \mathcal{A}_o^{\underline{\diamond}} = XB^k, \tag{13}$$

où $B = \mathcal{A}^{\rightarrow}$ et C_k représente l'espèce des cycles (orientés) de longueur k.

Le théorème de dissymétrie permet d'exprimer la série génératrice ordinaire $\widetilde{a}_o(x)$ des 2-arbres k-gonaux orientés non étiquetés, en termes des espèces pointées,

$$\widetilde{a}_o(x) = \widetilde{a}_o^-(x) + \widetilde{a}_o^\diamond(x) - \widetilde{a}_o^{\underline{\diamond}}(x), \tag{14}$$

et par la proposition 3.1, nous pouvons alors exprimer $\widetilde{a}_o(x)$ en fonction de $\widetilde{B}(x) = \widetilde{a}^{\rightarrow}(x)$.

Proposition 3.2. *La série génératrice ordinaire $\widetilde{a}_o(x)$ de l'espèce des 2-arbres k-gonaux orientés non étiquetés est donnée par l'expression*

$$\widetilde{a}_o(x) = \widetilde{B}(x) + \frac{x}{k}\sum_{\substack{d|k\\ d>1}} \phi(d)\widetilde{B}^{\frac{k}{d}}(x^d) - \frac{k-1}{k}x\widetilde{B}^k(x). \tag{15}$$

Corollaire 3.3. *Les nombres $a_{o,n}$ et $\widetilde{a}_{o,n}$ de 2-arbres k-gonaux orientés étiquetés et non étiquetés, sur n k-gones sont donnés par*

$$a_{o,n} = ((k-1)n+1)^{n-2} = m^{n-2}, \quad n \geq 2, \tag{16}$$

$$\widetilde{a}_{o,n} = b_n - \frac{k-1}{k}b_{n-1}^{(k)} + \frac{1}{k}\sum_{\substack{d|k\\ d>1}} \phi(d) b_{\frac{n-1}{d}}^{(\frac{k}{d})}, \tag{17}$$

où $b_i^{(j)} = \displaystyle\sum_{i_1+\cdots+i_j=i} b_{i_1}b_{i_2}\ldots b_{i_j}$, représente le coefficient de x^i dans la série $\widetilde{B}^j(x)$, avec $b_r^{(j)} = 0$ si r est non entier ou négatif.

Preuve. Pour le cas étiqueté, il suffit de remarquer que $a_n^{\rightarrow} = ma_{o,n}$. Dans le cas non étiqueté, l'équation (17) s'obtient directement de (15). ■

4 Cas non orienté

Dans le cas non orienté, le nombre a_n de 2-arbres k-gonaux étiquetés sur n polygones satisfait $2a_n = a_{o,n} + 1$, puisque le seul 2-arbre k-gonal orienté étiqueté laissé fixe par changement d'orientation pour un nombre de polygones donné, est celui dont les polygones partagent tous une arête commune. On obtient

Proposition 4.1. *Le nombre a_n de 2-arbres k-gonaux étiquetés sur n polygones est donné par*

$$a_n = \frac{1}{2}\left(m^{n-2}+1\right), \qquad n \geq 2, \tag{18}$$

où $m = (k-1)n+1$.

Pour le dénombrement non étiqueté des 2-arbres k-gonaux (non orientés), nous allons considérer certaines espèces quotients de la forme $F/\mathbb{Z}_2$, où F est une espèce de structures "orientées" et $\mathbb{Z}_2 = \{1, \tau\}$, est un groupe dont l'action de τ sur les F-structures est de renverser l'orientation. Une structure d'une telle espèce quotient consiste alors en une orbite $\{s, \tau\cdot s\}$ de F-structures selon l'action de $\mathbb{Z}_2$.

Par exemple, les diverses espèces pointées de 2-arbres k-gonaux , a^-, $a^\diamond$ et $a^{\underline{\diamond}}$, s'expriment comme espèces quotients des espèces de 2-arbres k-gonaux orientés correspondantes :

$$a^- = \frac{a^{\rightarrow}}{\mathbb{Z}_2}, \quad a^\diamond = \frac{a_o^\diamond}{\mathbb{Z}_2} = \frac{XC_k(B)}{\mathbb{Z}_2}, \quad a^{\underline{\diamond}} = \frac{a_o^{\underline{\diamond}}}{\mathbb{Z}_2} = \frac{XB^k}{\mathbb{Z}_2}. \tag{19}$$

Pour le dénombrement non étiqueté de telles espèces quotients, on utilise la formule suivante qui est évidente :

$$(F/\mathbb{Z}_2)^{\sim}(x) = \frac{1}{2}(\widetilde{F}(x) + \widetilde{F}_\tau(x)), \tag{20}$$

où $\widetilde{F}_\tau(x) = \sum_{n\geq 0} |\mathrm{Fix}_{\widetilde{F}_n}(\tau)|x^n$ est la série génératrice des F-structures non étiquetées laissées fixes par l'action de τ, c'est-à-dire par changement d'orientation. Toutefois, le calcul de ces séries $\widetilde{F}_\tau(x)$ est assez complexe et il est avantageux de différencier en deux cas selon la parité de k.

4.1 Cas k impair

On peut remarquer, en observant les figures 2 a) et b), que dans tout k-gone contenant l'arête pointée (mais non orientée), d'une $\mathcal{A}^-$-structure, il est possible d'orienter les $k-1$ autres arêtes, dans la direction s'éloignant de l'arête pointée comme dans la figure 2 a), lorsque k est impair, mais qu'il restera une arête ambiguë si k est pair. Ce phénomène permet d'introduire des espèces squelettes, lorsque k est impair, en analogie avec l'approche de Fowler et al. [2, 3] où $k = 3$. Ce sont les espèces à deux sortes $Q(X,Y)$, $S(X,Y)$ et $U(X,Y)$, où X représente la sorte des k-gones et Y celle des arêtes orientées, définies par les figures 3 a), b) et c), où $k = 5$. En analogie avec le cas $k = 3$, on a les propositions suivantes.

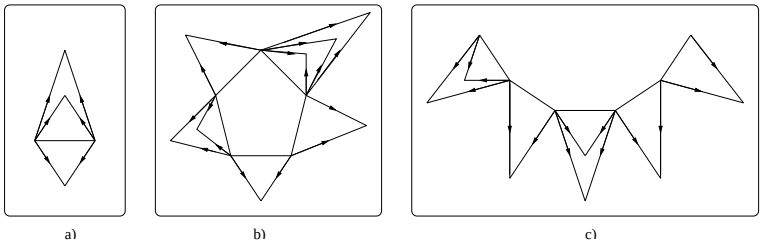

Figure 3: Espèces squelettes a) $Q(X,Y)$, b) $S(X,Y)$ et c) $U(X,Y)$

Proposition 4.2. *Les espèces squelettes Q, S et U admettent des expressions en termes d'espèces quotients :*

$$Q(X,Y) = E(XY^2)/\mathbb{Z}_2,\ S(X,Y) = C_k(E(XY^2))/\mathbb{Z}_2,\ U(X,Y) = (E(XY^2))^k/\mathbb{Z}_2. \tag{21}$$

Proposition 4.3. *Lorsque k est impair, $k \geq 3$, on a les expressions suivantes pour les espèces pointées de 2-arbres k-gonaux , où $B = \mathcal{A}^{\rightarrow}$:*

$$\mathcal{A}^- = Q(X, B^{\frac{k-1}{2}}), \quad \mathcal{A}^\circ = S(X, B^{\frac{k-1}{2}}), \quad \mathcal{A}^{\underline{\circ}} = U(X, B^{\frac{k-1}{2}}). \tag{22}$$

Dans le but d'obtenir des formules d'énumération, il faut préalablement calculer les séries indicatrices de cycles des espèces Q, S et U.

Proposition 4.4. *Les séries indicatrices de cycles des espèces $Q(X,Y)$, $S(X,Y)$ et $U(X,Y)$ sont données par la formule*

$$Z_Q = \frac{1}{2}\left(Z_{E(XY^2)} + q\right), \tag{23}$$

$$Z_S = \frac{1}{2}\left(Z_{C_k(E(XY^2))} + q\cdot(p_2\circ Z_{E(XY^2)})^{\frac{k-1}{2}}\right), \tag{24}$$

$$Z_U = \frac{1}{2}\left(Z_{(E(XY^2))^k} + q\cdot(p_2\circ Z_{E(XY^2)})^{\frac{k-1}{2}}\right), \tag{25}$$

où $q = h\circ(x_1y_2 + p_2\circ(x_1\frac{y_1^2-y_2}{2}))$, p_2 représente la fonction somme de puissances de degré deux, h la fonction symétrique homogène et $\circ$, la composition pléthystique.

Preuve. La formule (23) et la méthode utilisée se trouvent dans [2, 3]. Il s'agit de dénombrer les $F(X,Y)$-structures colorées non étiquetées laissées fixes par τ. Dans le cas de S, on doit laisser fixe une $C_k(E(XY^2))$-structure colorée. Pour cela le cycle de base de longueur k doit posséder au moins un axe de symétrie passant par le milieu d'un des côtés. On peut voir que lorsqu'une telle structure possède plusieurs axes de symétrie, le choix d'un axe est arbitraire. De part et d'autre de l'axe de symétrie, chaque $E(XY^2)$-structure colorée doit avoir son image miroir; ce qui contribue pour un terme de $(p_2\circ Z_{E(XY^2)})^{\frac{k-1}{2}}$. Ensuite, la structure attachée à l'arête distinguée doit être globalement laissée fixe, ce qui donne le facteur q. Le raisonnement est très similaire pour l'espèce U. ■

Combinant le théorème de dissymétrie, les équations (23), (24), (25) et les lois de substitution de la théorie des espèces, on obtient les séries génératrices des types de l'espèce des 2-arbres k-gonaux .

Proposition 4.5. *Soit $k \geq 3$ impair. La série génératrice ordinaire $\widetilde{a}(x)$ des 2-arbres k-gonaux non étiquetés est donnée par*

$$\widetilde{a}(x) = \frac{1}{2}\left(\widetilde{a}_o(x) + \exp\Big(\sum_{i\geq 1}\frac{1}{2i}(2x^i\widetilde{B}^{\frac{k-1}{2}}(x^{2i}) + x^{2i}\widetilde{B}^{k-1}(x^{2i}) - x^{2i}\widetilde{B}^{\frac{(k-1)}{2}}(x^{4i}))\Big)\right). \tag{26}$$

Corollaire 4.6. *Pour $k \geq 3$ impair, le nombre $\widetilde{a}_n$ de 2-arbres k-gonaux non étiquetés sur n k-gones satisfait la récurrence suivante*

$$\widetilde{a}_n = \frac{1}{2n}\sum_{j=1}^{n}\Big(\sum_{l|j} l\omega_l\Big)\Big(\widetilde{a}_{n-j} - \frac{1}{2}\widetilde{a}_{o,n-j}\Big) + \frac{1}{2}\widetilde{a}_{o,n}, \quad \widetilde{a}_k[0] = 1, \tag{27}$$

où, pour tout $n \geq 1$,

$$\omega_n = 2b_{\frac{n-1}{2}}^{(\frac{k-1}{2})} + b_{\frac{n-2}{2}}^{(k-1)} + b_{\frac{n-2}{4}}^{(\frac{k-1}{2})}, \tag{28}$$

et $b_i^{(j)}$ est défini au corollaire 3.3.

4.2 Cas k pair

Le cas où k est pair est plus délicat. Dans le but d'exprimer les séries génératrices ordinaires des types des trois espèces a^-, $a^\diamond$ et $a^{\underline{\diamond}}$, nous appliquons la formule (20) aux formules (19). Pour l'espèce a^-, on a

$$\widetilde{a}^-(x) = \frac{1}{2}(\widetilde{a}^{\rightarrow}(x) + \widetilde{a}^{\rightarrow}_{\tau}(x)), \tag{29}$$

où $\widetilde{a}^{\rightarrow}_{\tau}(x) = \sum_{n\geq 0} |\mathrm{Fix}_{\widetilde{a}^{\rightarrow}_n}(\tau)|x^n$ est la série génératrice des 2-arbres k-gonaux pointés en une arête orientée, non étiquetés, laissés fixes par changement d'orientation. Il faut donc calculer $\widetilde{a}^{\rightarrow}_{\tau}(x)$. Pour cela, introduisons quelques espèces auxiliaires. La première, notée a_{TS}, est l'espèce des 2-arbres k-gonaux pointés en une arête orientée et dont toutes les pages attachées autour de cette arête sont verticalement symétriques, sans symétries croisées (voir plus loin); on dira *totalement symétriques*. On peut caractériser cette espèce par l'équation fonctionnelle suivante

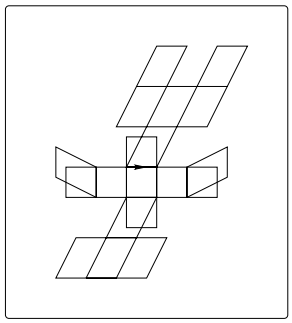

Figure 4: Une structure de l'espèce a_{TS}

(voir figure 4),

$$a_{\mathrm{TS}} = E(X \cdot X^2_{=} < B^{\frac{k-2}{2}} > \cdot a_{\mathrm{TS}}) = E(P_{\mathrm{TS}}), \tag{30}$$

où $X^2_{=} < F >$ représente l'espèce des couples de F-structures isomorphes et P_{TS} est l'espèce des *pages totalement symétriques*. Cette équation se traduit au niveau des séries génératrices des types par

$$\widetilde{a}_{\mathrm{TS}}(x) = \exp\left(\sum_{i\geq 1} \frac{1}{i} x^i \widetilde{B}^{\frac{k-2}{2}}(x^{2i})\widetilde{a}_{\mathrm{TS}}(x^i)\right). \tag{31}$$

Proposition 4.7. *Les nombres $\beta_n = |\widetilde{a}_{\mathrm{TS}}[n]|$, de a_{TS}-structures non étiquetées sur n polygones satisfont la récurrence*

$$\beta_n = \frac{1}{n}\sum_{i=1}^{n}\left(\sum_{d|i} d\omega_d\right)\beta_{n-i},\ n \geq 1 \quad \beta_0 = 1, \tag{32}$$

où

$$\omega_n = \sum_{\substack{i+j=n-1 \\ i\ pair}} b^{(\frac{k-2}{2})}_{\frac{i}{2}}\beta_j\,.$$

Preuve. Il suffit de prendre la dérivée logarithmique de l'expression (31). ■

Passons maintenant à l'introduction des deux espèces $P_{\rm CR}$ et $P_{\rm M}$, des *paires de pages croisées* et des *pages mixtes*. Une paire de pages *croisées* est, par définition, une paire de pages orientées (des $\mathcal{A}^{\rightarrow}$-structures comportant une seule page) de la forme $\{s, \tau\cdot s\}$ avec s et $\tau\cdot s$ non isomorphes. La figure 5 a) montre une structure de cette espèce. Une page *mixte* est une page symétrique possédant une (ou plusieurs) symétrie de type croisée. Une telle structure est dessinée en figure 5 b). On peut alors exprimer ces deux espèces l'une en fonction de l'autre, comme suit

$$\begin{aligned} P_{\rm CR} &= \Phi_2 < XB^{k-1} - (P_{\rm TS} + P_{\rm M}) >, & (33)\\ P_{\rm M} &= X\cdot X_{=}^2 < B^{\frac{k-2}{2}} > \cdot \mathcal{A}_{\rm TS}\cdot E_+(P_{\rm CR} + P_{\rm M}), & (34)\end{aligned}$$

où $\Phi_2 < F >$ représente l'espèce des paires de F-structures de la forme $\{s, \tau\cdot s\}$ et E_+ est l'espèce des ensembles non vides. Passant aux séries génératrices des types, il vient

$$\begin{aligned} \widetilde{P}_{\rm CR}(x) &= \frac{1}{2}\big(x^2\widetilde{B}^{k-1}(x^2) - \widetilde{P}_{\rm TS}(x^2) - \widetilde{P}_{\rm M}(x^2)\big), & (35)\\ \widetilde{P}_{\rm M}(x) &= x\widetilde{B}^{\frac{k-2}{2}}(x^2)\widetilde{\mathcal{A}}_{\rm TS}(x)\left(\exp\left(\sum_{i\geq 1}\frac{1}{i}(\widetilde{P}_{\rm CR}(x^i) + \widetilde{P}_{\rm M}(x^i))\right) - 1\right). & (36)\end{aligned}$$

Après manipulations et la prise de la dérivée logarithmique de (36), on obtient les nombres $\widetilde{P}_{{\rm CR},n}$ et $\widetilde{P}_{{\rm M},n}$ de pages croisées et mixtes respectivement sur n polygones

$$\begin{aligned} \widetilde{P}_{{\rm CR},n} &= b^{(k-1)}_{\frac{n-2}{2}} - \widetilde{P}_{{\rm TS},\frac{n}{2}} - \widetilde{P}_{{\rm M},\frac{n}{2}}, & (37)\\ \widetilde{P}_{{\rm M},n} &= \sum_{i=1}^{n}\left(\sum_{d|i}\varepsilon_d\right)c_{n-i} + f_n, & (38)\end{aligned}$$

où

$$\begin{aligned} \varepsilon_n &= \frac{k-2}{2}b^{(k-1)}_{n-1} + \widetilde{P}_{{\rm TS},n} + \widetilde{P}_{{\rm CR},n} + \widetilde{P}_{{\rm M},n}, & (39)\\ c_n &= \widetilde{P}_{{\rm M},n} + \sum_{i+j=n-1} b^{(\frac{k-2}{2})}_{\frac{1}{2}}\widetilde{a}_{{\rm TS},j}, & (40)\\ f_n &= \sum_{i+j=n-1} b^{(\frac{k-2}{2})}_{\frac{1}{2}}\widetilde{a}_{{\rm TS},j} + 2\sum_{i+j+l=n-2} b^{(\frac{k-4}{2})}_{\frac{1}{2}} j b_{\frac{j}{2}}\widetilde{a}_{{\rm TS},l} \\ &\qquad + \sum_{i+j=n-1} j b^{(\frac{k-2}{2})}_{\frac{1}{2}}\widetilde{a}_{{\rm TS},j}. & (41)\end{aligned}$$

Notons par $\widetilde{\mathcal{A}}_{\rm S}(x)$ la série génératrice des $\mathcal{A}^{\rightarrow}$-structures non étiquetées symétriques. On a alors (voir figure 6)

$$\begin{aligned} \widetilde{\mathcal{A}}_{\rm S}(x) &= E(P_{\rm TS} + P_{\rm CR} + P_{\rm M})^{\sim}(x), & (42)\\ &= \exp\left(\sum_{i\geq 1}\frac{1}{i}(\widetilde{P}_{\rm TS}(x^i) + \widetilde{P}_{\rm CR}(x^i) + \widetilde{P}_{\rm M}(x^i))\right). & (43)\end{aligned}$$

On en déduit alors une récurrence pour le nombre $\alpha_n = \widetilde{a}_{\mathrm{S},n}$ de 2-arbres k-gonaux pointés en une arête laissés fixes par changement d'orientation.

$$\alpha_n = \frac{1}{n}\sum_{i=1}^{n}\left(\sum_{d|i} d\omega_d\right)\alpha_{n-i}, \quad \alpha_0 = 1, \tag{44}$$

où

$$\omega_k = \widetilde{P}_{\mathrm{TS},k} + \widetilde{P}_{\mathrm{CR},k} + \widetilde{P}_{\mathrm{M},k}.$$

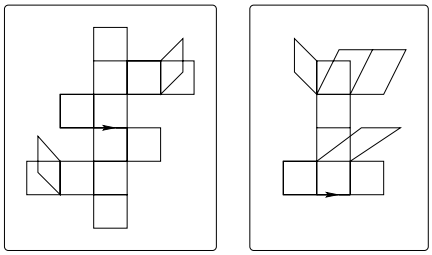

Figure 5: Une paire de pages croisées et une page mixte

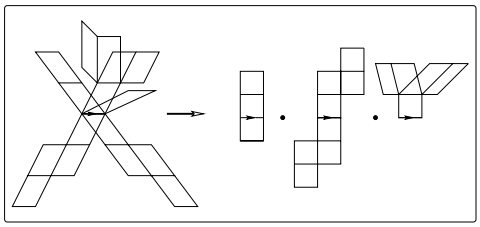

Figure 6: Décomposition d'une $\mathcal{A}^{\rightarrow}$-structure fixée sous τ

Proposition 4.8. *Si k est un entier pair, $k \geq 4$, alors le nombre de 2-arbres k-gonaux pointés en une arête (non orientée) sur n k-gones est donné par*

$$\widetilde{a}_n^{-} = \frac{1}{2}(b_n + \alpha_n). \tag{45}$$

Passons maintenant à l'espèce $\mathcal{A}^{\diamond}$ des 2-arbres k-gonaux pointés en un k-gone possédant une arête distinguée. On trouve

$$\widetilde{a}^{\diamond}(x) = \frac{1}{2}\left(\widetilde{a}_o^{\diamond}(x) + \widetilde{a}_{o,\tau}^{\diamond}(x)\right), \quad \text{où} \quad \widetilde{a}_{o,\tau}^{\diamond}(x) = x\,\widetilde{a}_{\mathrm{S}}^{2}(x)\,\widetilde{B}^{\frac{k-2}{2}}(x^2), \tag{46}$$

puisque une $\mathcal{A}_o^{\diamond}$-structure non étiquetée τ-symétrique possède un axe de symétrie qui est, en fait, la médiatrice de l'arête distinguée dans le polygone pointé, et, qui est donc aussi naturellement la médiatrice de l'arête opposée à celle pointée.

Les structures attachées à ces deux arêtes sont donc symétriques, d'où le terme $(\widetilde{a}_{\mathrm{S}}(x))^2$; ensuite, de part et d'autre de l'axe, les B-structures que l'on y attache doivent s'échanger par paire, soit une contribution d'un facteur $\widetilde{B}(x^2)$ pour chacune des $\frac{k-2}{2}$ paires. On en déduit alors une expression du nombre de $\underline{a^{\diamond}}$-structures non étiquetées $\widetilde{a}^{\diamond}_n$,

$$\widetilde{a}^{\diamond}_{\underline{n}} = \frac{1}{2}\left(\widetilde{a}^{\diamond}_{o,n} + \sum_{i+j=n-1} \alpha^{(2)}_i \cdot b^{(\frac{k-2}{2})}_{\underline{j}}\right), \tag{47}$$

où $\alpha^{(2)}_i = [x^i]\widetilde{a}^2_S(x)$.

Procédons de façon similaire pour l'espèce $\underline{a^{\diamond}}$, des 2-arbres k-gonaux pointés en un polygone. Une nouvelle fois, nous utilisons la relation (20), qui donne

$$\widetilde{a}^{\diamond}(x) = \frac{1}{2}\left(\widetilde{a}^{\diamond}_o(x) + \widetilde{a}^{\diamond}_{o,\tau}(x)\right). \tag{48}$$

Remarquons d'abord que pour qu'une $a^{\diamond}_o$-structure soit laissée fixe par changement d'orientation, elle doit comporter au moins un axe de symétrie, qui peut être de deux types :

1. un axe passant par le milieu de deux arêtes opposées, ou
2. un axe passant par deux sommets opposés,

du polygone pointé. Le dénombrement se fait en orientant d'abord l'axe de symétrie. On trouve

$$\widetilde{a}^{\diamond}_{o,\tau}(x) = \frac{x}{2}\widetilde{a}^2_{\mathrm{S}}(x)\widetilde{B}^{\frac{k-2}{2}}(x^2) + \frac{x}{2}\widetilde{B}^{\frac{k}{2}}(x^2), \tag{49}$$

où le premier terme correspond à une symétrie de type 1, et le deuxième, de type 2. Les structures qui possèdent les deux symétries sont précisément celles qui sont comptées une demi fois dans chacun des deux termes. Le théorème de dissymétrie donne donc, pour $k \geq 4$ pair,

$$\begin{aligned}\widetilde{a}(x) &= \frac{1}{2}\widetilde{a}_o(x) + \frac{1}{2}\widetilde{a}_{\mathrm{S}}(x) + \frac{1}{2}\widetilde{a}^{\diamond}_{o,\tau}(x) - \frac{1}{2}\widetilde{a}^{\diamond}_{o,\tau}(x), \\ &= \frac{1}{2}\widetilde{a}_o(x) + \frac{1}{2}\widetilde{a}_{\mathrm{S}}(x) + \frac{x}{4}(\widetilde{B}^{\frac{k}{2}}(x^2) - \widetilde{a}^2_{\mathrm{S}}(x)\widetilde{B}^{\frac{k-2}{2}}(x^2)),\end{aligned} \tag{50}$$

où $\widetilde{a}_o(x)$ est donné par (15) et $\widetilde{a}_{\mathrm{S}}(x)$ par (43).

Théorème 4.9. *Si $k \geq 4$ est pair, le nombre de 2-arbres k-gonaux non étiquetés sur n k-gones est donné par*

$$\widetilde{a}_n = \frac{1}{2}\widetilde{a}_{o,n} + \frac{1}{2}\alpha_n + \frac{1}{4}b^{(\frac{k}{2})}_{\frac{n-1}{2}} - \frac{1}{4}\sum_{i+j=n-1} \alpha^{(2)}_i \cdot b^{(\frac{k-2}{2})}_{\underline{j}}, \tag{51}$$

avec

$$b^{(m)}_l = [x^l]\widetilde{B}^m(x), \quad \alpha^{(2)}_i = [x^i]\widetilde{a}^2_{\mathrm{S}}(x).$$

5 Dénombrement asymptotique

Grâce au théorème de dissymétrie et aux diverses équations combinatoires qui lui sont associées, le dénombrement asymptotique des 2-arbres k-gonaux (étiquetés ou non) dépend essentiellement de celui des B-structures où B est l'espèce auxiliaire caractérisée par l'équation combinatoire (3). Dans le cas étiqueté, la situation est triviale puisque l'on dispose des formules closes simples (7), (16) et (18). Dans le cas non étiqueté, la situation est vraiment plus délicate puisque la série $\widetilde{B}(x)$ est caractérisée par l'équation fonctionnelle complexe (12).

Voici quelques notations préliminaires à l'énoncé du résultat principal de la présente section. Si $\lambda = (\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_\nu)$ est un partage d'un entier n en ν parts, on écrit $\lambda \vdash n$, $n = |\lambda|$, $\nu = l(\lambda)$, $m_i(\lambda) = |\{j : \lambda_j = i\}|$ = nombre de parts de taille i dans λ. De plus, on pose

$$\sigma_i(\lambda) = \sum_{d|i} d m_d(\lambda), \quad \sigma_i^*(\lambda) = \sum_{d|i,\, d<i} d m_d(\lambda) \tag{52}$$

$$\widehat{\lambda} = 1 + |\lambda| + l(\lambda), \quad \widehat{z}(\lambda) = 2^{m_1(\lambda)} m_1(\lambda)! 3^{m_2(\lambda)} m_2(\lambda)! \ldots . \tag{53}$$

On a le résultat suivant.

Proposition 5.1. *Posons $p = k - 1$ et $\widetilde{B}(x) = \sum b_n(p) x^n$. Alors*

i) $b_n(p)$ est un polynôme en p de degré $n-1$, $n \geq 1$,

ii) il existe des constantes α_p et β_p telles que

$$b_n(p) \sim \alpha_p \beta_p^n n^{-\frac{3}{2}}, \qquad \text{pour } n \to \infty. \tag{54}$$

De plus, $\alpha_p = \alpha(\xi_p) = \dfrac{1}{\sqrt{2\pi}} \dfrac{1}{(p\xi_p)^{\frac{1}{p}} p} \left(1 + \dfrac{p\xi_p \omega'(\xi_p)}{\omega(\xi_p)}\right)^{\frac{1}{2}}$ et $\beta_p = \dfrac{1}{\xi_p}$, où ξ_p est la plus petite racine de l'équation

$$\xi = \frac{1}{ep} \omega^{-p}(\xi), \tag{55}$$

où $\omega(x)$ est la série (absolument convergente au voisinage de ξ_p) donnée par (58). On a le développement convergent

$$\xi_p = \sum_{n=1}^{\infty} \frac{c_n}{p^n}, \tag{56}$$

où les coefficients c_n sont des constantes, indépendantes de p, données explicitement par

$$c_n = \sum_{\lambda \vdash n} \frac{e^{-\widehat{\lambda}}}{\widehat{\lambda}\widehat{z}(\lambda)} \prod_{i \geq 1} (\sigma_i(\lambda) - \widehat{\lambda})^{m_i(\lambda)-1} (\sigma_i^*(\lambda) - \widehat{\lambda}), \tag{57}$$

lorsque λ parcourt l'ensemble des partages de n.

Preuve. La partie *i)* de l'énoncé découle immédiatement de la formule explicite (8). Pour la partie *ii)* qui affirme l'existence des constantes α_n et β_n, on s'inspire de l'approche de Fowler et al. pour les 2-arbres ($k = 3$) en utilisant le théorème classique de Bender. Posons, pour simplifier $b(x) = \widetilde{B}(x)$. Alors, grâce à (12), $y = b(x)$ satisfait la relation

$$y = e^{xy^p}\omega(x), \quad \text{où} \quad \omega(x) = e^{\frac{1}{2}x^2b^p(x^2)+\frac{1}{3}x^3b^p(x^3)+\cdots} \tag{58}$$

Par le théorème de Bender, appliqué à la fonction $f(x,y) = y - e^{xy^p}\omega(x)$, on doit chercher un couple (ξ_p, τ_p) solution du système

$$f(x,y) = 0 \qquad \text{et} \qquad f_y(x,y) = 0. \tag{59}$$

Ceci équivaut à dire que ξ_p est solution de (55) et que $p\xi_p\tau_p^p = 1$. Les formules explicites (56) et (57) s'obtiennent en appliquant préalablement l'inversion de Lagrange à l'équation $\xi = zR(\xi)$ où $z = \frac{1}{ep}$ et $R(t) = \omega^{-p}(t)$, pour obtenir

$$\xi_p = \xi = \sum_{n\geq 0}\frac{a_n}{n!}\left(\frac{1}{ep}\right)^n, \quad \frac{a_n}{n!} = \frac{1}{n}[t^{n-1}]\omega^{-np}(t). \tag{60}$$

Ensuite, pour évaluer explicitement $\omega^{-np}(x)$, on utilise la version de Labelle [7] de la formule d'inversion de Good pour les séries indicatrices en tenant compte de (6) et en remarquant que

$$\omega^{-np}(x) = e^{-n(\frac{x_2}{2}+\frac{x_3}{3}+\cdots)} \circ Z_A(x_1, x_2, \ldots)|_{x_i:=px^i}, \tag{61}$$

où $A = XE(A)$ est l'espèce des arborescences. ■

Dans le cas orienté non pointé, une méthode similaire basée sur l'équation (15), mène à

$$\widetilde{a}_{o,n} \sim \overline{\alpha}_p\beta_p^n n^{-\frac{5}{2}}, \quad \text{où} \quad \overline{\alpha}_p = 2\pi p(p\xi_p)^{\frac{2}{p}}\alpha_p^3. \tag{62}$$

Enfin, une analyse fine de la formule (51) montre que

$$\widetilde{a}_n \sim \frac{1}{2}\widetilde{a}_{o,n}. \tag{63}$$

La table 1 donne, à 20 décimales, les constantes ξ_p, α_p et $\beta_p = \frac{1}{\xi_p}$ pour $p = 1, \ldots, 5$.

p	ξ_p	α_p	β_p

Table 1 : Valeurs numériques de ξ_p, α_p et β_p, $p = 1, \ldots, 5$.

Voici les premières valeurs des constantes universelles c_n apparaissant dans (56), pour $n = 1, \ldots 5$.

$$c_1 = \frac{1}{\mathrm{e}} = 0.36787944117144232160, \tag{64}$$

$$c_2 = -\frac{1}{2}\frac{1}{\mathrm{e}^3} = -0.02489353418393197149, \tag{65}$$

$$c_3 = \frac{1}{8}\frac{1}{\mathrm{e}^5} - \frac{1}{3}\frac{1}{\mathrm{e}^4} = -0.00526296958802571004, \tag{66}$$

$$c_4 = -\frac{1}{48}\frac{1}{\mathrm{e}^7} + \frac{1}{\mathrm{e}^6} - \frac{1}{4}\frac{1}{\mathrm{e}^5} = 0.00077526788594593923, \tag{67}$$

$$c_5 = \frac{1}{384}\frac{1}{\mathrm{e}^9} - \frac{4}{3}\frac{1}{\mathrm{e}^8} + \frac{49}{72}\frac{1}{\mathrm{e}^7} - \frac{1}{5}\frac{1}{\mathrm{e}^6} = 0.00032212622183609932. \tag{68}$$

Remarque 5.1. *Les calculs de cette section sont également valables pour le cas où $k = 2$ et $p = 1$, correspondant aux arborescences ordinaires (de Cayley) définies par l'équation $A = XE(A)$. Dans ce cas, la constante de croissance $\beta = \beta_1$, dans (54), est connue sous le nom de constante d'Otter (voir [10]). Il est intéressant de noter que cette constante prend la forme explicite $\beta = \frac{1}{\xi_1}$, avec*

$$\xi_1 = \sum_{n \geq 1} c_n. \tag{69}$$

Il est à noter que lorsque $k = 3$, nous retrouvons les résultats asymptotiques obtenus par Fowler et al. dans [2, 3].

Labelled and unlabelled enumeration of k-gonal 2-trees

Gilbert Labelle, Cédric Lamathe and Pierre Leroux

April 1, 2003

Abstract

In this paper[1], we generalize 2-trees by replacing triangles by quadrilaterals, pentagons or k-sided polygons (k-gons), where $k \geq 3$ is given. This generalization, to k-gonal 2-trees, is natural and is closely related, in the planar case, to some specializations of the cell-growth problem. Our goal is the labelled and unlabelled enumeration, of k-gonal 2-trees according to the number n of k-gons. We give explicit formulas in the labelled case, and, in the unlabelled case, recursive and asymptotic formulas. We also enumerate these structures according to their perimeter.

1 Introduction

The class of *bidimensional trees*, or in brief *2-trees*, is extensively studied in the literature. For instance, see [7] and [5, 6] and their references; see also [10, 11]. Essentially, a 2-tree is a connected simple graph composed by triangles glued along their edges in a tree-like fashion, that is, without cycles (of triangles). In [8], Harary et al. enumerated a variant of the cell-growth problem, namely plane and planar (in the sense that all faces, except possibly the external face, are also k-sided polygons, also called outerplanar) 2-trees, in which triangles have been replaced by quadrilaterals, pentagons or k-sided polygons (k-gons), where $k \geq 3$ is fixed. Such 2-trees, built on k-gons, are called *k-gonal 2-trees*. This generalization is natural and the purpose of this work is the enumeration of free k-gonal 2-trees, *i.e.*, seen as simple graphs, without any condition of planarity. Figure 1, a) and b), and Figure 2 a) show examples of k-gonal 2-trees, for $k = 3, 5$ and 4, respectively.

Our goal is the labelled and unlabelled enumeraton of k-gonal 2-trees, according to the number of k-gons. We give explicit formulas in the labelled case and recursive and asymptotic formulas in the unlabelled case. This is the full version of a paper presented at the "Mathematics and computer science" conference in Versailles, France, in September 2002 (see [15]). More complete proofs are given, in particular for the asymptotic formulas, and a section has been added on the enumeration of k-gonal 2-trees according to their perimeter.

[1]With the support of FCAR (Québec) and NSERC (Canada).

It was recently brought to our attention that Ton Kloks [10, 11] had enumerated unlabelled *biconnected partial 2-trees* according to the number of vertices, in his 1993 thesis. These structures are more general than k-gonal 2-trees since various size of polygons can occur in the same graph and some polygons may have missing edges.

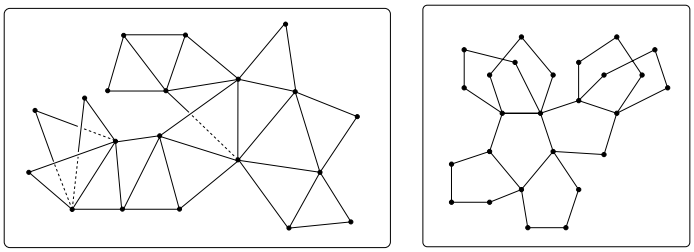

Figure 1: k-gonal 2-trees with $k = 3$ and $k = 5$

We say that a k-gonal 2-tree is *oriented* if its edges are oriented in such a way that each k-gon forms an oriented cycle; see Figure 2 b). In fact, for any k-gonal 2-tree s, the orientation of any one of its edges can be extended uniquely to all of s by first orienting all the polygons to which the edge belongs and then continuing recursively on all adjacent polygons. The coherence of the extension is ensured by the arborescent (acyclic) nature of 2-trees.

We denote by $\mathcal{A}$ and $\mathcal{A}_o$ the species of k-gonal 2-trees and of oriented k-gonal 2-trees. For these species, we use the symbols $-$, $\diamond$ and $\underline{\diamond}$ as upper indices to indicate that the structures are pointed at an edge, at a k-gon, and at a k-gon having itself a distinguished edge, respectively.

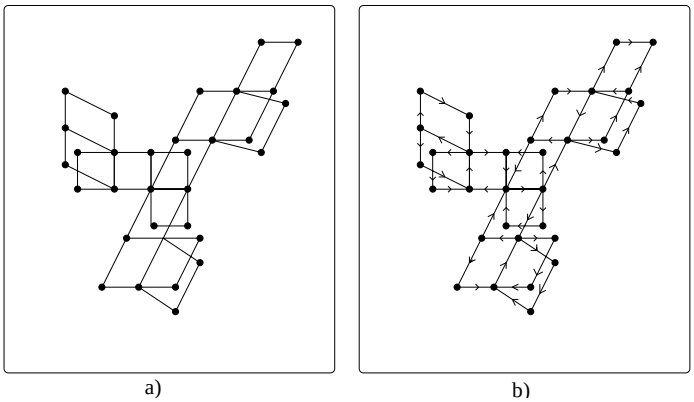

Figure 2: A unoriented and oriented 4-gonal 2-tree

Following the approach of Fowler et al. in [5, 6], which corresponds to the case $k = 3$, we label the 2-trees at their k-gons and give functional equations

which relate these various pointed species together and eventually lead to their enumeration. The main difficulty of this extension from triangles to k-gons comes, as we will see later, from the case where k is an even integer.

The first step is an extension of the dissymmetry theorem for 2-trees to the k-gonal case. The proof is similar to the case $k = 3$ and is omitted (see [5, 6]).

Theorem 1. DISSYMMETRY THEOREM FOR k-GONAL 2-TREES. The species $\mathcal{A}_o$ and $\mathcal{A}$ of oriented and unoriented k-gonal 2-trees, respectively, satisfy the following isomorphisms of species:

$$\mathcal{A}_o^- + \mathcal{A}_o^\diamond = \mathcal{A}_o + \mathcal{A}_{\overline{o}}^{\overline{\diamond}}, \tag{1}$$

$$\mathcal{A}^- + \mathcal{A}^\diamond = \mathcal{A} + \mathcal{A}^{\overline{\diamond}}. \tag{2}$$

There is yet another species to introduce, which plays an essential role in the process. It is the species $B = \mathcal{A}^\rightarrow$ of oriented-edge rooted (k-gonal) 2-trees, that is of 2-trees where an edge is selected and oriented. As mentionned above, the orientation of the rooted edge can be extended uniquely to an orientation of the 2-tree so that there is a canonical isomorphism $B = \mathcal{A}_o^-$ which can be used for all enumerative purposes. However, it is often useful not to perform this extension and to consider that only the rooted edge is oriented, as we will see.

In the next section, we characterize the species $B = \mathcal{A}^\rightarrow$ by a combinatorial functional equation and state some of its properties. The goal is to express the various pointed species occuring in the dissymmetry theorem in terms of B and to deduce enumerative results for the species $\mathcal{A}_o$ and $\mathcal{A}$. The oriented case is simpler, and carried out first, in Section 3. The unoriented case is analyzed in Section 4, distinguishing two cases according to the parity of the integer k. Enumeration of k-gonal 2-trees according to the perimeter is carried out in Section 5. Finally, asymptotic results are presented in Section 6.

This paper uses the framework of species theory. See Chapter 1 of [3] for an introduction. The main tool for our purposes is the composition theorem which can be stated as follows: let the species F be the (partitionnal) composition of two species, $F = G \circ H$. Then, the exponential generating function

$$F(x) = \sum_{n \geq 0} f_n \frac{x^n}{n!},$$

where $f_n = |F[n]|$ is the number of labelled F-structures of order n, and the tilde generating function

$$\widetilde{F}(x) = \sum_{n \geq 0} \widetilde{f}_n x^n,$$

where $\widetilde{f}_n = |F[n]/\mathbb{S}_n|$ is the number of unlabelled F-structures of order n, satisfy the following equations:

$$F(x) = G(H((x)), \tag{3}$$

$$\widetilde{F}(x) = Z_G(\widetilde{H}(x), \widetilde{H}(x^2), \ldots), \tag{4}$$

where $Z_G(x_1, x_2, \ldots)$ is the cycle index series of G.

2 The species B of oriented-edge rooted 2-trees

The species $B = \mathcal{A}^{\rightarrow}$ plays a central role in the study of k-gonal 2-trees. The following theorem is an extension to a general k of the case $k = 3$. Note that formula (5) also makes sense for $k = 2$ and corresponds to edge-labelled (ordinary) rooted trees.

Theorem 2. The species $B = \mathcal{A}^{\rightarrow}$ of oriented-edge rooted k-gonal 2-trees satisfies the following functional equation (isomorphism):

$$B = E(XB^{k-1}), \tag{5}$$

where E represents the species of sets and X is the species of singleton k-gons.

Proof. We decompose an $\mathcal{A}^{\rightarrow}$-structure as a set of *pages*, that is, of maximal subgraphs sharing only one k-gon with the rooted edge. For each page, the orientation of the rooted edge permits to define a linear order and an orientation on the $k-1$ remaining edges of the polygon having this edge, in some conventional way, for example in the fashion illustrated in Figure 3 a), for the odd case, and b), for the even case. These edges being oriented, we can glue on them some B-structures. We then deduce relation (5). ■

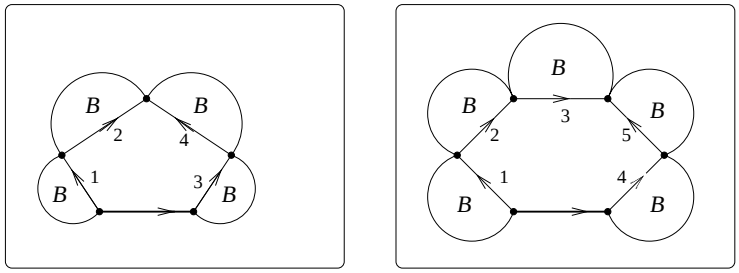

Figure 3: An oriented page for a) $k = 5$, b) $k = 6$

We can easily relate the species $B = \mathcal{A}^{\rightarrow}$ to the species of rooted trees denoted by A, characterized by the functional equation $A = XE(A)$, where X is now the species of singleton vertices. Indeed from (5), we deduce successively

$$(k-1)XB^{k-1} = (k-1)XE((k-1)XB^{k-1}), \tag{6}$$

knowing that $E^m(X) = E(mX)$, and, by unicity,

$$(k-1)XB^{k-1} = A((k-1)X). \tag{7}$$

Finally, we obtain the following expression for the species B in terms of the species of rooted trees.

Proposition 1. The species $B = \mathcal{A}^{\rightarrow}$ of oriented-edge-rooted k-gonal 2-trees satisfies

$$B = \sqrt[k-1]{\frac{A((k-1)X)}{(k-1)X}}. \tag{8}$$

Corollary 1. The numbers $a_n^{\rightarrow}$, $a_{n_1,n_2,\ldots}^{\rightarrow}$, and $b_n = \widetilde{a}_n^{\rightarrow}$ of k-gonal 2-trees pointed at an oriented edge and having n k-gons, respectively labelled, fixed by a permutation of cycle type $1^{n_1}2^{n_2}\ldots$ and unlabelled, satisfy the following formulas and recurrence:

$$a_n^{\rightarrow} = ((k-1)n+1)^{n-1} = m^{n-1}, \tag{9}$$

where $m = (k-1)n+1$ is the number of edges,

$$a_{n_1,n_2,\ldots}^{\rightarrow} = \prod_{i=1}^{\infty}(1+(k-1)\sum_{d|i} dn_d)^{n_i-1}(1+(k-1)\sum_{d|i,d<i} dn_d), \tag{10}$$

and

$$b_n = \frac{1}{n}\sum_{1\le j\le n}\sum_{\alpha}(|\alpha|+1)b_{\alpha_1}b_{\alpha_2}\ldots b_{\alpha_{k-1}}b_{n-j}, \qquad b_0 = 1, \tag{11}$$

the last sum is running over $(k-1)$-tuples of integers $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_{k-1})$ such that $|\alpha|+1$ divides the integer j, where $|\alpha| = \alpha_1 + \alpha_2 + \cdots + \alpha_{k-1}$.

Proof. Formulas (9) and (10) are obtained by specializing with $\mu = (k-1)^{-1}$ the following formulas, given by Fowler et al. in [5, 6],

$$\left(\frac{A(x)}{x}\right)^{\mu} = \sum_{n\ge 0}\mu(\mu+n)^{n-1}\frac{x^n}{n!}, \tag{12}$$

$$Z_{\left(\frac{A(X/\mu)}{X/\mu}\right)^{\mu}} =$$

$$\sum_{n_1,n_2,\ldots}\frac{x_1^{n_1}x_2^{n_2}\ldots}{1^{n_1}n_1!2^{n_2}n_2!\ldots}\prod_{i=1}^{\infty}(1+\frac{1}{\mu}\sum_{d|i}dn_d)^{n_i-1}(1+\frac{1}{\mu}\sum_{d|i,d<i}dn_d). \tag{13}$$

Formula (9) can also be established by a Prüfer-like bijection. To obtain the recurrence (11), it suffices to take the logarithmic derivative of the equation

$$\widetilde{B}(x) = \exp\left(\sum_{i\ge 1}\frac{x^i\widetilde{B}^{k-1}(x^i)}{i}\right), \tag{14}$$

where $\widetilde{B}(x) = \sum_{n\ge 0} b_n x^n$, which follows from relation (5), using (4). ∎

It is interesting to note that the sequences $\{b_n\}_{n\in\mathbb{N}}$, for $k = 2, 3, 4, 5$, are listed in the encyclopedia of integer sequences [18] and the equation (5), in the encyclopedia of combinatorial structures [9]. Also remark that, for each $n \geq 1$, b_n is a polynomial in k of degree $n-1$. This follows from (10) and the following explicit formula for b_n,

$$b_n = \sum_{n_1+2n_2+\cdots=n} \frac{a^{\rightarrow}_{n_1,n_2,\ldots}}{1^{n_1}n_1!2^{n_2}n_2!\ldots}, \tag{15}$$

which is a consequence of Burnside's lemma. The asymptotic behavior of the numbers b_n as $n \to \infty$, is studied, in particular as a function of k, in Section 7.

Remark 1. Equation (8) can also be used to compute the molecular expansion of the species B from the molecular expansion of A, using the binomial theorem. See [1] for more details.

3 Oriented case

We begin by determining relations for the pointed species appearing in the dissymmetry theorem. These relations are quite direct and the proof is left to the reader.

Proposition 2. The species a_o^-, $a_o^\diamond$, and $a_o^{\diamond}$ are characterized by the following isomorphisms:

$$a_o^- = B, \quad a_o^\diamond = XC_k(B), \quad a_o^{\diamond} = XB^k, \tag{16}$$

where $B = a^{\rightarrow}$ and C_k represents the species of oriented cycles of length k.

The dissymmetry theorem permits us to express the ordinary generating series $\widetilde{a}_o(x)$ of unlabelled oriented k-gonal 2-trees in terms of the corresponding series for the rooted species:

$$\widetilde{a}_o(x) = \widetilde{a}_o^-(x) + \widetilde{a}_o^\diamond(x) - \widetilde{a}_o^{\diamond}(x). \tag{17}$$

By Proposition 2, we can then express $\widetilde{a}_o(x)$ as function of $\widetilde{B}(x) = \widetilde{a}^{\rightarrow}(x)$.

Proposition 3. The ordinary generating series $\widetilde{a}_o(x)$ of unlabelled oriented k-gonal 2-trees is given by

$$\widetilde{a}_o(x) = \widetilde{B}(x) + \frac{x}{k}\sum_{\substack{d|k\\ d>1}} \phi(d)\widetilde{B}^{\frac{k}{d}}(x^d) - \frac{k-1}{k}x\widetilde{B}^k(x). \tag{18}$$

Corollary 2. The numbers $a_{o,n}$ and $\widetilde{a}_{o,n}$ of oriented k-gonal 2-trees labelled and unlabelled, over n k-gons, respectively, are given by

$$a_{o,n} = ((k-1)n+1)^{n-2} = m^{n-2}, \quad n \geq 2, \tag{19}$$

$$\widetilde{a}_{o,n} = b_n - \frac{k-1}{k}b^{(k)}_{n-1} + \frac{1}{k}\sum_{\substack{d|k\\ d>1}} \phi(d)b^{(\frac{k}{d})}_{\frac{n-1}{d}}, \tag{20}$$

where

$$b_i^{(j)} \;=\; [x^i]\widetilde{B}^j(x) \;=\; \sum_{i_1+\cdots+i_j=i} b_{i_1} b_{i_2} \dots b_{i_j},$$

denotes the coefficient of x^i in the series $\widetilde{B}^j(x)$, with $b_r^{(j)} = 0$ if r is non-integral or negative.

Proof. For the labelled case, it suffices to remark that $a_n^{\rightarrow} = m a_{o,n}$. In the unlabelled case, equation (20) is directly obtained from (18). ∎

4 Unoriented case

In the unoriented case, the number a_n of k-gonal 2-trees labelled over n polygons satisfies $2a_n = a_{o,n}+1$, since the only k-gonal 2-tree left fixed by a reversal of the orientation, for a given number of polygons, is the one in which every polygon share one common edge. We get

Proposition 4. The number a_n of labelled k-gonal 2-trees on n k-gons is given by

$$a_n = \frac{1}{2}\left(m^{n-2}+1\right), \qquad n \geq 2, \tag{21}$$

where $m = (k-1)n+1$.

For the unlabelled enumeration of k-gonal 2-trees (unoriented), we have to consider quotient species of the form $F/\mathbb{Z}_2$, where F is any species of "oriented" structures and $\mathbb{Z}_2 = \{1, \tau\}$, is the group where the action of τ is to reverse the orientation of the structure. A structure of such a species then consists in an orbit $\{s, \tau \cdot s\}$ of F-structures under the action of $\mathbb{Z}_2$.

For instance, the different pointed species of unoriented k-gonal 2-trees a^-, $a^\diamond$ and $a^{\underline{\diamond}}$, can be expressed as quotient species of the corresponding species of oriented k-gonal 2-trees:

$$a^- = \frac{a^{\rightarrow}}{\mathbb{Z}_2}, \quad a^\diamond = \frac{a_o^\diamond}{\mathbb{Z}_2} \;=\; \frac{XC_k(B)}{\mathbb{Z}_2}, \quad a^{\underline{\diamond}} = \frac{a_o^{\underline{\diamond}}}{\mathbb{Z}_2} \;=\; \frac{XB^k}{\mathbb{Z}_2}. \tag{22}$$

For the ordinary generating series (unlabelled structures) associated to such quotient species, we use the following formula, which is quite obvious,

$$(F/\mathbb{Z}_2)^\sim(x) = \frac{1}{2}(\widetilde{F}(x) + \widetilde{F}_\tau(x)), \tag{23}$$

where $\widetilde{F}_\tau(x) = \sum_{n\geq 0} |\mathrm{Fix}_{\widetilde{F}_n}(\tau)| x^n$ is the ordinary generating series of unlabelled F-structures left fixed by the action of τ, that is, by orientation reversal. However, the computation of the series $\widetilde{F}_\tau(x)$ is quite complicated and it is better to treat separately two cases according to the parity of k.

4.1 Case k odd

We can notice, observing Figures 3 a) and b), that in every k-gon containing the pointed (but not oriented) edge of an $\mathcal{A}^{-}$-structure, it is possible to orient the $k-1$ other edges in a "going away (from the root edge) direction" as in Figure 3 a), when k is odd, but there remains an ambiguous edge if k is even. This phenomenon permits us to introduce *skeleton* species, when k is odd, in analogy with the approach of Fowler et al. in [5, 6], where $k=3$. They are the two-sort quotient species $Q(X,Y)$, $S(X,Y)$ and $U(X,Y)$, where X represents the species of k-gons and Y the species of oriented edges, defined by Figures 4 a), b) and c), where $k=5$. In analogy with the case $k=3$, we get the following

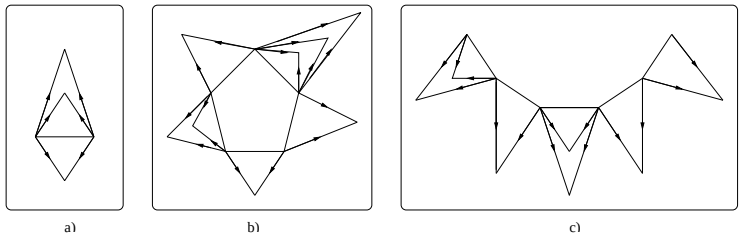

Figure 4: Skeleton species a) $Q(X,Y)$, b) $S(X,Y)$ and c) $U(X,Y)$

propositions.

Proposition 5. The skeleton species Q, S and U admit the following expressions in terms of quotients species

$$\begin{aligned} Q(X,Y) &= E(XY^2)/\mathbb{Z}_2, && (24)\\ S(X,Y) &= C_k(E(XY^2))/\mathbb{Z}_2, && (25)\\ U(X,Y) &= (E(XY^2))^k/\mathbb{Z}_2. && (26) \end{aligned}$$

Proposition 6. For k odd, $k \geq 3$, we have the following expressions for the pointed species of k-gonal 2-trees, where $B = \mathcal{A}^{\rightarrow}$:

$$\mathcal{A}^{-} = Q(X, B^{\frac{k-1}{2}}), \quad \mathcal{A}^{\circ} = X \cdot S(X, B^{\frac{k-1}{2}}), \quad \mathcal{A}^{\diamond} = X \cdot U(X, B^{\frac{k-1}{2}}). \quad (27)$$

In order to obtain enumeration formulas, we have first to compute the cycle index series of the species Q, S and U.

Proposition 7. The cycle index series of the species $Q(X,Y)$, $S(X,Y)$ and $U(X,Y)$ are given by

$$\begin{aligned} Z_Q &= \frac{1}{2}\left(Z_{E(XY^2)} + q\right), && (28)\\ Z_S &= \frac{1}{2}\left(Z_{C_k(E(XY^2))} + q \cdot (p_2 \circ Z_{E(XY^2)})^{\frac{k-1}{2}}\right), && (29)\\ Z_U &= \frac{1}{2}\left(Z_{(E(XY^2))^k} + q \cdot (p_2 \circ Z_{E(XY^2)})^{\frac{k-1}{2}}\right), && (30) \end{aligned}$$

where $q = h \circ (x_1 y_2 + p_2 \circ (x_1 \frac{y_1^2 - y_2}{2}))$, p_2 represents the power sum function of degree two, h the homogeneous symmetric function and $\circ$, the plethystic substitution.

Proof. Formula (28) and the method used can be found in [5, 6]. It is a matter of counting colored unlabelled $F(X,Y)$-structures left fixed by τ. In the case of S, we have to leave fixed a colored $C_k(E(XY^2))$-structure. For this, the basis cycle of length k must possess (at least) one symmetry axis passing through the middle of one of its sides. We can see that when such a structure has several axis of symmetry, the choice of the axis is arbitrary. On both sides of the axis, each colored $E(XY^2)$-structure must have its mirror image; this contributes for a term of $(p_2 \circ Z_{E(XY^2)})^{\frac{k-1}{2}}$. Next, the attached structure on the distinguished edge must be globally left fixed; this gives the factor q. The reasoning is very similar for the species U ■

Combining the dissymmetry theorem, equations (28), (29), (30) and the substitution rules of unlabelled enumeration, we obtain the ordinary generating series of the species of k-gonal 2-trees.

Proposition 8. Let $k \geq 3$ be an odd integer. The ordinary generating series $\widetilde{a}(x)$ of unlabelled k-gonal 2-trees is given by

$$\widetilde{a}(x) = \frac{1}{2}\left(\widetilde{a}_o(x) + \exp\Big(\sum_{i\geq 1} \frac{1}{2i}(2x^i \widetilde{B}^{\frac{k-1}{2}}(x^{2i}) + x^{2i}\widetilde{B}^{k-1}(x^{2i}) - x^{2i}\widetilde{B}^{\frac{k-1}{2}}(x^{4i}))\Big)\right). \tag{31}$$

Corollary 3. For $k \geq 3$, odd, the number $\widetilde{a}_n$ of unlabelled k-gonal 2-trees over n k-gons, satisfy the following recurrence

$$\widetilde{a}_n = \frac{1}{2n}\sum_{j=1}^{n}\Big(\sum_{l|j} l\omega_l\Big)\Big(\widetilde{a}_{n-j} - \frac{1}{2}\widetilde{a}_{o,n-j}\Big) + \frac{1}{2}\widetilde{a}_{o,n}, \quad \widetilde{a}_0 = 1, \tag{32}$$

where, for all $n \geq 1$,

$$\omega_n = 2b_{\frac{n-1}{2}}^{(\frac{k-1}{2})} + b_{\frac{n-2}{2}}^{(k-1)} - b_{\frac{n-2}{4}}^{(\frac{k-1}{2})}, \tag{33}$$

and $b_i^{(j)}$ is defined in Corollary 2.

4.2 Case k even

The case k even is much more delicate. In order to express the ordinary generating functions of the three species a^-, $a^\diamond$ and $a^{\hat{\diamond}}$, we apply relation (23) to formulas (22). For the species a^-, we have

$$\widetilde{a}^-(x) = \frac{1}{2}(\widetilde{a}^{\rightarrow}(x) + \widetilde{a}_\tau^{\rightarrow}(x)), \tag{34}$$

where $\widetilde{a}_{\tau}^{\rightarrow}(x) = \sum_{n\geq 0} |\mathrm{Fix}\widetilde{a}_{n}^{\rightarrow}(\tau)|x^n$ is the ordinary generating series of unlabelled oriented-edge-rooted 2-trees which are left fixed by reversing the orientation. Let a_{S} denotes the subspecies of $a^{\rightarrow}$ consisting of $a^{\rightarrow}$-structures s which are isomorphic to their image $\tau \cdot s$ under the orientation reversing map. We have to compute $\widetilde{a}_{\mathrm{S}}(x) = \widetilde{a}_{\tau}^{\rightarrow}(x)$. For this, let us introduce some auxiliary species. The first one, denoted a_{TS}, is the class of a_{S}-structures for which every page attached to the rooted edge is vertically symmetric without crossed symmetries (see below); we say *totally symmetric*. We can characterize this species by the

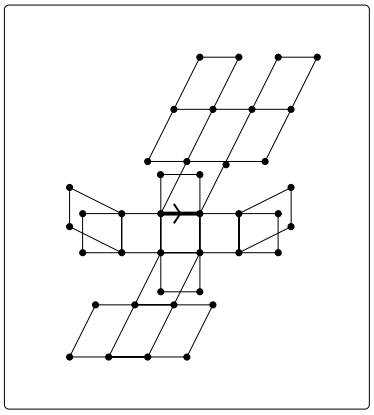

Figure 5: A structure of the species a_{TS}

following functional equation (see Figure 5)

$$a_{\mathrm{TS}} = E(X \cdot X_{=}^{2} < B^{\frac{k-2}{2}} > \cdot a_{\mathrm{TS}}) = E(P_{\mathrm{TS}}), \tag{35}$$

where $X_{=}^{2} < F >$ represents the species of ordered pairs of isomorphic F-structures and P_{TS} is the species of *totally symmetric pages*. Translating this equation in terms of generating series, we get

$$\widetilde{a}_{\mathrm{TS}}(x) = \exp\left(\sum_{i\geq 1} \frac{1}{i} x^i \widetilde{B}^{\frac{k-2}{2}}(x^{2i}) \widetilde{a}_{\mathrm{TS}}(x^i)\right). \tag{36}$$

Proposition 9. The numbers $\beta_n = |\widetilde{a}_{\mathrm{TS}}[n]|$ of unlabelled a_{TS}-structures on n polygons satisfy the recurrence

$$\beta_n = \frac{1}{n} \sum_{i=1}^{n} \left(\sum_{d|i} d\pi_d\right) \beta_{n-i}, \ n \geq 1 \quad \beta_0 = 1, \tag{37}$$

where

$$\pi_n = \widetilde{P}_{\mathrm{TS},n} = \sum_{\substack{i+j=n-1 \\ i \ even}} b_{\frac{i}{2}}^{(\frac{k-2}{2})} \beta_j. \tag{38}$$

Proof. It suffices to take the logarithmic derivative of (36), that is

$$x\frac{(\widetilde{a}_{\mathrm{TS}})'(x)}{\widetilde{a}_{\mathrm{TS}}(x)} = x\cdot\sum_{i\geq 1}\Omega'(x^i)x^{i-1}, \tag{39}$$

where $\Omega(x)=\sum_{n\geq 1}\omega_n x^n = x\widetilde{B}^{\frac{k-2}{2}}(x^2)\widetilde{a}_{\mathrm{TS}}(x)$. Next, extracting the coefficient of x^n in both sides of

$$x(\widetilde{a}_{\mathrm{TS}})'(x) = \Big(\sum_{i\geq 1}\Omega'(x^i)x^i\Big)\widetilde{a}_{\mathrm{TS}}(x) \tag{40}$$

leads to (37) using (35) since $\Omega(x)=\widetilde{P}_{\mathrm{TS}}(x)$. ■

Let us now introduce two other species, namely P_{AL} and P_{M}, of *pairs of alternated pages* and of *mixed pages*. A pair of *alternated pages* is, by definition, an unordered pair of oriented pages ($a^{\rightarrow}$-structures having only one page) of the form $\{s,\tau\cdot s\}$ with s and $\tau\cdot s$ non-isomorphic. Figure 6 a) shows a structure belonging to this species. A *mixed page* is a symmetric page having at least one alternated symmetry. Such a structure is drawn in Figure 6 b). We can then express each of these two species in terms of the other, as follows:

$$P_{\mathrm{AL}} = \Phi_2 < XB^{k-1} - (P_{\mathrm{TS}}+P_{\mathrm{M}}) >, \tag{41}$$

$$P_{\mathrm{M}} = X\cdot X_{=}^2 < B^{\frac{k-2}{2}} > \cdot(a_{\mathrm{S}} - a_{\mathrm{TS}}), \tag{42}$$

where $\Phi_2 < F >$ represents the species of pairs of F-structures of the form $\{s,\tau\cdot s\}$ and E_+ is the species of non empty sets. At the level of ordinary generating series, we get

$$\widetilde{P}_{\mathrm{AL}}(x) = \frac{1}{2}\big(x^2\widetilde{B}^{k-1}(x^2) - \widetilde{P}_{\mathrm{TS}}(x^2) - \widetilde{P}_{\mathrm{M}}(x^2)\big), \tag{43}$$

$$\widetilde{P}_{\mathrm{M}}(x) = \Big(XX_{=}^2 < B^{\frac{k-2}{2}} > \cdot a_{\mathrm{TS}}\cdot E_+(P_{\mathrm{AL}}+P_{\mathrm{M}})\Big)^{\sim}(x) \tag{44}$$

$$= x\widetilde{B}^{\frac{k-2}{2}}(x^2)\widetilde{a}_{\mathrm{TS}}(x)\left(\exp\left(\sum_{i\geq 1}\frac{1}{i}(\widetilde{P}_{\mathrm{AL}}(x^i)+\widetilde{P}_{\mathrm{M}}(x^i))\right)-1\right) \tag{45}$$

$$= x\widetilde{B}^{\frac{k-2}{2}}(x^2)(\widetilde{a}_{\mathrm{S}}(x) - \widetilde{a}_{\mathrm{TS}}(x)) \tag{46}$$

Let $\widetilde{a}_{\mathrm{S}}(x)$ denote the ordinary generating series of unlabelled symmetric $a^{\rightarrow}$-structures. We have (see Figure 7)

$$\widetilde{a}_{\mathrm{S}}(x) = E(P_{\mathrm{TS}}+P_{\mathrm{AL}}+P_{\mathrm{M}})^{\sim}(x), \tag{47}$$

$$= \exp\left(\sum_{i\geq 1}\frac{1}{i}(\widetilde{P}_{\mathrm{TS}}(x^i)+\widetilde{P}_{\mathrm{AL}}(x^i)+\widetilde{P}_{\mathrm{M}}(x^i))\right). \tag{48}$$

We then deduce a recurrence for the numbers $\alpha_n = \widetilde{a}_{\mathrm{S},n}$ of symmetric k-gonal 2-trees rooted at an edge left fixed by orientation reversing, $\widetilde{P}_{\mathrm{AL},n}$ and

$\widetilde{P}_{\mathrm{M},n}$ of alternated and mixed pages, respectively, on n k-gons:

$$\alpha_n = \frac{1}{n}\sum_{i=1}^{n}\Big(\sum_{d|i} d\omega_d\Big)\alpha_{n-i}, \quad \alpha_0 = 1, \tag{49}$$

$$\widetilde{P}_{\mathrm{M},n} = \sum_{i=0}^{n-1} b_{\frac{i}{2}}^{(\frac{k-2}{2})}\alpha_{n-1-i} - \widetilde{P}_{\mathrm{TS},n}, \tag{50}$$

$$\widetilde{P}_{\mathrm{AL},n} = \frac{1}{2}\left(b_{\frac{n-2}{2}}^{(k-1)} - \widetilde{P}_{\mathrm{TS},n/2} - \widetilde{P}_{\mathrm{M},n/2}\right), \tag{51}$$

where

$$\omega_k = \widetilde{P}_{\mathrm{TS},k} + \widetilde{P}_{\mathrm{AL},k} + \widetilde{P}_{\mathrm{M},k},$$

and $\widetilde{P}_{\mathrm{TS},n} = \pi_n$ is given by (38).

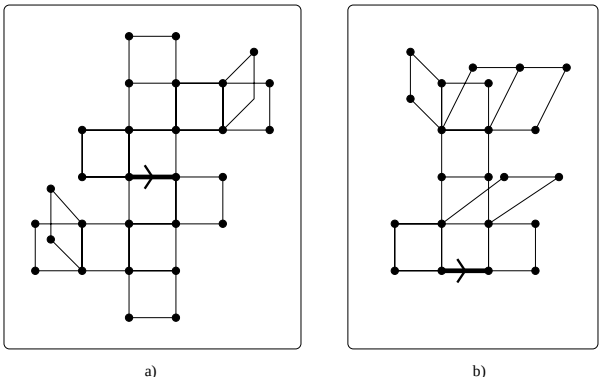

Figure 6: A pair of alternated pages and a mixed page

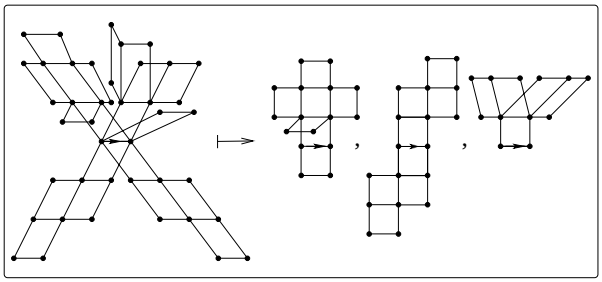

Figure 7: Decomposition of an $\widetilde{a}^{\rightarrow}$-structure fixed under τ

Proposition 10. If k is an even integer, then the number of edge rooted (unoriented) k-gonal 2-trees over n k-gons is given by

$$\widetilde{a}_n^{-} = \frac{1}{2}(b_n + \alpha_n). \tag{52}$$

Let us now turn to the species $\mathcal{A}^{\underline{\diamond}}$ of k-gonal 2-trees rooted at an edge-pointed k-gon.

Proposition 11. We have

$$\widetilde{a}^{\underline{\diamond}}(x) = \frac{1}{2}\left(\widetilde{a}_o^{\underline{\diamond}}(x) + \widetilde{a}_{o,\tau}^{\underline{\diamond}}(x)\right), \tag{53}$$

where

$$\widetilde{a}_{o,\tau}^{\underline{\diamond}}(x) = x\widetilde{a}_{\mathrm{S}}^2(x)\widetilde{B}^{\frac{k-2}{2}}(x^2).$$

Proof. An unlabelled τ-symmetric $\mathcal{A}_o^{\underline{\diamond}}$-structure possesses an axis of symmetry which is, in fact, the mediatrix of the distinguished edge of the rooted polygon, and also the mediatrix of the edge facing the rooted one, see Figure 8. The two structures s and t glued on these two edges are thus symmetric, which leads to the term $(\widetilde{a}_{\mathrm{S}}(x))^2$. Then, on each side of the axis, are found two $B^{\frac{k-2}{2}}$-structures α and β, which by symmetry satisfy $\beta = \tau \cdot \alpha$, contributing to the factor $\widetilde{B}^{\frac{k-2}{2}}(x^2)$. ■

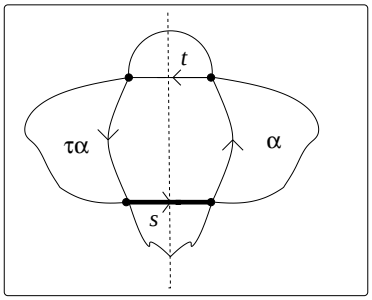

Figure 8: A τ-symmetric unlabelled $\mathcal{A}_o^{\underline{\diamond}}$-structures

Corollary 4. We have the following expression for the number $\widetilde{a}_n^{\underline{\diamond}}$ of unlabelled $\mathcal{A}^{\underline{\diamond}}$-structures,

$$\widetilde{a}_n^{\underline{\diamond}} = \frac{1}{2}\left(\widetilde{a}_{o,n}^{\underline{\diamond}} + \sum_{i+j=n-1} \alpha_i^{(2)} \cdot b_{\frac{j}{2}}^{(\frac{k-2}{2})}\right), \tag{54}$$

where $\alpha_i^{(2)} = [x^i]\widetilde{a}_S^2(x)$. □

We proceed in a similar way for the species $\mathcal{A}^{\diamond}$, of k-gon rooted k-gonal 2-trees. Once again, we use relation (23), giving

$$\widetilde{a}^{\diamond}(x) = \frac{1}{2}\left(\widetilde{a}_o^{\diamond}(x) + \widetilde{a}_{o,\tau}^{\diamond}(x)\right). \tag{55}$$

Proposition 12. Let $\widetilde{a}^{\diamond}_{o,\tau}(x)$ be the generating series of unlabelled $a^{\diamond}_{o}$-structures left fixed by orientation reversing. Then, we have

$$\widetilde{a}^{\diamond}_{o,\tau}(x) = \frac{x}{2}\widetilde{a}^{2}_{\mathrm{S}}(x)\widetilde{B}^{\frac{k-2}{2}}(x^2) + \frac{x}{2}\widetilde{B}^{\frac{k}{2}}(x^2). \tag{56}$$

Proof. Notice first that to be left fixed by orientation reversing, an $a^{\diamond}_{o}$-structure must admit at least one axis of symmetry, which can be of two kinds:

1. an axis passing through the middle of two opposite edges, or
2. an axis passing through two opposite vertices,

of the pointed polygon. The enumeration is carried out by first orienting the axis of symmetry. The first term of (56) then corresponds to a symmetry of the first kind, and the second term to a symmetry of the second kind. The structures having both symmetries are precisely those which are counted one half time in both of these terms. This is established for a general k by considering the largest power of 2, 2^m, such that $k/2^m$ is odd. We illustrate the proof in the following lines with $k = 12$; the reader will easily convince himself of the validity of this argument for any k.

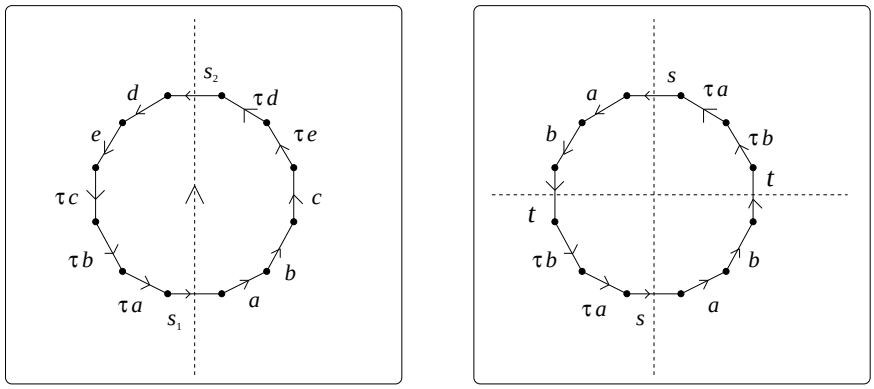

Figure 9: $\widetilde{a}^{\diamond}_{o,\tau}$-structures with an edge–edge symmetry

For $k = 12$, a general unlabelled τ-symmetric polygon-rooted oriented k-gonal 2-tree with an oriented edge–edge axis will be of the form illustrated in Figure 9 a), where s_1 and s_2 represent unlabelled a_{S}-structures, a, b, c, d and e are general unlabelled B-structures and τx represents the opposite of the B-structures x, obtained by reversing their orientation. Most of these structures are enumerated exactly by $\frac{1}{2}x\widetilde{a}^{2}_{\mathrm{S}}(x)\widetilde{B}^{5}(x^2)$. Indeed, the factor $x\widetilde{a}^{2}_{\mathrm{S}}(x)\widetilde{B}^{5}(x^2)$ is obtained in the same way as for $a^{\diamond}_{o,\tau}$-structures and the division by two is justified in the following cases:

1. $s_1 \neq s_2$ (two orientations of the axis),

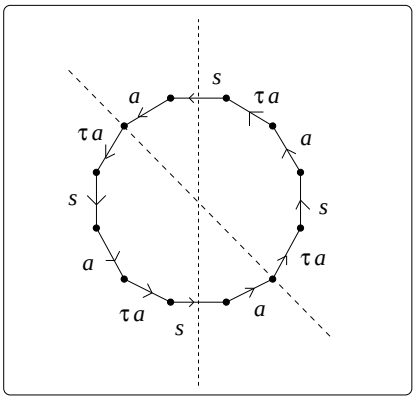

Figure 10: $\widetilde{a}^{\diamond}_{o,\tau}$-structures with edge–edge and vertex–vertex symmetries

2. $s_1 = s_2 = s$, $(a, b, c) \neq (d, e, \tau \cdot c)$ (two orientations),

3. $s_1 = s_2 = s$, $(a, b, c) = (d, e, \tau \cdot c)$, so that $c = \tau \cdot c = t \in \widetilde{a}_{\mathrm{S}}$, and either $i)$ $s \neq t$ or $ii)$ $s = t$ and $(a, b) \neq (\tau \cdot b, \tau \cdot a)$ (two choices for the symmetry axis, see Figure 9 b)),

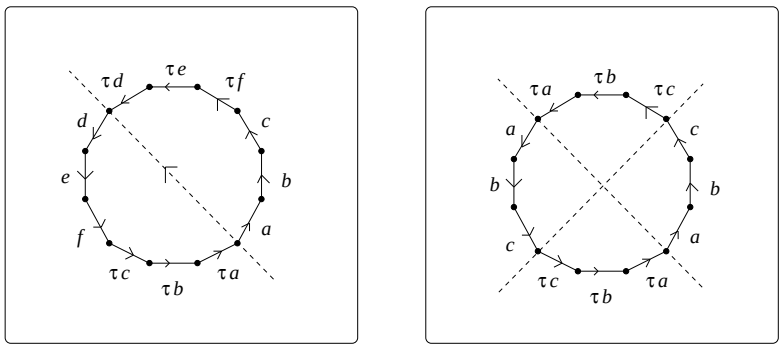

Figure 11: $\widetilde{a}^{\diamond}_{o,\tau}$-structure with a vertex–vertex symmetry axis

However, the structures with $s = t$ and $b = \tau \cdot a$ (see Figure 10) will occur only once and are counted only one half time in the formula. But, notice that these structures also admit a vertex–vertex symmetry axis and, as it will turn out, are also counted one half time in the second term of (56).

Similarly, an unlabelled $a^{\diamond}_{o,\tau}$-structure with an oriented vertex–vertex symmetry axis will be of the form illustrated in Figure 11 a), where a, b, ..., f are arbitrary unlabelled B-structures. Most of these terms are enumerated exactly by $\frac{1}{2}x\widetilde{B}^6(x^2)$, the division by two being justified in the following cases:

1. $(a,b,c) \neq (d,e,f)$ (two orientations of the symmetry axis),

2. $(a,b,c) = (d,e,f)$ and $(a,b,c) \neq (\tau\cdot c, \tau\cdot b, \tau\cdot a)$ (two choices for the symmetry axis, see Figure 11 b)),

However, the structures with $(a,b,c) = (d,e,f)$, $c = \tau\cdot a$ and $b = \tau\cdot b = s \in \widetilde{\mathcal{A}}_{\mathrm{S}}$ appear only once and are counted one half time here. But they also have an edge-edge symmetry axis and were also counted one half time in the first term of (56) (exchange a and $\tau\cdot a$ in Figure 10). ■

The dissymmetry theorem yields, for $k \geq 4$ even,

$$\widetilde{a}(x) = \frac{1}{2}\widetilde{a}_o(x) + \frac{1}{2}\widetilde{a}_{\mathrm{S}}(x) + \frac{1}{2}\widetilde{a}^{\diamond}_{o,\tau}(x) - \frac{1}{2}\widetilde{a}^{\diamond}_{\overline{o,\tau}}(x), \tag{57}$$

So, we have the following result.

Proposition 13. Let k be an even integer, $k \geq 4$. Then,the generating series $\widetilde{a}(x)$ of unlabelled k-gonal 2-trees is given by

$$\widetilde{a}(x) = \frac{1}{2}\widetilde{a}_o(x) + \frac{1}{2}\widetilde{a}_{\mathrm{S}}(x) + \frac{x}{4}(\widetilde{B}^{\frac{k}{2}}(x^2) - \widetilde{a}^2_{\mathrm{S}}(x)\widetilde{B}^{\frac{k-2}{2}}(x^2)), \tag{58}$$

where $\widetilde{a}_o(x)$ is given by (18) and $\widetilde{a}_{\mathrm{S}}(x)$ by (48). □

Corollary 5. If $k \geq 4$, is an even integer, then the number of unlabelled k-gonal 2-trees over n k-gons is given by

$$\widetilde{a}_n = \frac{1}{2}\widetilde{a}_{o,n} + \frac{1}{2}\alpha_n + \frac{1}{4}b^{(\frac{k}{2})}_{\frac{n-1}{2}} - \frac{1}{4}\sum_{i+j=n-1}\alpha^{(2)}_i \cdot b^{(\frac{k-2}{2})}_{\frac{j}{2}}, \tag{59}$$

with

$$b^{(m)}_l = [x^l]\widetilde{B}^m(x), \quad \alpha^{(2)}_i = [x^i]\widetilde{a}^2_{\mathrm{S}}(x).$$

5 Enumeration according to the perimeter

In this section, we are interested in the enumeration of k-gonal 2-trees according to the perimeter. The *perimeter* of a k-gonal 2-tree is the number of external edges (edges of degree at most one). In particular, if the structure s is the single edge, the perimeter is 1. In order to keep track of the perimeter, we introduce a weight function w over k-gonal 2-tree, defined by:

$$\begin{array}{rccc} w: & \mathcal{A} & \longrightarrow & \mathbb{Q}[t] \\ & s & \longmapsto & w(s) = t^{\mathrm{p}(s)}, \end{array} \tag{60}$$

where $\mathrm{p}(s)$ denotes the perimeter of the structure $s \in \mathcal{A}$. For example, the 2-tree of Figure 1 a) has perimeter 28.

5.1 A weighted version of the species B

Our first task is to determine the functional equation satisfied by the species B_w of k-gonal 2-trees pointed at an oriented edge and weighted by the perimeter counter t, with the precision that the rooted edge does not contribute to the perimeter of a B-structure except in the case of a single edge, which has perimeter 1. We have

Proposition 14. The weighted species B_w is characterized by the following functional equation

$$B_w(X) = t + E_+(XB_w^{k-1}(X)), \tag{61}$$

where E_+ is the species of non-empty sets.

Proof. The (unweighted) species B satisfies

$$B = E(XB^{k-1}) = 1 + E_+(XB^{k-1}(X)),$$

where the term 1 corresponds to the single edge. By taking into account the perimeter weight w and the fact that a single edge has weight t, we obtain (61). ■

Note that (61) is also valid for $k = 2$. The species B_w then represents weighted edge-labelled (ordinary) rooted trees where the variables t acts as a leaf counter.

We write the generating series associated to the weighted species B_w as follows:

$$B_w(x) = B(x,t) = \sum_{\substack{n\geq 0\\ \ell\geq 1}} a^{\rightarrow}_{n,\ell}\, t^\ell \frac{x^n}{n!}, = \sum_{n\geq 0} a^{\rightarrow}_n(t)\frac{x^n}{n!} \tag{62}$$

$$\widetilde{B}_w(x) = \widetilde{B}(x,t) = \sum_{\substack{n\geq 0\\ \ell\geq 1}} b_{n,\ell}\, t^\ell x^n = \sum_{n\geq 0} b_n(t)x^n, \tag{63}$$

where $a^{\rightarrow}_{n,\ell}$ and $b_{n,\ell}$ are the numbers of labelled and unlabelled k-gonal 2-trees rooted at an oriented edge having n k-gons and perimeter ℓ. From equation (61), we can deduce explicit formulas for $a^{\rightarrow}_n(t)$ and $a^{\rightarrow}_{n,\ell}$ and recursive formulas for $b_n(t)$ and $b_{n,\ell}$. Notice that, because of the nature of the structures, the integer ℓ is bounded: $(k-2)n + 1 \leq \ell \leq (k-1)n$.

Proposition 15. The polynomial $a^{\rightarrow}_n(t)$, giving the labelled weighted enumeration of B_w-structures over n k-gons is given by $a^{\rightarrow}_0(t) = t$ and, for $n \geq 1$,

$$a^{\rightarrow}_n(t) = \frac{n!}{m}\sum_{\ell=m-n}^{m-1}\ \sum_{i+j=m-\ell} (-1)^j i^n \binom{m}{\ell, i, j} t^\ell, \tag{64}$$

$$= \frac{1}{m}\sum_{i=1}^{n}\frac{m!}{(m-i)!}S(n,i)t^{m-i}, \tag{65}$$

where $m = (k-1)n+1$ is the number of edges and $S(n,j)$ denotes the Stirling numbers of the second kind, giving the number of partitions of an n-set in j blocks.

Proof. From (61), we have $B(x,t) = t + \exp(xB^{k-1}(x,t)) - 1$. So, we get

$$xB^{k-1}(x,t) = x(t + \exp(xB^{k-1}(x,t)) - 1)^{k-1}.$$

Putting $\mathcal{B}(x,t) = xB^{k-1}(x,t)$, we obtain that the series $\mathcal{B}(x,t)$ satisfies the functional equation $\mathcal{B}(x,t) = xR(\mathcal{B}(x,t))$, where $R(y) = (t + \exp(y) - 1)^{k-1}$. Moreover,

$$B(x,t) = \left(\frac{\mathcal{B}(x,t)}{x}\right)^{\frac{1}{k-1}}. \tag{66}$$

The composite form of Lagrange inversion applied to equation (66) gives (64). To obtain now (65), we apply the same method but we use the following well-known relation

$$\frac{(\mathrm{e}^x - 1)^j}{j!} = \sum_{n \geq j} S(n,j)\frac{x^n}{n!},$$

see [4] page 63. ■

We obtain now, in a straightforward way, expressions for $a^{\rightarrow}_{n,\ell}$. Formula (65) can also be given a Prüfer-type bijective proof.

Corollary 6. The number $a^{\rightarrow}_{n,\ell}$ of labelled B_w-structures over n k-gons and having perimeter ℓ, for $(k-2)n+1 \leq \ell \leq (k-1)n$ (a weight t^ℓ), is given by

$$a^{\rightarrow}_{n,\ell} = \frac{n!}{m} \sum_{i+j=m-\ell} (-1)^j i^n \binom{m}{\ell, i, j}, \tag{67}$$

$$= \frac{(m-1)!}{\ell!} S(n, m-\ell), \tag{68}$$

where $m = (k-1)n+1$ is the number of edges. □

We notice that, when $k = 3$, $\ell = n+1$ is the minimal perimeter and $a^{\rightarrow}_{n,n+1} = n!\mathbf{c_n}$, where $\mathbf{c_n}$ is the famous Catalan number, since, in this case, the B_w-structures obtained are outerplanar, see Labelle et al. [14]. These structures are the basic ones in the computation of the molecular expansion (a classification according to symmetries) of the species of outerplanar k-gonal 2-trees. For general k, $a^{\rightarrow}_{n,(k-2)n+1} = n!C_{k,n}$, where $C_{k,n} = \frac{1}{n}\binom{n(k-1)}{n-1}$ is the generalized Catalan numbers. See [16].

As in the unweighted case, we cannot obtain an explicit formula for the number $b_{n,\ell}$ as well as for the polynomial $b_n(t)$. However, we give recursive formulas.

Proposition 16. The polynomials $b_n(t)$, $n \geq 1$, satisfy the following recurrence

$$\begin{aligned} b_0(t) &= t, \\ b_n(t) &= \frac{1}{n}\left(\sum_{d|n} d \cdot b_{d-1}^{(k-1)}(t^{\frac{n}{d}}) + \sum_{i=1}^{n-1}\left(\sum_{d|i} d \cdot b_{d-1}^{(k-1)}(t^{\frac{i}{d}})\right) b_{n-i}(t)\right), \end{aligned} \tag{69}$$

where the summations are taken over integers $i, d \geq 1$, and where

$$b_n^{(k-1)}(t) = [x^n]\widetilde{B}^{k-1}(x,t) = \sum_{i_1+i_2+\cdots+i_{k-1}=n} b_{i_1}(t)b_{i_2}(t)\ldots b_{i_{k-1}}(t). \tag{70}$$

Proof. We obtain recurrence (69) by taking the derivative (with respect to x) of the following expression

$$\widetilde{B}(x,t) = t + \exp\left(\sum_{i\geq 1}\frac{1}{i}x^i\widetilde{B}^{k-1}(x^i,t^i)\right) - 1,$$

obtained from (61) by passing to the ordinary generating series for unlabelled enumeration. ■

We obtain the next proposition quite directly from the previous one.

Corollary 7. The number $b_{n,\ell}$ of unlabelled B_w-structures over n k-gons and having perimeter ℓ satisfies the following recurrence

$$b_{0,\ell} = \delta_{1,\ell}, \qquad b_{n,\ell} = \frac{1}{n}\omega_{n,\ell} + \frac{1}{n}\sum_{\substack{\nu+\mu=n \\ \nu,\mu\geq 1}}\sum_{\substack{p+q=\ell \\ p,q\geq 1}} \omega_{\nu,p}\cdot b_{\mu,q}, \tag{71}$$

where $\delta_{i,j}$ is the Kronecker symbol and

$$\omega_{n,\ell} = \sum_{d|(n,\ell)} \frac{n}{d} b_{\frac{n}{d}-1,\frac{\ell}{d}}^{(k-1)}. \tag{72}$$

□

As for the unweighted case, we can express the pointed weighted species of k-gonal 2-trees as function of the species B_w. We begin with the oriented case, which is simpler, and use it to obtain the unoriented case.

5.2 Oriented case

Let us denote by $a_w^- = (a_w)^-$, $a_w^\diamond = (a_w)^\diamond$, $a_w^{\diamond\!\!\diamond} = (a_w)^{\diamond\!\!\diamond}$, and $a_{o,w}^- = (a_{o,w})^-$, $a_{o,w}^\diamond = (a_{o,w})^\diamond$, $a_{o,w}^{\diamond\!\!\diamond} = (a_{o,w})^{\diamond\!\!\diamond}$, where w is defined by (60). Note in particular that $a_{o,w}^- \neq B_w$. The dissymetry theorem remains valid in this weighted context, for both the oriented and unoriented cases:

$$a_{o,w}^- + a_{o,w}^\diamond = a_{o,w} + a_{o,w}^{\diamond\!\!\diamond}, \tag{73}$$

$$a_w^- + a_w^\diamond = a_w + a_w^{\diamond\!\!\diamond}. \tag{74}$$

As in the unweighted case, we have to express these species in terms of the weighted species B_w. Enumeration formulas will then follow. The following proposition is quite obvious and the proof is omitted.

Proposition 17. The weighted species $\mathcal{A}^{-}_{o,w}$, $\mathcal{A}^{\diamond}_{o,w}$ and $\mathcal{A}^{\diamond}_{o,w}$ are characterized by

$$\begin{aligned}
\mathcal{A}^{-}_{o,w} &= B_w + (t-1)XB_w^{k-1}, && (75)\\
\mathcal{A}^{\diamond}_{o,w} &= XC_k(B_w), && (76)\\
\mathcal{A}^{\diamond}_{o,w} &= XB_w^k. && (77)
\end{aligned}$$

We then deduce easily the associated generating series of these species

$$\mathcal{A}^{-}_{o}(x,t) = B(x,t) + (t-1)xB^{k-1}(x,t) \tag{78}$$

and

$$\begin{aligned}
\widetilde{\mathcal{A}}^{-}_{o}(x,t) &= \widetilde{B}(x,t) + (t-1)x\widetilde{B}^{k-1}(x,t), && (79)\\
\widetilde{\mathcal{A}}^{\diamond}_{o}(x,t) &= \frac{x}{k}\sum_{d|k}\phi(d)\widetilde{B}^{\frac{k}{d}}(x^d,t^d), && (80)\\
\widetilde{\mathcal{A}}^{\diamond}_{o}(x,t) &= x(\widetilde{B}^{k}(x,t) + (t-1)\widetilde{B}^{k-1}(x,t)), && (81)
\end{aligned}$$

from which we deduce

$$a^{-}_{o,n}(t) = n![x^n]\mathcal{A}^{-}_{o}(x,t) = a^{\rightarrow}_{n}(t) + (t-1)na^{\rightarrow\,(k-1)}_{n-1}(t), \tag{82}$$

and, using the dissymmetry theorem,

$$\widetilde{\mathcal{A}}_{o}(x,t) = \widetilde{B}(x,t) + \frac{x}{k}\sum_{d|k}\phi(d)\widetilde{B}^{\frac{k}{d}}(x^d,t^d) - x\widetilde{B}^{k}(x,t) + (t-1)x\widetilde{B}^{k-1}(x,t). \tag{83}$$

We then get:

Proposition 18. We have, for $n \geq 2$,

$$\begin{aligned}
a_{o,n}(t) &= \frac{a^{-}_{o,n}(t)}{m}, && (84)\\
\widetilde{a}_{o,n}(t) &= [x^n]\widetilde{\mathcal{A}}_{o}(x,t) && (85)\\
&= b_n(t) - b^{(k)}_{n-1}(t) + \frac{1}{k}\sum_{\substack{d|k\\ d\geq 1}}\phi(d)b^{(\frac{k}{d})}_{\frac{n-1}{d}}(t^d) + (t-1)b^{(k-1)}_{n-1}(t), && (86)
\end{aligned}$$

where $m = (k-1)n+1$ is the number of edges and $b^{(i)}_n(t)$ is defined by (70).

Corollary 8. The numbers $a_o(n,\ell)$ and $\widetilde{a}_o(n,\ell)$ of labelled and unlabelled oriented k-gonal 2-trees , over n k-gons and having perimeter ℓ are given by

$$\begin{aligned}
a_o(n,\ell) &= \frac{1}{m}a^{-}_{o}(n,\ell) = \frac{1}{m}(a^{\rightarrow}_{n,\ell} + na^{\rightarrow\,(k-1)}_{n-1.\ell-1} - na^{\rightarrow\,(k-1)}_{n-1,\ell}), && (87)\\
\widetilde{a}_o(n,\ell) &= b_{n,\ell} - b^{(k)}_{n-1,\ell} + \frac{1}{k}\sum_{d|(k,\ell)}\phi(d)b^{(\frac{k}{d})}_{\frac{n-1}{d},\frac{\ell}{d}} + b^{(k-1)}_{n-1,\ell-1} - b^{(k-1)}_{n-1,\ell}. && (88)
\end{aligned}$$

5.3 Unoriented case

As in the unweighted case, unoriented species of k-gonal 2-trees can be expressed as quotient species of the oriented ones, as follows, where notations are obvious,

$$a_w^- = \frac{a_{o,w}^-}{\mathbb{Z}_2}, \qquad a_w^\diamond = \frac{a_{o,w}^\diamond}{\mathbb{Z}_2} \qquad a_w^\diamond = \frac{a_{o,w}^\diamond}{\mathbb{Z}_2} \tag{89}$$

It is very easy to obtain the number $a_{n,\ell}$ of labelled k-gonal 2-trees over n k-gons and having a perimeter of lenght ℓ,

$$a(n,\ell) = \begin{cases} \frac{1}{2}(a_o(n,\ell+1), & \text{if } \ell = (k-1)n, \\ \frac{1}{2}a_o(n,\ell), & \text{otherwise.} \end{cases} \tag{90}$$

since the only labelled k-gonal 2-trees fixed by orientation reversal for a given perimeter and number of polygons, is the one in which each k-gon share a common edge, which has $(k-1)n$ external edges (illustrated by Figure 12). So, the polynomial $a_n(t)$, giving the weighted enumeration of labelled k-gonal 2-trees, is given by

$$a_n(t) = \sum a_{n,\ell}\, t^\ell \;=\; \frac{1}{2}(a_{o,n}(t) + t^{(k-1)n}). \tag{91}$$

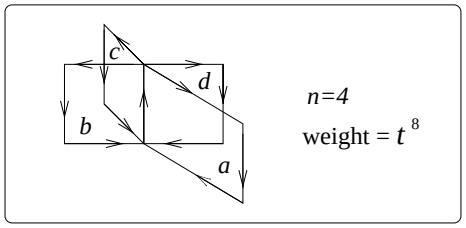

Figure 12: Labelled oriented 4-gonal 2-tree which is fixed by orientation reversion

For the unlabelled (weighted) enumeration, we have to adapt the results obtained in Section 4.2 and 4.3 to take into account the perimeter.

• k odd.

For k odd, we can easily see that the species a_w^-, $a_w^\diamond$ and $a_w^\diamond$ satisfy the following expressions in terms of the weighted quotient species Q_w, S_w and U_w, which are adapted from Section 4.1:

$$a_w^- = Q_w(X, B_{w^2}^{\frac{k-1}{2}}), \tag{92}$$

$$a_w^\diamond = X \cdot S_w(X, B_{w^2}^{\frac{k-1}{2}}), \tag{93}$$

$$a_w^\diamond = X \cdot U_w(X, B_{w^2}^{\frac{k-1}{2}}), \tag{94}$$

with

$$\begin{aligned} Q_w(X,Y) &= \left(t + tXY^2 + E_{\geq 2}(XY^2)\right)/\mathbb{Z}_2, & (95)\\ S_w(X,Y) &= C_k(t + E_+(XY^2))/\mathbb{Z}_2, & (96)\\ U_w(X,Y) &= \left((t + E_+(XY^2))^k\right)/\mathbb{Z}_2, & (97)\end{aligned}$$

where $E_{\geq 2}$ is the species of sets of cardinality at least two. The cycle index series of these species are given by:

$$\begin{aligned} Z_{Q_w} &= \frac{1}{2}(Z_{E_w(XY^2)} + q_w), & (98)\\ Z_{S_w} &= \frac{1}{2}\left(Z_{C_k(t+E_+(XY^2))} + q_w \cdot (p_2 \circ (t + Z_{E_+(XY^2)})^{\frac{k-1}{2}})\right), & (99)\\ Z_{U_w} &= \frac{1}{2}\left(Z_{(t+E_+(XY^2))^k} + q_w \cdot (p_2 \circ (t + Z_{E_+(XY^2)})^{\frac{k-1}{2}})\right), & (100)\end{aligned}$$

where $q_w = (t-1)(1+x_1y_2) + h \circ (x_1y_2 + p_2 \circ (x_1\frac{y_1^2-y_2}{2})) = q + (t-1)(1+x_1y_2)$, h being the homogeneous symmetric function, and p_i, $i \geq 1$, denotes the i^{th} power sum and $E_w(XY^2) = E(XY^2) + (t-1)(1+XY^2)$.

Another use of the dissymmetry theorem gives the ordinary generating series of unlabelled k-gonal 2-trees weighted by their perimeter:

$$\widetilde{a}(x,t) = \frac{1}{2}\left(\widetilde{a}_o(x,t) + q_w[x, \widetilde{B}^{\frac{k-1}{2}}(x,t)] + (t-1)(1 + x\widetilde{B}^{\frac{k-2}{2}}(x^2,t^2)\right), \quad (101)$$

where

$$q_w[x, \widetilde{B}^{\frac{k-1}{2}}(x,t)] := q_w(x, x^2, \ldots; \widetilde{B}^{\frac{k-1}{2}}(x,t), \widetilde{B}^{\frac{k-1}{2}}(x^2,t^2), \ldots).$$

- k **even**.

When k is even, it suffices to adapt all species introduced in Section 4.2 in the present weighted context. This is easily done, as follows, the index w meaning that the species are weighted according to perimeter. Note that the species $a_{\mathrm{S},w}$ is a sub weighted-species of $a^-_{o,w}$ by definition. We have:

$$\widetilde{a}_{\mathrm{S}}(x,t) = \left(E(P_{\mathrm{TS},w} + P_{\mathrm{M},w} + P_{\mathrm{AL},w}) + (t-1)(1 + P_{\mathrm{TS},w} + P_{\mathrm{M},w})\right)^{\sim}(x), \quad (102)$$

where

$$\begin{aligned} a_{\mathrm{TS},w} &= t + t \cdot P_{\mathrm{TS},w} + E_{\geq 2}(P_{\mathrm{TS},w}) & (103)\\ &= (t-1)(1 + P_{\mathrm{TS},w}) + E(P_{\mathrm{TS},w}), & (104)\\ P_{\mathrm{TS},w} &= X \cdot X_=^2 < B^{\frac{k-2}{2}} > \cdot (a_{\mathrm{TS},w} + (1-t)P_{\mathrm{TS},w}), & (105)\\ P_{\mathrm{AL},w} &= \Phi_2 < XB_w^{k-1} - (P_{\mathrm{TS},w} + P_{\mathrm{M},w}) >, & (106)\\ P_{\mathrm{M},w} &= X \cdot X_=^2 < B^{\frac{k-2}{2}} > \cdot (a_{\mathrm{S},w} + (1-t)P_{\mathrm{M},w} - a_{\mathrm{TS},w}). & (107)\end{aligned}$$

We then have

$$\widetilde{a}_{\mathrm{S}}(x,t) = \exp(\sum_{i\geq 1}\frac{1}{i}(\widetilde{P}_{\mathrm{TS}}(x^i,t^i)+\widetilde{P}_{\mathrm{M}}(x^i,t^i)+\widetilde{P}_{\mathrm{AL}}(x^i,t^i)))+(t-1)(1+\widetilde{P}_{\mathrm{TS}}(x,t)+\widetilde{P}_{\mathrm{M}}(x,t)), \tag{108}$$

where

$$\widetilde{a}_{\mathrm{TS}}(x,t) = (t-1)(1+\widetilde{P}_{\mathrm{TS}}(x,t)) + \exp\left(\sum_{i\geq 1}\frac{1}{i}\widetilde{P}_{\mathrm{TS}}(x^i,t^i)\right), \tag{109}$$

$$\widetilde{P}_{\mathrm{TS}}(x,t) = x\widetilde{B}^{\frac{k-2}{2}}(x^2,t^2)\left(\widetilde{a}_{\mathrm{TS}}(x,t)+(1-t)\widetilde{P}_{\mathrm{TS}}(x,t)\right), \tag{110}$$

$$\widetilde{P}_{\mathrm{AL}}(x,t) = \frac{1}{2}\big(x^2\widetilde{B}^{k-1}(x^2,t^2) - \widetilde{P}_{\mathrm{TS}}(x^2,t^2) - \widetilde{P}_{\mathrm{M}}(x^2,t^2)\big), \tag{111}$$

and

$$\begin{aligned}\widetilde{P}_{\mathrm{M}}(x,t) &= \left(XX_{=}^2 < B_w^{\frac{k-2}{2}} > \cdot(a_{\mathrm{TS},w}+(1-t)(1+P_{\mathrm{TS},w}))\cdot E_+(P_{\mathrm{AL},w}+P_{\mathrm{M},w})\right)^{\sim}(x)\\ &= x\widetilde{B}^{\frac{k-2}{2}}(x^2,t^2)\left(\widetilde{a}_{\mathrm{S}}(x,t)+(1-t)\widetilde{P}_{\mathrm{M}}(x,t)-\widetilde{a}_{\mathrm{TS}}(x,t)\right).\end{aligned} \tag{112}$$

It is then possible to compute the tilde generating functions of unlabelled structures associated to the species (89):

$$\begin{aligned}\widetilde{a}^{-}_{o,\tau}(x,t) &= \widetilde{a}_S(x,t),\\ \widetilde{a}^{\diamond}_{\cdot,\tau}(x,t) &= x\left(\widetilde{a}_S(x,t)+(1-t)(\widetilde{P}_{\mathrm{TS}}(x,t)+\widetilde{P}_{\mathrm{M}}(x,t)\right)^2\cdot\widetilde{B}^{\frac{k-2}{2}}(x^2,t^2),\\ \widetilde{a}^{\diamond}_{o,\tau}(x,t) &= \frac{x}{2}\left(\widetilde{a}_S(x,t)+(1-t)(\widetilde{P}_{\mathrm{TS}}(x,t)+\widetilde{P}_{\mathrm{M}}(x,t)\right)^2\cdot\widetilde{B}^{\frac{k-2}{2}}(x^2,t^2)+\frac{x}{2}\widetilde{B}^{\frac{k}{2}}(x^2,t^2).\end{aligned}$$

Finally, we obtain

$$\begin{aligned}\widetilde{a}(x,t) = \frac{1}{2}\widetilde{a}_o(x,t)+\frac{1}{2}\widetilde{a}_{\mathrm{S}}(x,t)+\frac{x}{4}\widetilde{B}^{\frac{k}{2}}(x^2,t^2)\\ -\frac{x}{4}\left(\widetilde{a}_S(x,t)+(1-t)(\widetilde{P}_{\mathrm{TS}}(x,t)+\widetilde{P}_{\mathrm{M}}(x,t)\right)^2\cdot\widetilde{B}^{\frac{k-2}{2}}(x^2,t^2).\end{aligned} \tag{113}$$

6 Asymptotics

Thanks to the dissymmetry theorem and to the various combinatorial equations related to it, the asymptotic enumeration of (labelled or unlabelled) k-gonal 2-trees depends essentially on the asymptotic enumeration of B-structures where B is the auxiliary species characterized by the functional equation (5). In the labelled case, the asymptotics is trivial since we have the simple explicit formulas (9), (19) and (21). The unlabelled case is more eleborate and makes use of the funtional equation (14) satisfied by the series $\widetilde{B}(x)$.

We need first the following result, which is a consequence of the classical theorem of Bender (see [2]) and is inspired form the approach of Fowler et al. for 2-trees (see [5, 6]).

Proposition 19. Let $p = k - 1$ and $\widetilde{B}(x) = \sum b_n(p)x^n$. Then, there exist constants α_p and β_p such that

$$b_n(p) \sim \alpha_p \beta_p^n n^{-3/2}, \qquad \text{as } n \to \infty. \tag{114}$$

Moreover,

$$\alpha_p = \alpha(\xi_p) = \frac{1}{\sqrt{2\pi}} \frac{1}{p^{1+\frac{1}{p}}} \xi_p^{-\frac{1}{p}} \left(1 + \frac{p\xi_p \omega'(\xi_p)}{\omega(\xi_p)}\right)^{\frac{1}{2}} \tag{115}$$

and

$$\beta_p = \frac{1}{\xi_p}, \tag{116}$$

where ξ_p is the smallest root of the equation

$$\xi = \frac{1}{ep} \omega^{-p}(\xi), \tag{117}$$

where $\omega(x)$ is the series given by

$$\omega(x) = \mathrm{e}^{\frac{1}{2}x^2 b^p(x^2) + \frac{1}{3}x^3 b^p(x^3) + \cdots}. \tag{118}$$

Proof. Write, for simplicity, $b(x) = \widetilde{B}(x)$. Then, thanks to (14), $y = b(x)$ satisfies the relation

$$y = e^{xy^p}\omega(x), \quad \text{where} \quad \omega(x) = e^{\frac{1}{2}x^2 b^p(x^2) + \frac{1}{3}x^3 b^p(x^3) + \cdots}. \tag{119}$$

By Bender's theorem applied to the function $f(x, y) = y - e^{xy^p}\omega(x)$, we have to find a solution (ξ_p, τ_p) of the system

$$f(x, y) = 0 \qquad \text{and} \qquad f_y(x, y) = 0. \tag{120}$$

It is equivalent to say that ξ_p is solution of (117) and that $p\xi_p\tau_p^p = 1$.

Since $f_{yy}(\xi_p, \tau_p) \neq 0$, ξ_p is an algebraic singularity of degree 2 of $b(x)$ and, for x near ξ_p, we have an expression of the form

$$b(x) = \tau_{p.0} + \tau_{p.1}(1 - \frac{x}{\xi_p})^{\frac{1}{2}} + \tau_{p,2}(1 - \frac{x}{\xi_p}) + \tau_{p.3}(1 - \frac{x}{\xi_p})^{\frac{3}{2}} + \cdots \tag{121}$$

where

$$\tau_{p,0} = \tau_p = b(\xi_p) = \left(\frac{1}{p\xi_p}\right)^{\frac{1}{p}}, \tag{122}$$

$$\tau_{p,1} = -\frac{\sqrt{2}}{p^{1+\frac{1}{p}}} \xi_p^{-\frac{1}{p}} \left(1 + \frac{p\xi_p \omega'(\xi_p)}{\omega(\xi_p)}\right)^{\frac{1}{2}}, \tag{123}$$

$$\tau_{p,2} = \frac{1}{3p^{2+\frac{1}{p}}} \xi_p^{-\frac{1}{p}} \left((2p+3) - p(p-3)\frac{\xi_p \omega'(\xi_p)}{\omega(\xi_p)}\right). \tag{124}$$

The asymptotic formula (114) with α_p and β_p given by (115) and (116) then follow from the fact that the main term of the asymptotic behavior of the coefficients $b_n(p)$ of x^n in (121) depends only on the term $\tau_{p,1}(1-\frac{x}{\xi_p})^{\frac{1}{2}}$ in (121) and is given by

$$b_n(p) \sim \binom{\frac{1}{2}}{n} \tau_{p,1}(-1)^n \frac{1}{\xi_p^n} \sim \alpha_p \beta_p^n n^{-\frac{3}{2}} \quad \text{as} \quad n \to \infty. \tag{125}$$

■

Note that ξ_p is the radius of convergence of $b(x)$ and that the radius of convergence of $\omega(x)$ is $\sqrt{\xi_p}$. It can be shown that $0 < \xi_p < \sqrt{\xi_p} < 1$. This implies that numerical approximations of ξ_p, for fixed p, can be computed by iteration using (117), and a suitable truncated polynomial approximations of $b(x)$. We now state our main asymptotic result.

Proposition 20. Let $p = k - 1$. Then, the number $\widetilde{a}_n$ of k-gonal 2-trees on n unlabelled k-gons satisfy

$$\widetilde{a}_n \sim \frac{1}{2}\widetilde{a}_{o,n}, \quad n \to \infty, \tag{126}$$

where $\widetilde{a}_{o,n}$ is the number of oriented k-gonal 2-trees over n unlabelled polygons. Moreover,

$$\widetilde{a}_{o,n} \sim \overline{\alpha}_p \beta_p^n n^{-5/2}, \quad n \to \infty, \tag{127}$$

where

$$\overline{\alpha_p} = 2\pi p^{1+\frac{2}{p}} \xi_p^{\frac{2}{p}} \alpha_p^3, \tag{128}$$

$$= \frac{1}{\sqrt{2\pi}} \frac{1}{p^{2+\frac{1}{p}}} \xi_p^{-\frac{1}{p}} \left(1 + p\frac{\omega'(\xi_p)}{\omega(\xi_p)}\right)^{\frac{3}{2}}, \tag{129}$$

and $\beta_p = \frac{1}{\xi_p}$ is the same growth as in Proposition 19.

Proof. The asymptotic formula (127) follows from the fact that the radius of convergence, ξ_p, of $\widetilde{a}(x)$, given by (31) for k odd and by (58) for k even, is equal to the radius of convergence of the dominating term $\frac{1}{2}\widetilde{a}_o(x)$. This is due to the easily checked fact that all terms in (31) and (58), except $\frac{1}{2}\widetilde{a}_o(x)$, have a radius of convergence greater or equal to $\sqrt{\xi_p} > \xi_p$. To establish (127), note first that, because of equation (18), the radius of convergence of $\widetilde{a}_o(x)$ is equal to the radius of covergence, ξ_p, of

$$b(x) - \frac{k-1}{k} x b^k(x), \tag{130}$$

where $b(x) = \widetilde{B}(x)$ and $k = p+1$. This implies that the asymptotic behavior of the coefficients $\widetilde{a}_{o,n}$ of $\widetilde{a}_o(x)$ is completely determined by that of (130). Substituting (121) into (130) and making use of (124) gives the following expansion

$$b(x) - \frac{k-1}{k} x b^k(x) = \overline{\tau}_{p,0} + \overline{\tau}_{p,1}\left(1 - \frac{x}{\xi_p}\right)^{\frac{1}{2}} + \overline{\tau}_{p,2}\left(1 - \frac{x}{\xi_p}\right) + \overline{\tau}_{p,3}\left(1 - \frac{x}{\xi_p}\right)^{\frac{3}{2}} + \cdots \tag{131}$$

where

$$\begin{aligned}
\overline{\tau}_{p,0} &= \frac{p}{p+1}\tau_{p,0}, && (132)\\
\overline{\tau}_{p,1} &= 0, && (133)\\
\overline{\tau}_{p,2} &= -\frac{1}{2}\frac{p(p+1)\tau_{p,1}^2 - 2\tau_{p,0}^2}{(p+1)\tau_{p,0}}, && (134)\\
\overline{\tau}_{p,3} &= -\frac{1}{6}\frac{\tau_{p,1}(6p\tau_{p,0}\tau_{p,2} + p(p-1)\tau_{p,1}^2 - 6\tau_{p,0}^2)}{\tau_{p,0}^2}, && (135)\\
&= -\frac{p}{3}\frac{\tau_{p,1}^3}{\tau_{p,0}^2}. && (136)
\end{aligned}$$

This implies that the dominating term for the asymptotic behavior of the coefficients $\widetilde{a}_{n,o}$ of x^n in $\widetilde{a}_o(x)$ depends only on the term $\overline{\tau}_{p,3}\left(1 - \frac{x}{\xi_p}\right)^{\frac{3}{2}}$ in (131) and is given by

$$\widetilde{a}_{n,o} \sim \binom{\frac{3}{2}}{n}\overline{\tau}_{p,3}(-1)^n \frac{1}{\xi_p^n} \sim \overline{\alpha}_p \beta_p n^{-\frac{5}{2}}, \quad \text{as } n \to \infty. \tag{137}$$

Computations making use of (136), (122) and (123), show that $\overline{\alpha}_p$ is indeed given by (128) and (129). ■

Our final result gives an explicit formula in terms of integer partitions for the common radius of convergence ξ_p of the series $\widetilde{B}(x)$, $\widetilde{a}(x)$ and $\widetilde{a}_o(x)$ from which the growth constant $\beta_p = \frac{1}{\xi_p}$ is obtained. We need the following special notations. If $\lambda = (\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_\nu)$ is a partition of an integer n in ν parts, we write $\lambda \vdash n$, $n = |\lambda|$, $\nu = l(\lambda)$, $m_i(\lambda) = |\{j : \lambda_j = i\}|$ = number of parts of size i in λ. Furthermore, we put

$$\sigma_i(\lambda) = \sum_{d|i} d m_d(\lambda), \quad \sigma_i^*(\lambda) = \sum_{d|i, d<i} d m_d(\lambda), \tag{138}$$

$$\widehat{\lambda} = 1 + |\lambda| + l(\lambda), \quad \widehat{z}(\lambda) = 2^{m_1(\lambda)} m_1(\lambda)! 3^{m_2(\lambda)} m_2(\lambda)! \ldots. \tag{139}$$

Proposition 21. We have the convergent expansion

$$\xi_p = \sum_{n=1}^{\infty} \frac{c_n}{p^n}, \tag{140}$$

where the coefficients c_n are constants, independent of p, explicitely given by

$$c_n = \sum_{\lambda \vdash n} \frac{e^{-\widehat{\lambda}}}{\widehat{\lambda}\widehat{z}(\lambda)} \prod_{i \geq 1} (\sigma_i(\lambda) - \widehat{\lambda})^{m_i(\lambda)-1} (\sigma_i^*(\lambda) - \widehat{\lambda}), \tag{141}$$

where λ runs over the set of partitions of n.

Proof. We establish the explicit formulas (140) and (141) by applying first Lagrange inversion to the equation $\xi = zR(\xi)$ where $z = \frac{1}{\mathrm{e}p}$ and $R(t) = \omega^{-p}(t)$, to get

$$\xi_p = \xi = \sum_{n \geq 1} \gamma_n \left(\frac{1}{\mathrm{e}p}\right)^n, \quad \text{and} \quad \gamma_n = \frac{1}{n}[t^{n-1}]\omega^{-np}(t). \tag{142}$$

Next, to explicitely evaluate $\omega^{-np}(x)$, we use Labelle's version ([12]) of the Good inversion formula in the context of cycle index series as follows. We begin with

$$\omega^p(x) = \exp(\frac{1}{2}px^2 b^p(x^2) + \frac{1}{3}px^3 b^p(x^3) + \cdots), \tag{143}$$

$$= \exp(\frac{1}{2}px_2 + \frac{1}{3}px_3 + \cdots) \circ Z_{XB^p(X)}\Big|_{x_i := x^i} \tag{144}$$

where the $\circ$ denotes the plethystic substitution. Using (7), we can then write $XB^p(X) = \frac{A(pX)}{p}$. This implies that

$$\omega^p(x) = \exp(\frac{1}{2}px_2 + \frac{1}{3}px_3 + \cdots) \circ \frac{Z_A(px_1, px_2, \ldots)}{p}\Big|_{x_i := x^i}, \tag{145}$$

and we get

$$\omega^{-np}(x) = \exp(-\frac{n}{2}px_2 - \frac{n}{3}px_3 - \cdots) \circ \left(\frac{1}{p} Z_A(px_1, px_2, \ldots)\right)\Big|_{x_i := x^i} \tag{146}$$

$$= \exp(-\frac{n}{2}x_2 - \frac{n}{3}x_3 - \cdots) \circ Z_A(x_1, x_2, \ldots)\Big|_{x_i := px^i}. \tag{147}$$

Then, using Labelle's inversion formula for cycle index series, we have, for any formal cycle index series $g(x_1, x_2, \ldots)$

$$[x_1^{n_1} x_2^{n_2} \ldots]\, g \circ Z_A(x_1, x_2, \ldots) = [t_1^{n_1} t_2^{n_2} \ldots] g(t_1, t_2, \ldots) \prod_{i=1}^{\infty} (1 - t_i) \exp(n_i(t_i + \frac{1}{2}t_{2i} + \cdots)), \tag{148}$$

and

$$\prod_{j=1}^{\infty} \exp(n_j(t_j + \frac{1}{2}t_{2j} + \cdots)) = \prod_{i=1}^{\infty} \exp(\sum_{d|i} d n_d \frac{t_i}{i}). \tag{149}$$

Taking $g(x_1, x_2, \ldots) = \exp(-\frac{\nu}{2}px_2 - \frac{\nu}{3}px_3 - \cdots)$, gives, after some computations,

$$[x_1^{n_1} x_2^{n_2} \ldots] \left(\exp(-\frac{\nu}{2}x_2 - \frac{\nu}{3}x_3 - \cdots) \circ Z_A\right) =$$

$$\left\{ \begin{array}{ll} 0 & \text{if} \quad n_1 > 0, \\ \left(\dfrac{\prod\limits_{i\geq 2}(-\nu+\sum\limits_{d|i} dn_d)^{n_i-1}(-\nu+\sum\limits_{d|i,d<i} dn_d)}{2^{n_2}n_2!3^{n_3}n_3!\ldots} \right) & \text{if} \quad n_1 = 0. \end{array} \right. \tag{150}$$

Making the substitution $x_i := px^i$, for $i = 1, 2, 3, \ldots$, gives the explicit formula

$$\omega^{-\nu p}(x) = \sum_{n\geq 0} \left(\sum_{2n_2+3n_3+\cdots=n} p^{n_2+n_3+\cdots} \frac{\prod\limits_{i\geq 2}(-\nu+\sum\limits_{d|i} dn_d)^{n_i-1}(-\nu+\sum\limits_{d|i,d<i} dn_d)}{2^{n_2}n_2!3^{n_3}n_3!\ldots} \right) x^n.$$

This implies, taking $\nu = n$ and using (142), that

$$\begin{aligned} \xi_p &= \sum_{n\geq 1} \frac{1}{n} \left(\sum_{2n_2+3n_3+\cdots=n-1} p^{n_2+n_3+\cdots} \frac{\prod\limits_{i\geq 2}(1-n+\sum\limits_{d|i} dn_d)^{n_i-1}(1-n+\sum\limits_{d|i,d<i} dn_d)}{2^{n_2}n_2!3^{n_3}n_3!\ldots} \right) \left(\frac{1}{ep}\right)^n, \\ &= \sum_{n\geq 1} \frac{c_n}{p^n}, \end{aligned}$$

where the coefficients c_n, $n \geq 1$, are given by (141). ■

Table 1, in the Appendix, gives, to 20 decimal places, the constants ξ_p, α_p, $\overline{\alpha}_p$ and $\beta_p = \frac{1}{\xi_p}$ for $p = 1, \ldots, 5$. Table 2 gives the exact values of the numbers $\widetilde{a}_n$, for k from 2 up to 12 and for $n = 0, 1, \ldots 20$, of the number of unlabelled k-gonal 2-trees built over n k-gons.

Here are the first few values of the universal constants c_n occuring in (140), for $n = 1, \ldots, 5$.

$$\begin{aligned} c_1 &= \frac{1}{\mathrm{e}} = 0.36787944117144232160, \\ c_2 &= -\frac{1}{2}\frac{1}{\mathrm{e}^3} = -0.02489353418393197149, \\ c_3 &= \frac{1}{8}\frac{1}{\mathrm{e}^5} - \frac{1}{3}\frac{1}{\mathrm{e}^4} = -0.00526296958802571004, \\ c_4 &= -\frac{1}{48}\frac{1}{\mathrm{e}^7} + \frac{1}{\mathrm{e}^6} - \frac{1}{4}\frac{1}{\mathrm{e}^5} = 0.00077526788594593923, \\ c_5 &= \frac{1}{384}\frac{1}{\mathrm{e}^9} - \frac{4}{3}\frac{1}{\mathrm{e}^8} + \frac{49}{72}\frac{1}{\mathrm{e}^7} - \frac{1}{5}\frac{1}{\mathrm{e}^6} = 0.00032212622183609932. \end{aligned} \tag{151}$$

Remark 2. The computations of this section are also valid for the case $k = 2$ ($p = 1$), corresponding to the case of classical rooted trees (*Cayley trees*) defined

by the functional equation $A = XE(A)$. In this case, the growth constant $\beta = \beta_1$, in (114), is known as the Otter constant (see [17]). It is interesting to note that this constant takes the explicit form $\beta = \frac{1}{\xi_1}$, with

$$\xi_1 = \sum_{n \geq 1} c_n. \tag{152}$$

Notice also that, when $k = 3$, we recover the asymptotic results of Fowler et al. in [5, 6].

The Electronic Journal of Combinatorics

Abstract for R12 of Volume 3(2), 1996

Abstract for Gilbert Labelle and Pierre Leroux, An Extension of the Exponential Formula in Enumerative Combinatorics

Let α be a formal variable and $F_{\mathfrak{w}}$ be a weighted species of structures (class of structures closed under weight-preserving isomorphisms) of the form $F_{\mathfrak{w}} = E(F^{\mathrm{c}}_{\mathfrak{w}})$, where E and $F^{\mathrm{c}}_{\mathfrak{w}}$ respectively denote the species of *sets* and of *connected* $F_{\mathfrak{w}}$*-structures*. Multiplying by α the weight of each $F^{\mathrm{c}}_{\mathfrak{w}}$-structure yields the species $F_{\mathfrak{w}(\alpha)} = E(F^{\mathrm{c}}_{\alpha\mathfrak{w}})$. We introduce a "universal" virtual weighted species, $\Lambda^{(\alpha)}$, such that $F_{\mathfrak{w}(\alpha)} = \Lambda^{(\alpha)} \circ F^{+}_{\mathfrak{w}}$, where $F^{+}_{\mathfrak{w}}$ denotes the species of non-empty $F_{\mathfrak{w}}$-structures. Using general properties of $\Lambda^{(\alpha)}$, we compute the various enumerative power series $G(x)$, $\widetilde{G}(x)$, $\overline{G}(x)$, $G(x;q)$, $\widetilde{G}(x;q)$, $Z_G(x_1, x_2, x_3, \ldots)$, $\Gamma_G(x_1, x_2, x_3, \ldots)$, for $G = F_{\mathfrak{w}(\alpha)}$, in terms of $F_{\mathfrak{w}}$. Special instances of our formulas include the exponential formula, $F_{\mathfrak{w}(\alpha)}(x) = \exp(\alpha F_{\mathfrak{w}}(x)) = (F_{\mathfrak{w}}(x))^{\alpha}$, cyclotomic identities, and their q-analogues. The virtual weighted species, $\Lambda^{(\alpha)}$, is, in fact, a new combinatorial lifting of the function $(1+x)^{\alpha}$.

Stirling Numbers Interpolation using Permutations with Forbidden Subsequences

G. Labelle *, P. Leroux *, E. Pergola †, R. Pinzani †

September 1, 2000

Abstract. We present a family of number sequences which interpolates between the sequences B_n, of Bell numbers, and $n!$. It is defined in terms of permutations with forbidden patterns or subsequences. The introduction, as a parameter, of the number m of right–to–left minima yields an interpolation between Stirling numbers of the second kind $S(n,m)$ and of the first kind (signless) $c(n,m)$. Moreover, q-counting the restricted permutations by special inversions gives an interpolation between variants of the usual q-analogues of these numbers.

Résumé. Nous présentons une famille de suites de nombres qui interpole entre la suite B_n des nombres de Bell et la suite $n!$. Cette famille est définie en termes de permutations à motifs interdits. L'introduction comme paramètre du nombre d'éléments saillants minimums de gauche à droite donne une interpolation plus fine entre les nombres de Stirling de deuxième espèce $S(n,m)$ et de première espèce (sans signe) $c(n,m)$. De plus, un q-comptage de ces permutations selon des inversions particulières donne une interpolation entre des variantes des q-analogues habituels de ces nombres.

1 Introduction

The study of Stirling numbers and their q–analogues has a long history; in the last twenty years mathematicians have been interested in models giving combinatorial interpretations of classical relations involving the q–analogues of Stirling numbers. In 1961, Gould [13] gives expressions in terms of symmetric functions. A combinatorial treatment of q–Stirling numbers of second kind, involving finite dimensional vector spaces over a field $\mathcal{K}_q$ of cardinality q and inversions of restricted growth functions corresponding to set partitions is due

*LaCIM, Département de mathématiques, Université du Québec à Montréal, C.P. 8888, Succ. Centre–Ville, Montréal (Québec), Canada, H3C 3P8. e–mail: labelle.gilbert@uqam.ca, leroux.pierre@uqam.ca

to Milne [18, 19, 20]. In [11], Garsia and Remmel introduce particular rook placements in Ferrers boards. Later, Leroux [15] introduces 0–1 tableaux to prove the conjecture of Butler [8] concerning the q–log concavity for q–Stirling numbers, and De Médicis and Leroux [16, 17] study and generalize q–Stirling numbers of both kinds, using this interpretation. See also Wachs and White [25].

On the other hand, the study of permutations with forbidden subsequences has made meaningful progresses in the last thirty years: Simion and Schmidt have showed that the n–th Catalan number is the common value for the number of permutations with a single forbidden subsequence of length three [23]; Bóna in [5, 6] and Gessel in [12] provide some other results for permutations avoiding a single forbidden subsequence of length four. Concerning permutations avoiding a single subsequence of length greater than four, Regev [21] obtained an interesting result, that is: the number of permutations of length n avoiding the pattern $1\ldots(k+1)$ is asymptotically equal to $c(k-1)^{2n}n^{(2k-k^2)/2}$, where c is a constant. Pell, Fibonacci, Motzkin and Schröder numbers are sequences which count permutations avoiding more than one forbidden subsequence. We refer to Guibert [14] and West [26] for an exhaustive survey on the results and on the tools used to study permutations with forbidden subsequences and to Bóna [7] for recent results.

In this paper we put these two research areas together. In particular, we give combinatorial interpretations of q–analogues of Stirling numbers of both kinds in terms of permutations with forbidden subsequences. More precisely, in the spirit of two previous works of Barcucci, Del Lungo, Pergola, Pinzani [3, 4], we introduce an infinite family $\left\{\mathcal{B}_n^j\right\}_{j\geq 1}$ of permutations with forbidden subsequences whose cardinalities interpolate between the Bell number B_n and $n!$. By considering right–to–left minima and j^{th}-kind inversions (see the definition in Section 2), this specializes to an interpolation between Stirling numbers of the second kind $S(n,m)$ and of the first kind (signless) $c(n,m)$ and their q–analogues. In fact, for j large $\mathcal{B}_n^j$ is the set of all permutations. For $j=1$, there is a simple bijection between $\mathcal{B}_n^1$ and set partitions of $\{1,2,\ldots,n\}$ for which right–to–left minima of permutations correspond to blocks, and first-kind inversions, essentially to usual inversions in partitions.

In Section 2, we recall the concept of permutation with forbidden subsequences and generalize some classical definitions about permutations. We also recall the classical definitions of the q-analogues $S_q[n,m]$ and $c_q[n,m]$ of the Stirling numbers. In Section 3, we introduce a class of permutations with one forbidden subsequence, counted by the Bell numbers and we call them Bell permutations for this reason. This is the case $j=1$. These permutations avoid the subsequence $4\bar{1}32$; this is a natural extension of the forbidden pattern which consists of three decreasing elements in a permutation [23]. A bijection with set partitions is established and also the connection with the classical q–analogue. In Section 4, the forbidden subsequence characterizing Bell permutations is generalized, and we obtain an infinite family B^j of classes of permutations. The n–th term of each number sequence associated to the class lies between the

n–th Bell number and $n!$. An evaluation of Bell polynomials is obtained in the particular case $j = 2$, and the q–analogue is given a combinatorial interpretation. The permutations of length n counted by the n–th term of this sequence are in bijection with bicolored set partition on a $(n-1)$–element set, and both a recursive and a direct bijection is presented in Section 5. Section 6 contains enumerative results on the classes of permutations $\mathcal{B}^j = \bigcup_{n\geq 1} \mathcal{B}_n^j$, $j \geq 1$, and a combinatorial interpretation of polynomials $a_{n,m}^{(k,j)}(q)$ such that $a_{n,m}^{(m+1,1)}(q) = q^{n-m} S_q[n,m]$ and $a_{n,m}^{(n+1,\infty)}(q) = q^{n-m} c_q[n,m]$.

2 Notations and Definitions

In this section we recall the concepts of permutations with forbidden subsequences and generalize some classical definitions about permutations. In particular, the concept of j^{th}–kind inversion is introduced. We also recall the classical q-analogues of Stirling numbers and the concept of generating tree.

A permutation $\pi = \pi(1)\pi(2)\ldots\pi(n)$ on $[n] = \{1, 2, \ldots, n\}$ is a bijection from $[n]$ to $[n]$. Let S_n be the set of permutations on $[n]$. A permutation $\pi \in S_n$ *contains a subsequence of type* $\tau \in S_k$ if and only if a sequence of indices $1 \leq i_1 < i_2 < \ldots < i_k \leq n$ exists such that $\pi(i_1)\pi(i_2)\ldots\pi(i_k)$ is ordered as τ. We denote the set of permutations of S_n *avoiding* subsequences of type τ by $S_n(\tau)$. The concept of permutation avoiding a subsequence of type τ can be extended to any totally ordered set ℓ, for example, for ℓ an l–element subset of $[n]$, we can use the notation $S_\ell(\tau)$ in this case.

Example 2.1 The permutation 58132674 belongs to $S_8(4321)$ because none of its subsequences of length 4 are of type 4321. This permutation does not belong to $S_8(4132)$ because there exist some subsequences of type 4132 like, for example, $\pi(2)\pi(3)\pi(6)\pi(8) = 8164$.

A *barred* subsequence $\bar{\tau}$ on $[k]$ is a permutation of S_k having a bar over one of its elements. Let τ be a permutation on $[k]$ identical to $\bar{\tau}$ but unbarred and $\hat{\tau}$ be the permutation on $[k-1]$ made up of the $(k-1)$ unbarred elements of $\bar{\tau}$, rewritten to be a permutation on $[k-1]$. A permutation $\pi \in S_n$ *contains a type* $\bar{\tau}$ *subsequence* if π contains a type $\hat{\tau}$ subsequence that, in turn, does not expand to a type τ subsequence. We denote the set of permutations of S_n not containing type $\bar{\tau}$ subsequences by $S_n(\bar{\tau})$ and we set $S(\bar{\tau}) = \bigcup_{n\geq 1} S_n(\bar{\tau})$ In words, $\pi \in S_n(\bar{\tau})$ if and only if any subsequence of type $\hat{\tau}$ of π can be extended to a subsequence of type τ.

Example 2.2 If $\bar{\tau} = 4\bar{1}32$ then $\tau = 4132$ and $\hat{\tau} = 321$. The permutation $\pi = 58132674$ belongs to $S_8(\bar{\tau})$ because all its subsequences of type $\hat{\tau}$:
$\pi(1)\pi(4)\pi(5) = 532$, $\pi(2)\pi(4)\pi 5) = 832$, $\pi(2)\pi(6)\pi(8) = 864$ and
$\pi(2)\pi(7)\pi(8) = 874$ are subsequences of a sequence of type τ, because
$\pi(1)\pi(3)\pi(4)\pi(5) = 5132$, $\pi(2)\pi(3)\pi(4)\pi(5) = 8132$,
$\pi(2)\pi(4)\pi(6)\pi(8) = 8364$ and $\pi(2)\pi(5)\pi(7)\pi(8) = 8274$ are of type τ.

If we have the set $\tau_1 \in S_{k_1}, \ldots, \tau_p \in S_{k_p}$ of barred or unbarred permutations, we denote the set $S_n(\tau_1) \cap \ldots \cap S_n(\tau_p)$ by $S_n(\tau_1, \ldots, \tau_p)$ or by $S_n(F)$, if $F = \{\tau_1, \ldots, \tau_p\}$. For $\pi \in S_n$, we call *insertion sites* the $n+1$ positions lying on the left of $\pi(i)$, $1 \leq i \leq n$, and on the right of $\pi(n)$; the site i is the one on the left of $\pi(i)$ and the site $(n+1)$ is on the right of $\pi(n)$. The site i of $\pi \in S_n(F)$ is called *active* if the insertion of $n+1$ into the position between $\pi(i-1)$ and $\pi(i)$ gives a permutation belonging to the set $S_{n+1}(F)$; otherwise it is said to be *inactive*.

Example 2.3 The permutation $\pi = 58132674 \in S_8(4\bar{1}32)$ has 4 active sites that is the sites: $3, 5, 8$ and 9. Indeed, the permutations: $589132674, 581392674$, 581326794 and 581326749 belong to $S_9(4\bar{1}32)$, while the remaining sites are inactive, for example 581326974 has the subsequence 974 of type 321 but it is not a subsequence of a sequence of type 4132.

Let π be a permutation on $[n]$. The element $\pi(i)$, $1 \leq i \leq n$, is a *right–to–left minimum* if $\pi(i) < \pi(t)$, for all $t \in [i+1, n]$. This means that an index i_1, $i+1 \leq i_1 \leq n$, such that $\pi(i) > \pi(i_1)$ does not exist. We propose to generalize the concept of right–to–left minimum as follows: let π be a permutation on $[n]$; the element $\pi(i)$, $1 \leq i \leq n$, is a *j–th kind right–to–left minimum* if and only if a sequence of indices of length j: $i_1, ..., i_j$, $i+1 \leq i_1 < ... < i_j \leq n$, such that $\pi(i) > \pi(i_l)$, $1 \leq l \leq j$ does not exist. This implies that the j rightmost elements of π are trivially j–th kind right–to–left minima. Of course a right–to–left minimum is the same as a first kind right–to–left minimum while each element of the permutation is an ∞–kind right–to–left minimum. Hence the number of ∞–kind right–to–left minima is the length of the permutation.

Example 2.4 The permutation $\pi = 58132764$ has:

- 3 right–to–left minima: $\pi(3) = 1$, $\pi(5) = 2$ and $\pi(8) = 4$;
- 5 second kind right–to–left minima: $\pi(3) = 1, \pi(4) = 3, \pi(5) = 2, \pi(7) = 6$ and $\pi(8) = 4$;
- 6 third kind right–to–left minima: $\pi(3) = 1$, $\pi(4) = 3$ $\pi(5) = 2$, $\pi(6) = 7$, $\pi(7) = 6$ and $\pi(8) = 4$;
- 8 ∞–kind right–to–left minima.

Let π be a permutation on $[n]$. An *inversion* is a pair of indices, (s, t), $1 \leq s < t \leq n$, such that $\pi(s) > \pi(t)$; furthermore, we say that it is a *j–th kind inversion* if $\pi(t)$ is a j–th kind right–to–left minimum. Following this definition the classical concept of an inversion becomes an ∞–kind inversion, while the number of inversions with respect to the right–to–left minima are first kind inversions. We use the notation $\mathrm{inv}_j(\pi)$ to denote the number of j–th kind inversions of π.

Example 2.5 The permutation $\pi = 58132764$ of Example 2.4 has:

- 9 first kind inversions: $(1,3)$,$(1,5)$,$(1,8)$,$(2,3)$,$(2,5)$,$(2,8)$,$(4,5)$,$(6,8)$,$(7,8)$;
- 12 second kind inversions: $(1,3)$,$(1,4)$,$(1,5)$,$(1,8)$,$(2,3)$,$(2,4)$,$(2,5)$,$(2,7)$, $(2,8)$,$(4,5)$,$(6,8)$,$(7,8)$;
- 13 third kind inversions: $(1,3)$,$(1,4)$,$(1,5)$,$(1,8)$,$(2,3)$,$(2,4)$,$(2,5)$,$(2,6)$, $(2,7)$,$(2,8)$,$(4,5)$,$(6,8)$,$(7,8)$;
- 13 ∞–kind inversions: $(1,3)$,$(1,4)$,$(1,5)$,$(1,8)$,$(2,3)$,$(2,4)$,$(2,5)$,$(2,6)$, $(2,7)$,$(2,8)$,$(4,5)$,$(6,8)$,$(7,8)$.

Hence we have $\mathrm{inv}_1(\pi) = 9$, $\mathrm{inv}_2(\pi) = 12$, $\mathrm{inv}_3(\pi) = 13$, $\mathrm{inv}_\infty(\pi) = 13$.

The classical q-analogues of the Stirling numbers of the first kind (signless) $c_q[n,m]$ and of the second kind $S_q[n,m]$, as defined by Gould [13] in 1961, are characterized by the generating functions

$$\sum_{m=0}^{n} c_q[n,m] z^{n-m} y^m = \prod_{i=0}^{n-1} (y + [i]_q z), \tag{2.1}$$

$$\sum_{n=m}^{\infty} S_q[n,m] z^{n-m} = \prod_{i=1}^{m} \frac{1}{1-[i]_q z}, \tag{2.2}$$

where $[i]_q := 1 + q + \ldots + q^{i-1} = (q^i - 1)/(q-1)$ denotes the usual q-analogues of i. They satisfy the recurrences

$$c_q[n+1,m] = c_q[n,m-1] + [n]_q c_q[n,m], \tag{2.3}$$

$$S_q[n+1,m] = S_q[n,m-1] + [m]_q S_q[n,m]. \tag{2.4}$$

A combinatorial interpretation of the polynomial $S_q[n,m]$ as the generating function of the partitions of an n-element set into m blocks, where the variable q marks the "inversions", has been given by Milne [19, formula (4.9)], Leroux [15, formula (2.1)] and Wachs and White [25, the statistics **1b**]. The definition is as follows. Let p be a partition of the set $[n] = \{1, 2, \ldots, n\}$, written in standard form (see example 3.1). An *inversion* of p is a pair (α, β) of elements of $[n]$ such that $\alpha > \beta$, α appears to the left of β, and β is a block minimum. Let $\mathrm{inv}(p)$ denote the number of inversions of p. Then we have:

$$S_q[n,m] = \sum_{p \in \mathrm{Par}(n,m)} q^{\mathrm{inv}(p)},$$

where $\mathrm{Par}(n,m)$ denotes the set of partitions of $[n]$ into m blocks.

A combinatorial interpretation of the polynomials $c_q[n,m]$ is given by Leroux in [15].

The concept of generating tree was introduced by Chung, Graham, Hoggatt and Kleiman in [9] for the study of Baxter permutations. Later West applied it

to the study of various permutations with forbidden subsequences [27]. Generating trees and succession rules can be used in combinatorics to deduce enumerative results about various combinatorial objects [1], permitting also their random generation [2].

The *generating trees* used in this paper to study permutations are rooted trees, labelled in $\mathbb{N}$, having the property that the labels of the set of children of each node x can be determined from the label of x itself. More precisely, such a generating tree is specified by a recursive definition consisting of:

1. the basis: the label of the root,
2. the inductive step: a set of succession rules that yields a multiset of labelled children which depends solely on the label of the parent. Moreover, the number of labelled children produced by a parent with label k, is exactly k; so the label size gives the degree of the node itself.

A succession rule can be used to describe the growth of the objects to which it is related and also to obtain the number sequence counting the objects themselves. The introduction of a parameter, say j, in a succession rule allows us to obtain a denumerable family of number sequences. In [3] the introduction of such a parameter into the classical succession rule for the Motzkin numbers allowed the authors to define number sequences such that the n–th number of each of them is lying between the n–th Motzkin and Catalan numbers. Moreover, the permutations enumerated by each number sequence are identified: they are permutations with two forbidden subsequences; the first, of length three, is fixed and the second has a length which increases with j. In [4] the introduction of the parameter j in the classical succession rule for the Catalan numbers defines number sequences such that the n–th term interpolates between the n–th Catalan number and $n!$. The objects that each sequence counts are permutations with $j!$ forbidden subsequences of length $(j+2)$.

3 Bell permutations and set partitions

The Stirling numbers of the second kind, denoted by $S(n,m)$, for $n \geq m \geq 0$, count the ways of partitioning a set of n objects into m nonempty subsets, called blocks. The number of partitions of an n–element set is given by the sum over m, $0 \leq m \leq n$, of $S(n,m)$; this defines the n–th Bell number, denoted by B_n [22]. For example, there are 7 ways of partitioning a 4–element set into two blocks:

$$\{1,2,3\}\ \{4\};\ \{1,2,4\}\ \{3\};\ \{1,3,4\}\ \{2\};\ \{1,2\}\ \{3,4\};\ \{1,3\}\ \{2,4\};\ \{1,4\}\ \{2,3\};\ \{1\}\ \{2,3,4\},$$

and the total number of partitions is

$$B_4 = \sum_{m=0}^{4} S(4,m) = 0+1+7+6+1 = 15. \text{ Note that } S(0,0) = B(0) = 1.$$

The standard representation of a given set partition consists in using the increasing order within each block and, in listing the blocks according to the increasing order of their minimum elements. We consider a new representation of the partition by moving the minimum element from the first to the last position in each block and then erasing the curly braces. The sequence of elements thus obtained is a permutation such that its (first kind) right–to–left minima are exactly the minimum elements of the blocks in the partition.

Example 3.1 Let us consider the following partition of an 8–element set into three blocks, written in standard form:

$$p = \{1,5,8\}\ \{2,3\}\ \{4,6,7\}.$$

The new representation described above is the permutation:

$$\pi(p) = 5\ 8\ \underline{1}\ 3\ \underline{2}\ 6\ 7\ \underline{4}$$

which has exactly three (underlined) right–to–left minima.

We observe that the permutation $\pi = \pi(p)$ obtained from a partition p of an n–element set contains a subsequence of type $\hat{\tau} = 321$ if and only if it is a subsequence of some sequence of type $\tau = 4132$. In other words, three indices i_1, i_2, i_3, $i_1 < i_2 < i_3$, such that $\pi(i_1) > \pi(i_2) > \pi(i_3)$ can be found in π if and only if it exists an index j, $i_1 < j < i_2 < i_3$, such that $\pi(i_1)\,\pi(j)\,\pi(i_2)\,\pi(i_3)$ is of type 4132. Such a condition is described by the forbidden subsequence $4\bar{1}32$. Let $\pi(i_1) < \cdots < \pi(i_m)$ be the m right–to–left minima of π; then $\pi(i_l)$, $1 \le l \le m$, is the first element of the l^{th} block in the corresponding partition, while the elements to the left of $\pi(i_l)$ and to the right of $\pi(i_{l-1})$ (if $l > 1$) are all the elements belonging to the l^{th} block of the partition. Permutations in $S_n(4\bar{1}32)$ with m right–to–left minima are counted by the Stirling numbers of the second kind, and $S_n(4\bar{1}32)$ is enumerated by the Bell numbers, B_n. Moreover, the first-kind inversions of π, i.e. the inversions with respect to the right–to–left minima, are essentially the same as the classical inversions of the original partition p. The difference here is that each non minimum element contributes one more to the inversions since in $\pi(p)$ it is written to the left of the minimum element of its block. Hence we have

$$\mathrm{inv}_1(\pi(p)) = \mathrm{inv}(p) + n - m, \tag{3.1}$$

if the partition has m blocks, and we see that the q-counting of permutations in $S_n(4\bar{1}32)$ with m right–to–left minima, according to the number of first-kind inversions, is given by $q^{n-m}S_q[n,m]$.

Proposition 3.1 *We have*

$$\sum_{\pi \in S_n(4\bar{1}32)} q^{\mathrm{inv}_1(\pi)} \quad = \quad q^{n-m}S_q[n,m]. \tag{3.2}$$

The first construction we take into consideration for the class $S(4\bar{1}32)$ is a recursive construction which allows to obtain $S_{n+1}(4\bar{1}32)$, starting with $S_n(4\bar{1}32)$. It uses the concept of active site of a permutation introduced in Section 2. Let $\pi \in S_n(4\bar{1}32)$ and $i_1 < i_2 < ... < i_{m-2} < n$ be the indices of its $(m-1)$ right–to–left minima, namely $\pi(i_1), \pi(i_2), ..., \pi(i_{m-2}), \pi(n)$. The active sites of π are the sites on the immediate left of each right–to–left minimum and on the right of the last element, that is, sites of π are i_1, i_2, ..., i_{m-2}, n and $n+1$. Indeed, the insertion of $n+1$ into the site $(n+1)$ does not cause any occurrence of the forbidden subsequence 321; by inserting $n+1$ into the site l, $l = i_1, ..., i_{m-2}, n$ we can obtain the forbidden subsequences 321 if and only if there exist two indices t_1, t_2 such that $l < t_1 < t_2$ and $n+1 > \pi(t_1) > \pi(t_2)$, but in this case $n+1\pi(l)\pi(t_1)\pi(t_2)$ is of type 4132. Each other site is inactive: take a site lying on the left of $\pi(i)$ that is not a right–to–left minimum. This means that there exists $i_1 > i :\ \pi(i) > \pi(i_1)$, and the insertion of $n+1$ on the left of $\pi(i)$ gives $n+1\pi(i)\pi(i_1)$, that is a decreasing sequence of length three, with $n+1$ and $\pi(i)$ adjacent elements and we get a forbidden subsequence 321. Observe that the insertion of $n+1$ into the site $n+1$ increases the number of right–to–left minima of π while each other insertion does not change this number in the permutation. The above arguments prove the following proposition:

Proposition 3.2 *Let $\pi \in S_n(4\bar{1}32)$ be a permutation with $k \geq 2$ active sites, that is the sites i_1, i_2, ..., i_{k-2}, n and $(n+1)$. Then the number of active sites is still k in the permutation obtained by inserting $n+1$ into any active site different from the rightmost one; the permutation obtained from π by inserting $n+1$ into the site $n+1$ has $(k+1)$ active sites: i_1, i_2, ..., i_{k-2}, n, $(n+1)$ and $(n+2)$.*

If we classify the permutations of $S_n(4\bar{1}32)$, $n \geq 1$, according to their number of active sites then we can synthetically describe this recursive construction by the succession rule:

$$\begin{cases} basis: & (2) \\ inductive\ \ step: & (k) \rightarrow (k)^{k-1}(k+1), \end{cases} \tag{3.3}$$

since the only permutation of $S_1(4\bar{1}32)$, that is 1, has two active sites.

The expansion of this succession rule gives the generating tree of Fig. 1, where the active sites are denoted by "_". Consequently if $p_{n,k} = |\{\pi \in S_n(4\bar{1}32) :\ \pi \text{ has } k \text{ active sites}\}|$ then

$$\begin{cases} p_{1,2} &= 1, \\ p_{n+1,k} &= p_{n,k-1} + (k-1)p_{n,k}, \quad 2 \leq k \leq n+2, \end{cases} \tag{3.4}$$

which is the recursive relation of the Stirling numbers of the second kind (see Comtet [10]), replacing $p_{n,k}$ by $S(n, k-1)$. Moreover the number of new first-kind inversions which are created by inserting $n+1$ into the k active sites $i_1, i_2, \ldots, i_{k-2}, n$, and $n+1$ is respectively $k-1, k-2, \ldots, 2, 1$, and 0. Hence

the polynomial $p_{n,k}(q)$ which q-counts these permutations according to first-kind inversions satisfies the recurrence

$$p_{n,k}(q) \quad = \quad p_{n,k-1}(q) + q[k-1]_q p_{n,k}(q). \tag{3.5}$$

This is coherent with our previous observation that $p_{n,m+1}(q) = q^{n-m} S_q[n,m]$ using (2.4).

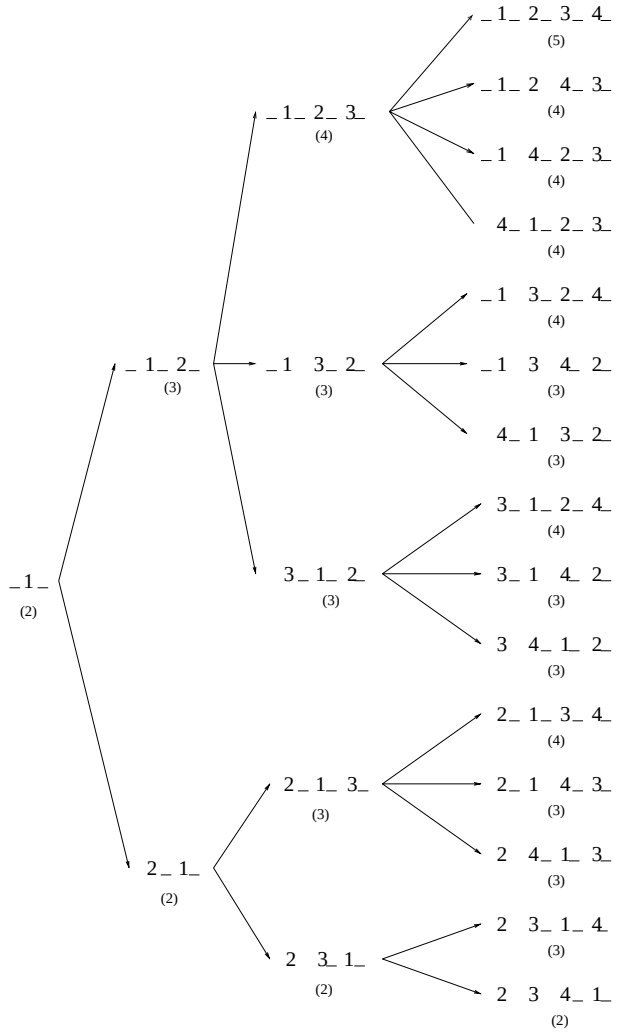

Figure 1: The generating tree for $4\bar{1}32$–avoiding permutations.

Proposition 3.3 *Permutations in $S_n(4\bar{1}32)$ are counted by the n–th Bell number, $S(n,m)$ counts the number of permutations in $S_n(4\bar{1}32)$ with m right–to–*

left minima or equivalently with $(m+1)$ active sites, and $q^{n-m}S_q[n,m]$ q-counts these permutations according to first-kind inversions.

Definition 3.4 *Permutations in $S_n(4\bar{1}32)$ are called Bell permutations.*

Another approach in order to generate $S(4\bar{1}32)$ permutations, is to construct $S_{n+1}(4\bar{1}32)$, using $S_1(4\bar{1}32), S_2(4\bar{1}32), ..., S_n(4\bar{1}32)$. Indeed, the permutations in $S_{n+1}(4\bar{1}32)$ with m right–to–left minima can be obtained in the following way. For each l such that $0 \leq l \leq n$:

- extract an l–element subset ℓ from the set $\{2, ..., n+1\}$,
- construct the permutations in $S_\ell(4\bar{1}32)$ with $(m-1)$ right–to–left minima,
- add the element 1 on its left,
- place on the left of 1 the remaining $(n-l)$ elements in an increasing order.

Here the notation $S_\ell(\tau)$ refers to the permutations of the totally ordered set ℓ which avoid the pattern τ. The principle of this approach is represented by Fig. 2.

This implies that:

$$p_{n+1,k+1} = \sum_{l=m}^{n} \binom{n}{l} p_{l,k}\,. \tag{3.6}$$

As $p_{n,m+1} = S(n,m)$ we obtain a combinatorial interpretation of the well known relation involving the second kind Stirling numbers (see Comtet, [10]), by means of Bell permutations. There is a q-analogue of (3.6) due to Mercier and Sundaram (see [16, formula (2.12)]), whose combinatorial proof uses the concept of non-inversions of a partition p. We can define the concept of (first-kind) non-inversions for permutations as follows: a *non-inversion* of π is a pair (i,j), with $i<j$ such that $\pi(i)$ is a right–to–left minimum and $\pi(i) < \pi(j)$. For $\pi = \pi(p)$, this corresponds to the statistics **ls** of [6]. Let us denote by $\overline{S}_q[n,m]$ the polynomial which q-counts the permutations in $S_n(4\bar{1}32)$ having m right–to–left minima, according to non-inversions. Our first recursive construction of permutations in $S_{n+1}(4\bar{1}32)$, which inserts the element $n+1$ in permutations of $S_n(4\bar{1}32)$ shows that

$$\overline{S}_q[n+1,m] \quad = \quad q^{m-1}\overline{S}_q[n,m-1] + [m]_q\overline{S}_q[n,m]. \tag{3.7}$$

This implies that in fact

$$\overline{S}_q[n,m] \quad = \quad q^{\binom{m}{2}}S_q[n,m]. \tag{3.8}$$

The q-analogue of (3.6) is then given by

$$\overline{S}_q[n+1,m] \quad = \quad \sum_{l=m-1}^{n} \binom{n}{l} q^l \overline{S}_q[l,m-1], \tag{3.9}$$

since, in the second construction of $S_{n+1}(4\bar{1}32)$ described above, and summarized by Figure 2, the only new non-inversions that are created come from the l elements which are to the right of 1.

By summing over m, we obtain the q-analogue $B_n(q)$ of the Bell numbers as defined by Milne in [15],

$$B_n(q) \quad = \quad \sum_{m=0}^{n} \overline{S}_q[n,m] \tag{3.10}$$

with the combinatorial interpretation

$$B_n(q) \quad = \quad \sum_{\pi \in S_n(4\bar{1}32)} q^{\mathrm{nin}(\pi)} \tag{3.11}$$

where $\mathrm{nin}(\pi)$ denotes the number of non-inversions of π. Moreover, the second construction of the permutations in $S_n(4\bar{1}32)$, giving rise to (3.9) also yields the reccurence formula

$$B_{n+1}(q) \quad = \quad \sum_{l=0}^{n} \binom{n}{l} q^l B_l(q), \tag{3.12}$$

which is due to Milne [18] and extends the classical recursion for Bell numbers (see [10]).

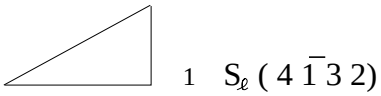

Figure 2: The second construction for $S(4\bar{1}32)$ permutations.

4 Generalized Bell permutations

In this section we introduce a parameter j in the succession rule (3.3) giving the Bell numbers. Each value of j yields a number sequence such that the n–th term lies between B_n and $n!$. We are interested in characterizing the permutations enumerated by these number sequences.

Let us carefully examine the succession rule (3.3): the "exponents" of the terms on the right hand side of the inductive step are $k-1$ for the label (k) and 1 for the label $(k+1)$. We can make these "exponents" depend on a parameter j, thus giving the "exponent" $k-j$ to the label (k) and j to the label $(k+1)$; moreover if $k \leq j$ then only the label $(k+1)$ is obtained exactly k times. The exact form of the succession rule we obtain is

$$\begin{cases} basis: & (2) & & \\ inductive\ \ step: & (k) \to (k+1)^k, & k \le j \\ inductive\ \ step: & (k) \to (k)^{k-j}(k+1)^j, & k > j. \end{cases} \tag{4.1}$$

It is easy to verify that if $j = 1$, then the succession rule (4.1) reduces to (3.3).

In (4.1) the "exponent" of a label means the number of times the label must be repeated and the number of terms on the right hand side of the inductive step is exactly k. The idea is to perform (4.1) on permutations and try to characterize the class we obtain. The first step is to give an interpretation of (4.1) in terms of active sites in a permutation; we have to decide how the active sites are modified when a new element is added into a permutation with a fixed number of active sites. The second step is to describe the resulting permutations in terms of forbidden subsequences. We refer to the first active site as the leftmost active site in the permutation and so on, and we make the following choices:

- if a new element is inserted in the l^{th} active site, $l \le k - j$, then the site on the left of the inserted element is inactive and the number of active sites do not change in the new permutation (see Fig 3, (case $\bullet$)),
- if a new element is inserted in the l^{th} active site, $l \ge k - j + 1$, then the site on the left of the inserted element is also active and the number of active sites grows by one (see Fig. 3, (case $\circ$)).

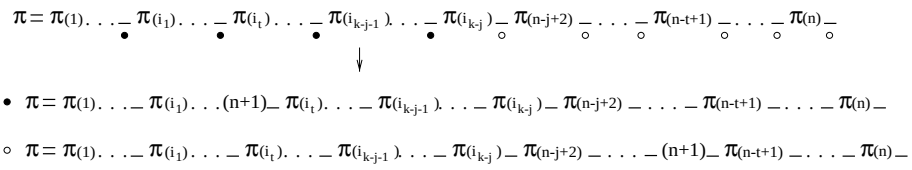

Figure 3: The active sites in the permutations obtained from a permutation of length n with $(k-1)$ right–to–left minima of j–th kind, by inserting $n+1$.

The permutations we obtain avoid the subsequences $(j+2)(j+1)\sigma$ where $\sigma \in S_j$ and the elements corresponding to $(j+2)$ and $(j+1)$ are consecutive. In terms of permutations with forbidden subsequences such a condition is given by the union of j sets of permutations with forbidden subsequences: $\bigcup_{i=1}^{j} S\left(\bar{F}_i^j\right)$ where $\bar{F}_i^j$ is a set of barred subsequences $\bar{\tau} = (j+3)\bar{i}(j+2)\sigma_i$ with σ_i a permutation on the set $\{(j+1), ..., (i+1), (i-1), ..., 1\}$; so $\left|\bar{F}_i^j\right| = j!$ and $|\bar{\tau}| = j+3$.

Example 4.1 Let $j = 2$ then $1 \le i \le 2$. The set $\bar{F}_2^2$ obtained for $i = 2$ is $\{5\bar{2}431, 5\bar{2}413\}$.

Let us note that in the union i can assume all values between 1 and j. This means that we are not interested in the value of the element lying between $(j+3)$ and $(j+2)$, but at least one element must exist between $(j+3)$ and $(j+2)$. Such a condition avoids subpatterns of two adjacent decreasing elements having at least j smaller elements on their right. Moreover, i cannot be equal to $(j+1)$ because the subsequence $(j+3)(j+1)\sigma$ (σ being a permutation of length j) is of the forbidden type. Let $\mathcal{B}^j$ be the class of permutations defined by $\mathcal{B}^j = \bigcup_{n\geq 1} \mathcal{B}_n^j$ where $\mathcal{B}_n^j = \bigcup_{i=1}^{j} S_n(\bar{F}_i^j)$.

Proposition 4.1 *For $j \geq 1$, let π be a permutation in $\mathcal{B}_n^j$ having $k \geq 2$ active sites: $i_1, \ldots, i_{k-j}, n-j+2, n-j+1, \ldots, n+1$. Then the number of active sites does not change in the permutation obtained by inserting $n+1$ into the site i_t, $t = 1, ..., k-j$; the permutation obtained from π by inserting $n+1$ into the site $(n+1-t)$, $0 \leq t \leq j-1$, has $(k+1)$ active sites: $i_1, \ldots, i_{k-j}, n-j+2, \ldots, n+1, n+2$.*

Corollary 4.2 *The class $\mathcal{B}^j$ has a recursive construction described by the succession rule* (4.1).

5 Bicolored set partitions and permutations

In Section 3 we illustrated the case $j = 1$, that is we showed that $4\bar{1}32$–avoiding permutations are counted by the Bell numbers and gave a bijection with set partitions. We also presented q-analogues. For $j = 2$ we now show that the number of $\mathcal{B}^2$-permutations, that is of $(5\bar{1}432, 5\bar{1}423)$ or $(5\bar{2}431, 5\bar{2}413)$–avoiding permutations are values of Bell polynomials whose n–th term is defined by $\sum_{m\geq 0} 2^m S(n-1, m)$ (see [24], sequence M1662). These numbers count bicolored set partitions (that is to say each block can be red or black) and there is a bijection between these two classes of structures. This correspondence can be easily obtained by applying the succession rules:

$$\begin{cases} basis: & (2) \\ inductive\ \ step: & (k) \rightarrow (k)^{k-2}(k+1)^2, \quad k \geq 2, \end{cases} \tag{5.1}$$

to the bicolored set partitions, obtaining a recursive bijection. In bicolored set partitions the label k represents the number of blocks plus two. Given an n–element set bicolored partition with $k-2$ blocks, labeled by (k), we can add on its right the block $\{(n+1)\}$ that can be red or black and in this case the number of blocks becomes $k-1$, so the label of these new partitions is $(k+1)$; or we can insert $n+1$ into any of the blocks of the partition, the color remaining the same. This bijection is represented in Fig. 4, where the red blocks are those with the underlined elements.

Under this bijection $p \longmapsto \pi(p)$ between bicolored set partitions and $\mathcal{B}^2$-permutations, we have the following parameter correspondences:

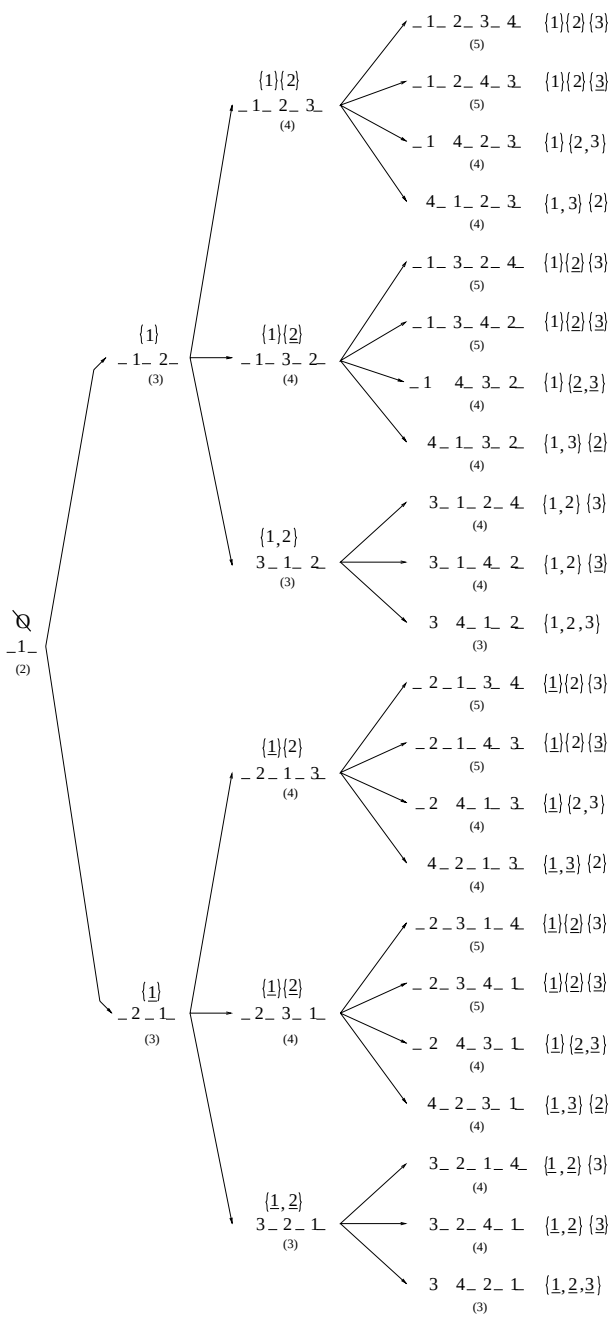

Figure 4: The first four levels of the generating tree for permutations in $\mathcal{B}^2$ and the constructive bijection with the bicolored set partitions.

bicolored set partitions	**$\mathcal{B}^2$-permutations**
cardinality of the partitioned set $+1$	n = length of the permutations
nb of black blocks	nb of right–to–left minima -1
m = nb of blocks	nb of second kind right–to–left minima -1
nb of red blocks + nb of inversions $+2(n-m-1)$	nb of second–kind inversions

In particular, if p is a colored partition of $[n-1]$ having m blocks, r of which are red, then we have

$$\mathrm{inv}_2(\pi(p)) \quad = \quad \mathrm{inv}(p) + 2(n-m-1) + r \tag{5.2}$$

and it follows that the q-counting, with respect to second-kind inversions, of the set $\mathcal{B}^2_{n,m}$ of permutations in $\mathcal{B}^2_n$ having $m+1$ second-kind left–to–right minima is given by

$$\sum_{\pi \in \mathcal{B}^2_{n,m}} q^{\mathrm{inv}_2(\pi)} \quad = \quad q^{2(n-m-1)} S_q[n-1,m](1+q)^m. \tag{5.3}$$

The standard representation for bicolored set partitions is the same as for the set partition, but, in this case, the blocks can be red or black. In order to directly obtain a permutation in $S_n(5\bar{1}432, 5\bar{1}423) \bigcup S_n(5\bar{2}431, 5\bar{2}413)$ from a $(n-1)$–element set bicolored partition we consider a new representation of the partition. It is obtained by performing the following steps:

1. shift each number in the bicolored set partition of one unit obtaining a $(n-1)$–element set bicolored partition on $\{2, \ldots, n\}$;

2. move the minimum element from the first to the last position into each block;

3. add on the left of the resulting partition the black block $\{1\}$;

4. erase the curly braces but maintain the color of numbers;

5. starting from the left to the right, place each black number which is a right–to–left minimum in the position on the left of the position occupied by the nearest black number on its right which is a right–to–left minimum; the last (right-most) black left–to–right minimum should be at the extreme right, jumping over red elements if necessary;

6. use only the black color for the numbers in the obtained sequence.

Example 5.1 The following bicolored set partition p, where the red elements are underlined,

$$p = \{1,4\}\{\underline{2},\underline{3},\underline{7}\}\{\underline{5},\underline{8},\underline{9}\}\{6,11\}\{\underline{10}\}, \tag{5.4}$$

bijectively corresponds to the permutation:

$$\pi(p) = 5\ 1\ 4\ 8\ 3\ 9\ 10\ 6\ 12\ 2\ 11\ 7. \tag{5.5}$$

As a matter of fact, this is the final result obtained by performing the above described 6 steps on (5.4) as follows:

1. $\{2,5\}\{\underline{3},\underline{4},\underline{8}\}\{\underline{6},\underline{9},\underline{10}\}\{7,12\}\{\underline{11}\}$;
2. $\{5,2\}\{\underline{4},\underline{8},\underline{3}\}\{\underline{9},\underline{10},\underline{6}\}\{12,7\}\{\underline{11}\}$;
3. $\{1\}\{5,2\}\{\underline{4},\underline{8},\underline{3}\}\{\underline{9},\underline{10},\underline{6}\}\{12,7\}\{\underline{11}\}$;
4. $1\ 5\ 2\ \underline{4}\ \underline{8}\ \underline{3}\ \underline{9}\ \underline{10}\ \underline{6}\ 12\ 7\ \underline{11}$;
5. $5\ 1\ \underline{4}\ \underline{8}\ \underline{3}\ \underline{9}\ \underline{10}\ \underline{6}\ 12\ 2\ \underline{11}\ 7$;
6. $5\ 1\ 4\ 8\ 3\ 9\ 10\ 6\ 12\ 2\ 11\ 7$.

These 6 steps can be performed in an inverse order allowing us to pass from a particular number sequence in $S_n(5\bar{1}432, 5\bar{1}423) \bigcup S_n(5\bar{2}431, 5\bar{2}413)$ to a bicolored set partition in one and only one way. In particular it suffices to search second kind right–to–left minima from the permutation in order to perform steps 6 and 5 in reverse order.

Moreover, the permutation $\pi(p)$ that we obtain belongs to $S_n(5\bar{1}432, 5\bar{1}423) \bigcup S_n(5\bar{2}431, 5\bar{2}413)$ because the sequence of numbers does not contain two consecutive decreasing elements having on their right two smaller elements.

If $j = \infty$, then we obtain all permutations and $n!$ appears. Moreover the ∞-kind inversions are simply the usual inversions in a permutation. Let $c_{n,m}(q)$ denote the polynomial obtained by q-counting by inversions the permutations of $[n]$ having m right–to–left minima. The recursive construction of these permutations, inserting the element $n+1$ into one of the $n+1$ active sites, shows that

$$c_{n+1,m}(q) = c_{n,m-1}(q) + q[n]_q c_{n,m}(q). \tag{5.6}$$

It follows, using (2.3), that

$$c_{n,m}(q) = q^{n-m} c_q[n,m] \tag{5.7}$$

and, summing over m, we find that

$$[n]!_q = \sum_{m=0}^{n} q^{n-m} c_q[n,m], \tag{5.8}$$

where $[n]!_q = \prod_{i=1}^{n} [i]_q$ is the q-analogues of $n!$.

For each other value of $j \geq 3$ we obtain sequences of numbers such the n–th term of each of them is between B_n and $n!$ (see Fig. 5). These sequences do not appear in the Sloane–Plouffe book [24]: "The Encyclopedia of Integer Sequences".

6 Enumerative results for $\mathcal{B}^j$-permutations

For each j, we are interested in the enumeration of the permutations in $\mathcal{B}^j$ according to the length, number of right–to–left minima and the number of j–th kind inversions. The reason we introduce this last parameter is to give a combinatorial interpretation of the q–analogue that we obtain in a natural way from (4.1) by giving a "weight" to the label on the right–hand side of each inductive step in (4.1). More precisely the i–th child of a label (k) is given the weight q^{k-i}.

Let $a_k^j(x,y,q)$ be the generating function of $\mathcal{B}^j$–permutations with k active sites, according to their length (variable x), the number of right–to–left minima (y) and the number of j–th kind inversions (q). A detailed analysis of the parameter modifications in the recursive construction of the permutations yield the following recursive relations for $a_k^j(x,y,q)$:

$$\begin{aligned} a_2^j(x,y,q) &= xy, \\ a_k^j(x,y,q) &= xya_{k-1}^j(x,y,q) + xq[k-2]_q a_{k-1}^j(x,y,q), 3 \le k \le j, \\ a_k^j(x,y,q) &= xya_{k-1}^j(x,y,q) + xq[j-1]_q a_{k-1}^j(x,y,q) + xq^j[k-j]_q a_k^j(x,y,q), \\ & \qquad\qquad k \ge j+1; \end{aligned} \tag{6.1}$$

Solving the recursions, we obtain the following:

Proposition 6.1 *The generating function $a_k^j(x,y,q)$ for $\mathcal{B}^j$–permutations verify:*

$$\begin{aligned} a_k^j(x,y,q) &= x^{k-1}\prod_{i=0}^{k-2}(y+q[i]_q), && 2 \le k \le j; \\ a_k^j(x,y,q) &= x^{k-1}(y+q[j-1]_q)^{k-j}\frac{\prod_{i=0}^{j-2}(y+q[i]_q)}{\prod_{i=1}^{k-j}(1-xq^j[i]_q)}, && k \ge j+1. \end{aligned}$$

The coefficient $[x^n y^m]\, a_k^j(x,y,q)$ gives a polynomial in q-counting the $\mathcal{B}^j$–permutations of length n, having m right–to–left minima and k active sites, according to their number of j–th kind inversions.

Corollary 6.2 *Let $a_{n,m}^{(k,j)}(q) = [x^n y^m]\, a_k^j(x,y,q)$, $m \le k-1$; then we have*

$$a_{n,m}^{(k,j)}(q) = \delta_{n,k-1} c_q[k-1,m] q^{k-1-m}, \quad 2 \le k \le j; \tag{6.2}$$

$$a_{n,m}^{(k,j)}(q) = q^{j(n+1-k)+(k-m-1)} S_q[n+1-j,k-j]\,([j-1]_q)^{k-j-m} \sum_{i=0}^{j-1} \binom{k-j}{m-i} c_q[j-1,i]\,([j-1]_q)^i, \quad k \ge j+1; \tag{6.3}$$

where $\delta_{i,j}$ is the Kronecker delta.

Let us now examine the polynomials $a_{n,m}^{(k,j)}(q)$ for some particular values of j.

- If $j=1$, then equation (6.3) should be used and the result is different from 0 if and only if the exponent of $([j-1]_q) = 0$ is zero, that is $k = m+1$. Once n and m are fixed the only possibility is $a_{n,m}^{(m+1,1)}(q) = S_q[n,m] q^{n-m}$ which confirms the results of Section 3.

- If $j=2$ then equations (6.2) and (6.3) give:

$$\begin{aligned} a_{1,1}^{(2,2)}(q) &= 1, \\ a_{n,m}^{(k,2)}(q) &= \tbinom{k-2}{m-1} S_q[n-1,k-2] q^{2n+1-k-m}, \quad k \ge 3. \end{aligned}$$

  By summing over m we obtain the polynomials for the permutations with forbidden subsequences $(5\bar{1}432, 5\bar{1}423)$ or $(5\bar{2}431, 5\bar{2}413)$ of length n having k active sites according to the number of their second kind inversions:

$$\sum_{1 \le m \le n} a_{n,m}^{(k,2)}(q) = q^{2(n+1-k)} S_q[n-1,k-2](1+q)^{k-2}, \quad n \ge 2. \tag{6.4}$$

  This is coherent with (5.3) since k active sites in $\pi(p)$ corresponds to $k-2$ blocks in p.

- If $j=\infty$ then equation (6.2) gives:

$$a_{n,m}^{(n+1,\infty)}(q) = c_q[n,m] q^{n-m}, \quad n \ge 1,$$

  as expected.

The meaning of "Stirling numbers interpolation" lies in the observation that the permutations of length n having m right–to–left minima are counted by the second kind Stirling numbers for $j=1$ and by the first kind Stirling numbers $c(n,m)$ for $j=\infty$. In the intermediate cases this number, $p_{n,m}^{(j)}$, is such that $S(n,m) \le p_{n,m}^{(j)} \le c(n,m)$, and it is given by

$$p_{n,m}^{(j)} = \sum_{k=2}^{n} a_{n,m}^{(k,j)}(1), \tag{6.5}$$

where $a_{n,m}^{(k,j)}(1)$ can be computed by setting $q = 1$ in (6.3).

Partitions of an Integer into Powers

Matthieu Latapy

LIAFA, *Université Paris 7, 2 place Jussieu, 75005 Paris. latapy@liafa.jussieu.fr*

In this paper, we use a simple discrete dynamical model to study partitions of integers into powers of another integer. We extend and generalize some known results about their enumeration and counting, and we give new structural results. In particular, we show that the set of these partitions can be ordered in a natural way which gives the distributive lattice structure to this set. We also give a tree structure which allow efficient and simple enumeration of the partitions of an integer.

Keywords: Integer partition, Composition, Lattice, Distributive Lattice, Discrete Dynamical Models, Chip Firing Game

1 Introduction

We study here the problem of writing a non-negative integer n as the sum of powers of another positive integer b:

$$n = p_0 b^0 + p_1 b^1 + \cdots + p_{k-1} b^{k-1}$$

with $p_{k-1} \neq 0$ and $p_i \in \mathbb{N}$ for all i. Following [Rod69], we call the k-tuple $(p_0, p_1, \ldots, p_{k-1})$ a *b-ary partition* of n. The integers p_i are called the *parts* of the partition and k is the *length* of the partition. A b-ary partition of n can be viewed as a representation of n in the basis b, with digits in $\mathbb{N}$. Conversely, given a k-tuple $(p_0, \ldots, p_{k-1})$ and a basis b, we will denote by $v_b(p_0, \ldots, p_{k-1})$ the integer $p_0 b^0 + p_1 b^1 + \cdots + p_{k-1} b^{k-1}$. There is a unique b-ary partition such that $p_i < b$ for all i, and it is the usual (canonical) representation of n in the basis b. Here, we consider the problem without any restriction over the parts: $p_i \in \mathbb{N}$, which is actually equivalent to say that $p_i \in \{0, 1, \ldots, n\}$ for all i. We will mainly be concerned with the enumeration and counting of the b-ary partitions of n, for given integers n and b.

This natural combinatorial problem has been introduced by Mahler [Mah40], who showed that the logarithm of the number of b-ary partitions of n grows as $\frac{(\log n)^2}{2 \log b}$. This asymptotic approximation was later improved by de Bruijn [dB48] and Pennington [Pen53]. Knuth [Knu66] studied the special case where $b = 2$. In this case, the function counting the b-ary partitions for a given n is called the *binary partition function*. This function has been widely studied. Euler and Tanturri [Eul50, Tan18a, Tan18b] studied its exact computation and Churchhouse [Chu69, Chu71] studied its congruence properties, while Fröberg [Fro77] gave a final solution to its asymptotical approximation. Later, Rödseth [Rod69] generalized some of these results to b-ary partitions for any b. Finally, Pfaltz [Pfa95] studied the subcase of the binary partitions of integers which are powers of two.

We are concerned here with the exact computation of the number of b-ary partitions of a given integer n, for any b. We will use a powerful technique we developped in [LP99] and [LMMP98]: incremental construction of the set of b-ary partitions of n, infinite extension and coding by an infinite tree. This method gives a deep understanding of the structure of the set of b-ary partitions of n. We will obtain this way a tree structure which permits the enumeration of all the b-ary partitions of n in linear time with respect to their number. We will also order these partitions in a natural way which gives the distributive lattice structure to this set. We recall that a *lattice* is a partially ordered set such that any two elements a and b have a least upper bound (called *supremum* of a and b and denoted by $a \vee b$) and a greatest lower bound (called *infimum* of a and b and denoted by $a \wedge b$). The element $a \vee b$ is the smallest element among the elements greater than both a and b. The element $a \wedge b$ is defined dually. A lattice is *distributive* if for all a, b and c: $(a \vee b) \wedge (a \vee c) = a \vee (b \wedge c)$ and $(a \wedge b) \vee (a \wedge c) = a \wedge (b \vee c)$. A distributive lattice is a strongly structured set, and many general results, for example efficient coding and algorithms, are known about such sets. For more details, see for example [DP90].

Notice that if we consider $b = 1$ and restrict the problem to partitions of length at most n, then we obtain the *compositions* of n, i.e. the series of at most n integers, the sum of which equals n. Many studies already deal with this special case. In particular, the (infinite) distributive lattice $R_1(\infty)$ which we will introduce in Section 4 is isomorphic to the well known Young lattice [Ber71]. Therefore, we will suppose $b > 1$ in the following. Notice however that some of the results we present here are already known in this special case (for example the distributive lattice structure), therefore they can be seen as an extension of the existing ones.

2 The lattice structure

In this section, we define a simple dynamical model which generates *all* the b-ary partitions of an integer. We will show that the set of b-ary partitions, ordered by the reflexive and transitive closure of the successor relation, has the distributive lattice structure.

Let us consider a b-ary partition $p = (p_0, p_1, \ldots, p_{k-1})$ of n, and let us define the following transition (or rewriting) rule: $p \xrightarrow{i} q$ if and only if for all $j \notin \{i, i+1\}$, $q_j = p_j$, $p_i \geq b$, $q_i = p_i - b$ and $q_{i+1} = p_{i+1} + 1$ (with the assumption that $p_k = 0$). In other words, if p_i is at least equal to b then q is obtained from p by removing b units from p_i and adding one unit to p_{i+1}. We call this operation *firing* i. The important point is to notice that q is then a b-ary partition of n. We call q a *successor* [†] of p, and we denote by $Succ_b(p)$ the set of all the successors of p, with respect to the rule. We denote by $R_b(n)$ the set of b-ary partitions of n reachable from (n) by iterating the evolution rule, ordered by the reflexive and transitive closure of the successor relation. Notice that the successor relation is the covering relation of the order, since it is defined as the transitive and reflexive closure of the successor relation, and one can easily verify that this relation has no reflexive ($x \longrightarrow x$) and no transitive ($x \longrightarrow z$ with $x \longrightarrow y$ and $y \longrightarrow z$) edge. See Figure 1 for some examples.

Given a sequence f of firings, we denote by $|f|_i$ the number of firings of i during f. Now, consider an element p of $R_b(n)$, and two sequences f and f' of firings which transform (n) into p. Then, $p_i = |f|_{i-1} - b \cdot |f|_i = |f'|_{i-1} - b \cdot |f'|_i$. Suppose that there exists an integer i such that $|f|_i \neq |f'|_i$, and let i be the smallest such integer. Then, $|f|_{i-1} = |f'|_{i-1}$ and the equality $|f|_{i-1} - b \cdot |f|_i = |f'|_{i-1} - b \cdot |f'|_i$ is

[†] Notice that the term *successor* can have many different meanings. We follow here the standard usage in discrete dynamical models, but in order theory the term has another meaning, and one may also consider that a *successor* of an integer n should be the integer $n+1$, which is not the case here.

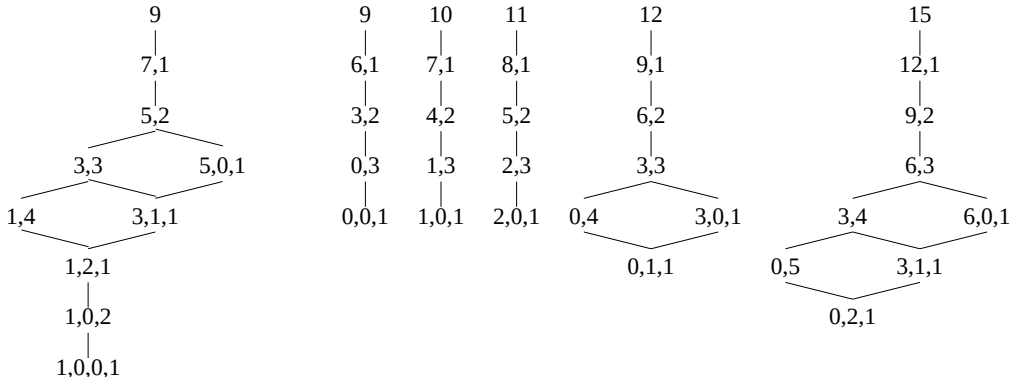

Fig. 1: From left to right, the sets $R_2(9)$, $R_3(9)$, $R_3(10)$, $R_3(11)$, $R_3(12)$ and $R_3(15)$. From Theorem 1, both of these sets is a distributive lattice.

impossible. Therefore, we have $|f|_i = |f'|_i$ for all i. This leads to the definition of the *shot vector* $s(p)$: $s(p)_i$ is the number of times one have to fire i in order to obtain p from (n). Now we can prove:

Lemma 1 *For all p and q in $R_b(n)$, $p \leq q$ if and only if for all i, $s(p)_i \geq s(q)_i$.*

Proof : If $p \leq q$, i.e. p is reachable from q then it is clear that for all i, $s(p)_i \geq s(q)_i$. Conversely, if there exists i such that $s(p)_i > s(q)_i$, then let j be the smallest such integer. Therefore, $q_j > p_j + b$ and so q can be fired at j. By iterating this process, we finally obtain p, and so $p \leq q$. □

Theorem 1 *For all integers b and n, the order $R_b(n)$ is a* distributive lattice *which contains* all *the b-ary partitions of n, with the infimum and supremum of any two elements p and q defined by:*

$$s(p \vee q)_i = \min(s(p)_i, s(q)_i) \text{ and } s(p \wedge q)_i = \max(s(p)_i, s(q)_i).$$

Proof : We first show that $R_b(n)$ contains all the b-ary partitions of n. Consider p a b-ary partition of n. If $p = (n)$, then $p \in R_b(n)$, so we suppose that $p \neq (n)$. Therefore, there must be an integer $i > 0$ such that $p_i > 0$. Let us define q such that $q_j = p_j$ for all $j \notin \{i-1, i\}$, $q_{i-1} = p_{i-1} + b$ and $q_i = p_i - 1$. It is clear that q is a b-ary partition of n, and that if $q \in R_b(n)$ then $p \in R_b(n)$ since $q \xrightarrow{i-1} p$. It is also obvious that, if we iterate this process, we go back to (n), and so $p \in R_b(n)$.

We now prove the formula for the infimum and the supremum. Let p and q be in $R_b(n)$, and r such that $s(r)_i = \min(s(p)_i, s(q)_i)$. From Lemma 1, p and q are reachable from r. Moreover, if p and q are reachable from $t \in R_b(n)$, then, from Lemma 1, r is reachable from t since we must have $s(t)_i \leq \min(s(p)_i, s(q)_i)$ (else one can not transform t into p or q). Therefore, r is the supremum of p and q, as claimed in the theorem. The argument for the infimum is symmetric. Finally, to prove that the lattice is *distributive*, we only have to check that the formulae satisfy the distributivity laws. □

We will now show that the dynamical model defined here can be viewed as a special Chip Firing Game (CFG). A CFG [BLS91, BL92] is defined over a directed multigraph. A configuration of the game is a repartition of a number of chips over the vertices of the graph, and it obeys the following evolution rule: if a vertex ν contains as many chips as its outgoing degree d, then one can transfer one chip along each of

its outgoing edges. In other words, the number of chips at ν is decreased by d and, for each vertex $v \neq \nu$, the number of chips at v is increased by the number of edges from ν to v. This model is very general and has been introduced in various contexts, such as physics, computer science, economics, and others. It is in particular very close to the famous Abelian Sandpile Model [LP00].

It is known that the set of reachable configurations of such a game, ordered with the reflexive and transitive closure of the transition rule, is a Lower Locally Distributive (LLD) lattice (see [Mon90] for a definition and properties), but it is not distributive in general [BL92, LP00, MPV01]. However, if a lattice is LLD and its dual, i.e. the lattice obtained by reversing the order relation, also is LLD, then the lattice is distributive. Therefore, we can give another proof of the fact that $R_b(n)$ is a distributive lattice by showing that it is the set of reachable configurations of a CFG, and that its dual too [‡].

Given two integers n and b, let us consider the following multigraph $G = (V,E)$ defined by: $V = \{0,\ldots,n\}$ and there are b^{i+1} edges from the i-th vertex to the $(i+1)$-th, for all $n < i \leq 0$. Now, let us consider the CFG C defined over G by the initial configuration where the vertex 0 contains n chips, the other ones being empty. Now, given a configuration c of the CFG, where c_i denotes the number of chips in the vertex number i, let us denote by $\overline{c}$ the vector such that $\overline{c_i} = \frac{c_i}{b^i}$. Then, if the CFG is in the configuration c, an application of the rule to the vertex number i gives the configuration c' such that $c'_i = c_i - b^{i+1}$, $c'_{i+1} = c_{i+1} + b^{i+1}$ and $c'_j = c_j$ for all $j \notin \{i, i+1\}$. Notice that this means exactly that $\overline{c_i}$ is decreased by b and that $\overline{c_{i+1}}$ is increased by 1, therefore an application of the CFG rule corresponds exactly to an application of the evolution rule we defined above, and so the set of reachable configurations of the CFG is isomorphic to $R_b(n)$. This leads to the fact that $R_b(n)$ is a LLD lattice.

Conversely, let G' be the multigraph obtained from G by reversing each edge, and let us consider the CFG C' over G' such that the initial configuration of C' is the final configuration of C. Then it is clear that the set of reachable configurations of C' is nothing but the dual of the one of C, therefore it is isomorphic to the dual of $R_b(n)$. This leads to the fact that the dual of $R_b(n)$ is a LLD lattice, which allows us to conclude that $R_b(n)$ is a distributive lattice.

3 From $R_b(n)$ to $R_b(n+1)$

In this section, we give a method to construct the transitive reduction (i.e. the successor relation) of $R_b(n+1)$ from the one of $R_b(n)$. In the following, we will simply call this the *construction of* $R_b(n+1)$ *from* $R_b(n)$. This will show the self-similarity of these sets, and give a new way, purely structural, to obtain a recursive formula for $|R_b(n)|$, which is previously known from [Rod69] (the special case where $b = 2$ is due to Euler [Eul50]). This construction will also show the special role played by certain b-ary partitions, which will be widely used in the rest of the paper. Therefore, we introduce a few notations about them. We denote by $P_i(b,n)$ the set of the partitions p in $R_b(n)$ such that $p_0 = p_1 = \cdots = p_{i-1} = b-1$. Notice that for all i we have $P_i(b,n) \subseteq P_{i+1}(b,n)$ and that $P_0(b,n) = R_b(n)$. If $p = (p_0,\ldots,p_{k-1})$ is in $P_i(b,n)$, we denote by $p^{\hookrightarrow_i}$ the k-uple $(0,\ldots,0,p_i+1,p_{i+1},\ldots,p_{k-1})$. In other words, $p^{\hookrightarrow_i}$ is obtained from p by switching all the i first components of p from $b-1$ to 0 and adding one unit to its i-th componend [§]. Notice that the k-uple $p^{\hookrightarrow_0}$, which is simply obtained from p by adding one unit to its first component, is always a b-ary partition of $n+1$. If S is a subset of $P_i(b,n)$, we denote by $S^{\hookrightarrow_i}$ the set $\{p^{\hookrightarrow_i} \mid p \in S\}$.

[‡] This idea is due to Clémence Magnien, who introduced this new way to prove that a set is a distributive lattice using two Chip Firing Games.

[§] This operator is known in numeration studies as an odometer. See [GLT95] for more precisions.

Notice that, if $p \xrightarrow{i} q$ in $R_b(n)$, then $p^{\hookrightarrow_0} \xrightarrow{i} q^{\hookrightarrow_0}$ in $R_b(n+1)$. This remark makes it possible to construct $R_b(n+1)$ from $R_b(n)$: the construction procedure starts with the lattice $R_b(n)^{\hookrightarrow_0}$ given by its diagram. Then, we look for those elements in $R_b(n)^{\hookrightarrow_0}$ that have a successor out of $R_b(n)^{\hookrightarrow_0}$. The set of these elements will be denoted by I_0, with $I_0 \subseteq R_b(n)^{\hookrightarrow_0}$. At this point, we add all the missing successors of the elements of I_0. The set of these new elements will be denoted by C_0. Now, we look for the elements in C_0 that have a successor out of the constructed set. The set of these elements is denoted by I_1. More generally, at the i-th step of the procedure we look for the elements in C_{i-1} with missing successors and call I_i the set of these elements. We add the new successors of the elements of I_i and call the set of these new elements C_i. At each step, when we add a new element, we also add its covering relations. Since $R_b(n+1)$ is a finite set, this procedure terminates. At the end, we obtain the whole set $R_b(n+1)$. In the rest of this section, we study more precisely this construction process.

Lemma 2 *Let p be a b-ary partition in $P_i(b,n)$. If $p_i \neq b-1$ then $Succ_b(p^{\hookrightarrow_i}) = Succ_b(p)^{\hookrightarrow_i}$. Else, $Succ_b(p^{\hookrightarrow_i}) = Succ_b(p)^{\hookrightarrow_i} \cup \{p^{\hookrightarrow_{i+1}}\}$.*

Proof : If a transition $p \xrightarrow{j} q$ is possible, then $p^{\hookrightarrow_i} \xrightarrow{j} q^{\hookrightarrow_i}$ is obviously possible. Moreover, an additional transition is possible from $p^{\hookrightarrow_i}$ if and only if $p_i = b-1$. In this case, $p^{\hookrightarrow_i} \xrightarrow{i} p^{\hookrightarrow_{i+1}}$. □

Lemma 3 *For all integer b, n and i, we define the function $r_i : P_i(b,n) \to R_b(\frac{n+1}{b^i} - 1)$ by: $r_i(p)$ is obtained from $p \in P_i(b,n)$ by removing its i first components (which are equal to $b-1$). Then, r_i is a bijection.*

Proof : Let us consider p in $P_i(b,n)$: $p = (b-1, b-1, \ldots, b-1, p_i, \ldots, p_k)$. Then, it is clear that $r_i(p) = (p_i, \ldots, p_k)$ is in $R_b(\frac{n-(b-1)-(b-1)b-\cdots-(b-1)b^{i-1}}{b^i}) = R_b(\frac{n+1-b^i}{b^i}) = R_b(\frac{n+1}{b^{i+1}} - 1)$. Conversely, if we consider p in $R_b(\frac{n+1}{b^i} - 1)$, then $r_i^{-1}(p) = (b-1, b-1, \ldots, b-1, p_0, p_1, \ldots, p_k)$ is a b-ary partition of $m = (b-1) + (b-1)b + \cdots + (b-1)b^{i-1} + \frac{n+1-b^i}{b^i}$, which is nothing but n. Therefore, $r_i^{-1}(p)$ is in $R_b(n)$. □

Lemma 4 *For all integer b, n and i, we have $I_i = P_{i+1}(b,n)^{\hookrightarrow_i}$ and $C_i = P_{i+1}(b,n)^{\hookrightarrow_{i+1}}$.*

Proof : By induction over i. For $i = 0$, it is clear from Lemma 2 that the set of elements in $R_b(n)^{\hookrightarrow_0}$ with a missing successor, namely I_0, is exactly $P_1(b,n)^{\hookrightarrow_0}$. Moreover, the set of these missing successors, namely C_0, is clearly $P_1(b,n)^{\hookrightarrow_1}$. Now, let us suppose that the claim is proved for i and let us prove it for $i+1$. The set I_{i+1} is the set of elements in C_i with one missing successor. By induction hypothesis, we have $C_i = P_{i+1}(b,n)^{\hookrightarrow_{i+1}}$ and so, from Lemma 2, $I_{i+1} = P_{i+2}(b,n)^{\hookrightarrow_{i+1}}$. Then, by application of the evolution rule, it is clear that the set C_{i+1} of the missing successor is $P_{i+2}(b,n)^{\hookrightarrow_{i+2}}$, which proves the claim. □

Theorem 2 *For any positive integer b and n, we have:*

$$R_b(n) = \bigsqcup_{i \geq 0} r_i^{-1}\left(R_b\left(\frac{n}{b^i} - 1\right)\right)^{\hookrightarrow_i}$$

$$|R_b(n)| = \sum_{i=0}^{\lfloor n/b \rfloor} \Big| \; R_b(\tfrac{i}{b}) \; \Big|$$

where $\bigsqcup$ denotes the disjoint union, where $R_b(n)$ is taken as $\emptyset$ when n is not a positive integer, and with $R_b(0) = \{0\}$.

Proof : From the construction procedure described above, we have $R_b(n) = R_b(n-1)^{\hookrightarrow_0} \sqcup \bigsqcup_{i\geq 0} C_i$. From Lemma 4, we obtain $R_b(n) = R_b(n-1)^{\hookrightarrow_0} \sqcup \bigsqcup_{i\geq 0} P_{i+1}(b,n)^{\hookrightarrow_{i+1}}$. Moreover, since $R_b(n-1)^{\hookrightarrow_0}$ is nothing but $P_0(b,n)^{\hookrightarrow_0}$, this is equivalent to $R_b(n) = \bigsqcup_{i\geq 0} P_i(b,n)^{\hookrightarrow_i}$. Finally, from Lemma 3, we obtain the announced formula.

From this formula, we have $R_b(\frac{n}{b}) = \bigsqcup_{i\geq 0} r^{-1}(R_b(\frac{n}{b^{i+1}}-1)^{\hookrightarrow_i})$. Therefore, $|R_b(n)| = \sum_{i\geq 0} |R_b(\frac{n}{b^i} - 1)| = |R_b(n-1)| + \sum_{i\geq 0} |R_b(\frac{n}{b^{i+1}}-1)| = |R_b(n-1)| + |R_b(\frac{n}{b})|$. We obtain the claim by iterating this last formula. □

The first formula given in this theorem can be used to compute the sets $R_b(n)$ efficiently since it only involves *disjoint* unions. We will give in Section 5 another method to compute $R_b(n)$ which is much simplier, as it gives $R_b(n)$ a tree structure. However, the formula is interesting since it points out the self-similar structure of the set (see Figure 4).

The second formula is previouly known from [Rod69], and from [Eul50] in the special case where $b = 2$. Notice that this does not give a way to compute $|R_b(n)|$ in linear time with respect to n, which is an unsolved problem in the general case, but it gives a very simple way to compute recursively $|R_b(n)|$.

4 Infinite extension

$R_b(n)$ is the lattice of the b-ary partitions of n reachable from (n) by iteration of the evolution rule. We now define $R_b(\infty)$ as the set of all b-ary partitions reachable from (∞). The order on $R_b(\infty)$ is the reflexive and transitive closure of the successor relation. For $b = 2$, the first b-ary partitions in $R_b(\infty)$ are given in Figure 2 along with their covering relation (the first component, which is always infinity, is not represented on this diagram). Notice that it is still possible to define the shot vector $s(p)$ of an element p of $R_b(\infty)$ by: $s(p)_i$ is the number of times one has to fire i in order to obtain p from (∞).

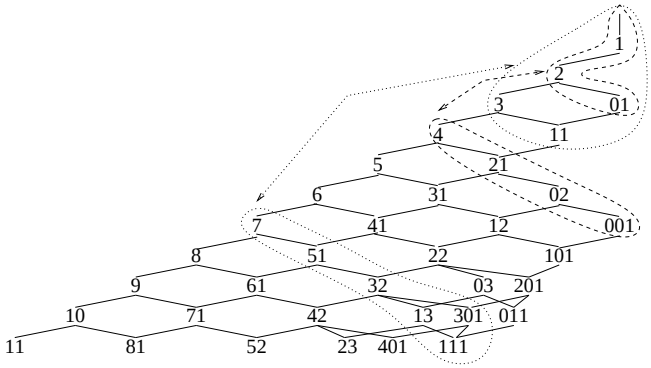

Fig. 2: The first b-ary partitions obtained in $R_b(\infty)$ when $b = 2$. Two parts isomorphic to $R_2(4)$ are distinguished, as well as two parts isomorphic to $R_2(7)$.

Theorem 3 *The set $R_b(\infty)$ is a distributive lattice with:*

$$s(p \vee q)_i = \min(s(p)_i, s(q)_i) \text{ and } s(p \wedge q)_i = \max(s(p)_i, s(q)_i)$$

for all p and q in $R_b(\infty)$. Moreover, for all n the functions

$$\pi : s = (s_1, s_2, \cdots, s_k) \longrightarrow \pi(s) = (\infty, s_2, \ldots, s_k)$$

and

$$\tau : s = (s_1, s_2, \cdots, s_k) \longrightarrow \tau(s) = (\infty, s_1, s_2, \ldots, s_k)$$

are lattice embeddings of $R_b(n)$ into $R_b(\infty)$.

Proof : The proof for the distributive lattice structure and for the formulae of the infimum and supremum is very similar to the proof of Theorem 1. Therefore, it is left to the reader.

Given p and q in $R_b(n)$, we now prove that $\pi(p) \vee \pi(q) = \pi(p \vee q)$. From Theorem 1, we have $s(p \vee q)_i = \min(s(p)_i, s(q)_i)$. Moreover, it is clear that $s(\pi(x))_i = s(x)_i$ for all x in $R_b(n)$. Therefore, $s(\pi(p \vee q))_i = \min(s(\pi(p))_i, s(\pi(q))_i))$, which shows that π preserves the supremum. The proof of $\pi(p) \wedge \pi(q) = \pi(p \wedge q)$ is symmetric. Therefore, π is a lattice embedding.

The proof for τ is very similar when one has noticed that the shot vector of $\tau(s)$ is obtained from the one of s by adding a new first component equal to n. □

With similar arguments, one can easily show that $\pi(R_b(n))$ is a sublattice of $\pi(R_b(n+1))$, and so we have an infinite chain of distributive lattices:

$$\pi(R_b(0)) \leq \pi(R_b(1)) \leq \cdots \leq \pi(R_b(n)) \leq \pi(R_b(n+1)) \leq \cdots \leq R_b(\infty),$$

where $\leq$ denotes the sublattice relation. Moreover, one can use the self-similarity estalished here to construct filters of $R_b(\infty)$ (a *filter* of a poset is an upper closed part of the poset). Indeed, if one defines $R_b(\leq n)$ as the sub-order of $R_b(\infty)$ over $\cup_{i \leq n} R_b(i)$, then one can construct efficiently $R_b(\leq n+1)$ from $R_b(\leq n)$ by extracting from $R_b(\leq n)$ a part isomorphic to $R_b(n+1)$ and pasting it to $R_b(\leq n)$. See Figures 2 and 4.

Notice that, for all integer b, $R_b(\infty)$ contains exactly all the finite sequences of integers, since any such sequence can be viewed as a b-ary partition of an integer n. Therefore, we provide infinitely many ways to give the set of finite sequences of integers the distributive lattice structure.

5 Infinite tree

As shown in our construction of $R_b(n+1)$ from $R_b(n)$, each b-ary partition p in $R_b(n+1)$ is obtained from another one $p' \in R_b(n)$ by application of the $\hookrightarrow$ operator: $p = p'^{\hookrightarrow_i}$ with i an integer between 0 and $l(p')$, where $l(p')$ denotes the number of $b-1$ at the beginning of p'. Thus, we can define an infinite tree $T_b(\infty)$ whose nodes are the elements of $\bigsqcup_{n \geq 0} R_b(n)$ and in which the fatherhood relation is defined by:

$$q \text{ is the } (i+1)\text{-th son of } p \text{ if and only if } q = p^{\hookrightarrow_i} \text{ for some } i,\ 0 \leq i \leq l(p).$$

The root of this tree is (0) and each node p of $T_b(\infty)$ has $l(p)+1$ sons. The first levels of $T_b(\infty)$ when $b = 2$ are shown in Figure 3 (we call the set of elements of depth n the "level n" of the tree).

Proposition 1 *The level n of $T_b(\infty)$ contains exactly the elements of $R_b(n)$.*

Proof : Straightforward from the construction of $R_b(n+1)$ from $R_b(n)$ given above and the definition of the tree. □

If we define $\overline{R_b(n)}$ as $\{(s_2, \ldots, s_k) \mid (s_1, s_2, \ldots, s_k) \in R_b(n)\}$, then:

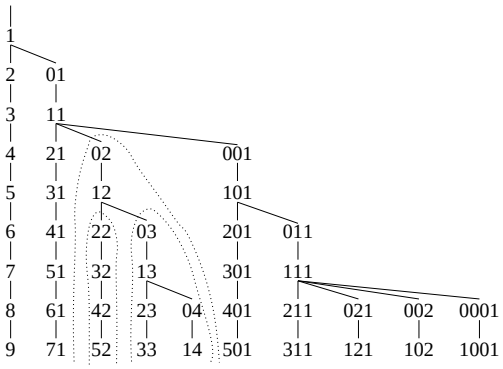

Fig. 3: The first levels of $T_b(\infty)$ when $b = 2$. We distinguished some special subtrees, which will play an important role in the following.

Proposition 2 *For all integer n, the elements of* $\overline{R_b(n)}$ *are exactly the elements of the* $\lfloor \frac{n}{b} \rfloor$ *first levels of* $T_b(\infty)$.

Proof : Let us first prove that the elements of $R_b(n)$ are the nodes of a subtree of $T_b(\infty)$ that contains its root. This is obviously true for $n = 0$. The general case follows by induction, since by construction the elements of $\overline{R_b(n+1)} \setminus \overline{R_b(n)}$ are sons of elements of $\overline{R_b(n)}$.

Now, let us consider an element e of the l-th level of $T_b(\infty)$. If there is a b-ary partition p of n such that $\overline{p} = e$, then clearly $p_i = e_{i-1}$ for all $i > 0$ and $p_0 = n - b \cdot l$. Therefore, if e is in $\overline{R_b(n)}$ then all the elements of the l-th level are in $\overline{R_b(n)}$, and this is clearly the case exactly when $0 \leq l < \lfloor \frac{n}{b} \rfloor$. This ends the proof. □

Notice that this proposition gives a simple way to enumerate the elements of $R_b(n)$ for any n in linear time with respect to their number, since it gives this set a tree structure. Algorithm 1 acheives this.

We will now show that $T_b(\infty)$ can be described recursively, which allows us to give a new recursive formula for $|R_b(n)|$. In order to do this, we will use a series known as the b-ary carry sequence [Slo73]: $c_b(n) = k$ if b^k divides n but b^{k+1} does not. Notice that this function is defined only for $n > 0$ (or one can consider that $c_b(0) = \infty$). These series appear in many contexts, and have many equivalent definitions ¶. Here, we will mainly use the fact that the first n such that $c_b(n) = k$ is $n = b^k$, and the fact that $c_b(n)$ is nothing but the number of components equal to $b-1$ at the begining of the canonical representation of $n-1$ in the basis b.

Definition 1 *Let* $p \in T_b(\infty)$. *Let us consider the rightmost branch of* $T_b(\infty)$ *rooted at p (p is considered as the first node of the branch). We say that p is the root of a* $X_{b,k}$ subtree (of $T_b(\infty)$) *if this rightmost branch is as follows: for* $i \leq b^{k-1}$, *the i-th node on the branch has* $j = c_b(i) + 1$ *sons, and the l-th* $(1 \leq l < j)$ *of these sons is the root of a* $X_{b,l}$ *subtree. Moreover, the* $(b^{k-1}+1)$*-th node of the branch is itself the root of a* $X_{b,k}$ *subtree.*

For example, we show in Figure 3 a $X_{2,2}$ subtree of $T_2(\infty)$, composed of a $X_{2,1}$ subtree and another $X_{2,2}$ subtree. Notice that a $X_{b,1}$ subtree is simply a chain.

¶ For example, if one defines the series $C_{b,0} = 0$ and $C_{b,i} = C_{b,i-1}, \overbrace{i, C_{b,i-1}}^{b-1 \text{ times}}$, then $c_b(i)$ is nothing but the i-th integer of the series $C_{b,i}$. The ten first values for $c_2(i)$ are $0,1,0,2,0,1,0,3,0,1$ and the ten first ones for $c_3(i)$ are $0,0,1,0,0,1,0,0,2,0$.

Algorithm 1 Efficient enumeration of the elements of $R_b(n)$.

Input: An integer n and a basis b
Output: The elements of $R_b(n)$
begin
  Resu $\leftarrow \{(n)\}$;
  CurrentLevel $\leftarrow\leftarrow \{()\}$;
  OldLevel $\leftarrow \emptyset$; $l \leftarrow 0$;
  while $l < \lfloor \frac{n}{b} \rfloor$ **do**
    OldLevel $\leftarrow$ CurrentLevel;
    CurrentLevel $\leftarrow \emptyset$;
    $l \leftarrow l + 1$;
    for each *p in OldLevel* **do**
      $i \leftarrow 0$;
      repeat
        Add $p^{\hookrightarrow_i}$ to CurrentLevel;
        $i \leftarrow i + 1$;
      until $p_{i-1} \neq b - 1$;
    for each *e in CurrentLevel* **do**
      Create p such that $p_i = e_{i-1}$ for all $i > 0$ and $p_0 = n - b \cdot l$;
      Add p to Resu;
  Return(Resu);
end

Proposition 3 *Let $p = (0,0,\dots,0,p_k,\dots)$ in $T_b(\infty)$ with $p_k > b-1$. Then, p is the root of a $X_{b,k+1}$ subtree of $T_b(\infty)$.*

Proof : The proof is by induction over k and the depth of p. Let us consider the rightmost branch rooted at p. Since, for all q in $T_b(\infty)$, the rightmost son of q is $q^{\hookrightarrow_i}$ with i the number of $b-1$ at the beginning of q, it is clear that the j-th node of this branch for $j \leq b^k$ is $q = (q_0,\dots,q_{k-1},p_k,\dots)$ where $(q_0,\dots,q_{k-1})$ is the canonical representation of $j-1$ in the basis b. Therefore, q begins with $c_b(j)$ components equal to $b-1$, and so, for $l = 1,\dots,c_b(j)$, the l-th son of q starts with $l-1$ zeroes followed by a component equal to $b > b-1$. By induction hypothesis, we then have that the sons of q are the roots of $X_{b,l}$ subtrees. Moreover, the (b^k+1)-th node on the rightmost branch begins with exactly k zeroes followed by a component greater than $b-1$, and so it is the root of a $X_{b,k+1}$ subtree by induction hypothesis. □

Theorem 4 *The infinite tree $T_b(\infty)$ is a $X_{b,\infty}$ tree: it is a chain (its rightmost branch) such that its i-th node has $c_b(i)$ sons and the j-th of these sons, $1 \leq j \leq c_b(i)$, is the root of a $X_{b,j}$ subtree. Moreover, the i-th node of the chain is the canonical representation of $i-1$ in the basis b.*

Proof : Since the rightmost son of $p \in T_b(\infty)$ is $p^{\hookrightarrow_i}$, where i is the number of $b-1$ at the beginning of p, and since the root of $T_b(\infty)$ is nothing but the canonical representation of 0, it is clear by induction that the i-th node of the rightmost branch of $T_b(\infty)$ is the canonical representation of $i-1$ in the basis b. Then, the theorem follows from Proposition 3. □

We now have a recursive description of $T_b(\infty)$, which allows us to give recursive formula for the cardinal of some special sets. Let us denote by $\pi_b(l,k)$ the number of paths of length exactly l starting from the root of a $X_{b,k}$ subtree of $T_b(\infty)$. We have:

Theorem 5

$$\pi_b(l,k) = \begin{cases} 1 & \text{if } 0 \leq l < b \\ 1 + \sum_{i=1}^{l} \sum_{j=1}^{c_b(i)} \pi_b(l-i,j) & \text{if } b \leq l \leq b^{k-1} \\ \pi_b(l-b^{k-1},k) + \sum_{i=1}^{b^{k-1}} \sum_{j=1}^{c_b(i)} \pi_b(l-i,j) & \text{otherwise } (l > b^{k-1}) \end{cases}$$

Moreover, $|R_b(n)| = \pi_b(n,n)$ and the number of b-ary partitions of n into exactly l parts is $\pi_b(n-(b-1)^l,l)$.

Proof : The formula for $\pi_b(l,k)$ is directly deduced from the definition of the $X_{b,k}$ subtrees. The other formulae derive from Theorem 4 and from the fact that all the b-ary partitions of length l are in a $X_{b,l}$ subtree of $T_b(\infty)$which is rooted at the $(b-1)^l$-th node of the righmost branch of $T_b(\infty)$. □

6 Perspectives

The results presented in this paper mainly point out the strong self-similarity and the structure of the sets $R_b(n)$. As already noticed, it is an open question to compute the cardinal of $R_b(n)$ in linear time with respect to n, and one may expect to obtain a solution using these results.

Another interesting direction is to investigate how one can extend the dynamics we study. A first idea is to consider non-integer basis, in particular complex basis or Fibonnacci basis. For example, if we consider the complex basis $b = i-1$ then we can obtain all the ways to write an integer n as the sum of powers of b by iterating the following evolution rule from (n): q is a successor of p if $p - q =$

$(0,\ldots,0,2,0,-1,-1,0\ldots,0)$. In other words, we can decrease by two the j-th component of p and increase by one its $(j+2)$-th and its $(j+3)$-th components for some integer j. This gives to the set of representations of n in the complex basis $b = i-1$ the lattice structure, since this can be encoded by a Chip Firing Game [LP00] (notice however that in this case the lattice is no longer distributive). Another interesting case is when $b = 1$. As already noticed, we obtain the Young lattice, or equivalently the lattice of the compositions of n.

7 Acknowledgments

I thank Christiane Frougny and Clémence Magnien for many useful comments on preliminary versions, which deeply improved the manuscript.

I1 Prolégomènes (ce chapitre préliminaire peut être sauté sans inconvénient)
I2 Magmas et arborescences (ce chapitre est réellement essentiel).
I3 Parenthésage et codage polonais (c'est également important).
I4 Génèse de permutations (introduction au tri et à la combinatoire des permutations).
I5 Sur la combinatoire des permutations.

Livre II. Graphes et cheminements.
II1 Généralités, exemples, connexité forte.
II2 Connexités.
II3 Chemins hamiltoniens, tripartitions, duels.
II4 Compléments.
II5 Graphes, séries formelles, et morphismes.
II6 Treillis et logiques.

Livre III. Numérique et non-numérique.
III1 A propos de quelques modes de représentation des entiers.
III2 Numérique et non-numérique.
III3 Sur les traçés de courbes.
III4 Traçons encore.
III5 Sur les transformations de fourier discrètes.

III6 Tracer droit.
III7 Grand Vrac, pour finir: sons, couleurs, périodes...et autres.

Le livre I, à partir du chapitre 2, traite plus spécialement des fondamentales et omniprésentes structures arborescentes, au sens où l'entendent habituellement les programmeurs. Il n'expose pas nécessairement les représentations informatiques adéquates de ces objets, ce qui est sommairement fait ultérieurement (livre II) mais plutôt, ce qui est en premier lieu le plus important, leurs divers aspects formels et linguistiques. Le livre I traite aussi de la génèse des permutations, de leur lien éventuel avec les structures arborescentes, sous les angles simultanés de la programmation, de la combinatoire énumérative, des preuves bijectives.

Le livre II est plutôt orienté vers les représentations de graphes, surtout les questions de cheminement dans les graphes, une fois encore particulièrement sous l'angle des algorithmes énumératifs.

Le livre III est plutôt une vague tentative de réflexion sur l'ambiguïté de la frontière entre calculs dits numériques et calculs dits non-numériques.

Finalement, du vrac, à l'usage de ceux qui aiment, des exercices, très mélangés, de difficultés extrèmement variable, du plus simple au plus compliqué. Un outil de travail, désordonné, sans table des matières. Certains thèmes sont largement développés, d'autres à peine effleurés, seulement suggérés. Les exercices, divers, sont souvent totalement résolus, parfois seulement esquissés, d'autres étant seulement l'occasion de faire état de conjectures qui résisteront encore longtemps.

Les cours sont au format pdf

- I.0 Préface

Livre I. Arbres et permutations.

- I.0 Couverture
- I.1 Prolégomènes
- I.2 Magmas, Arborescences
- I.3 Parenthèses, Mots polonais
- I.4 Engendrer les permutations
- I.5 Permutations combinatoires

Livre II. Graphes et cheminements.

- II.0 Couverture
- II.1 Généralité, Transitivité
- II.2 Connexité

- II.3 Chemins, Duels
- II.4 Compléments
- II.5 Séries. Morphismes
- II.6 Treillis, Logiques

Livre III. Numérique et non-numérique.

- III.0 Couverture
- III.1 Numération
- III.2 Numérique, Non-numérique
- III.3 Courbes
- III.4 Tracer
- III.5 Fourier
- III.6 Droit
- III.7 Divers

Sommaire

De quoi s'agit-il ?

Voici donc des compléments d'informatique fondamentale,
mathématiques, combinatoires, linguistiques, arbitrairement divisés en trois parties

Livre I : Arbres et Permutations
Livre II : Graphes et Cheminements
Livre III : Numérique et non-numérique

à l'usage d'utilisateurs de computeurs**.**

Il convient de suivre le texte muni d'un crayon et de feuilles de papier, afin de construire arbres, graphes, configurations géométriques, et tout dessin utile à l'intuition. Puis, programmer.

Le livre I, à partir du chapitre 2, traite plus spécialement des fondamentales et omniprésentes structures arborescentes, au sens où l'entendent habituellement les programmeurs. Il n'expose pas nécessairement les représentations informatiques adéquates de ces objets fondamentaux, ce qui est sommairement fait ultérieurement, dans le livre II, mais plutôt, ce qui est en premier lieu le plus important, leurs divers aspects formels et linguistiques. Le livre I traite aussi de la génèse des permutations, de leur lien éventuel avec les structures arborescentes, sous les angles simultanés de la programmation, de la combinatoire énumérative, des preuves bijectives.

Le livre II est plutôt orienté vers les représentations de graphes, surtout les questions de cheminement dans les graphes, une fois encore particulièrement sous l'angle des algorithmes énumératifs.

Le livre III est plutôt une vague tentative de réflexion sur l'ambiguïté de la frontière entre calculs dits numériques et calculs dits non-numériques.

On me pardonnera ces textes. Les bonnes leçons sont orales. Socrate n'a rien écrit. L'apprentissage, processus contraire aux évidences du bon sens, est un effort ingrat qui nécessite échanges, stimulation, travail, compétence, mémoire, intelligence, émotions même, curiosité, sens esthétique, préalablement à tout moyen technique.

Algorithmique et programmation.

L'invention de cet outil, la machine à calculer, ne fait que souligner ce fait qu'il n'est d'autre manière de comprendre le monde que de le mettre en forme, et chacun sait aujourd'hui que les machines à calculer ne manipulent pas des nombres, mais des caractères typographiques, bizarrement comme le vivant, d'ailleurs.
Au-delà des modes du moment, le calcul automatique n'en est qu'à ses débuts.
Le savoir bien étayé repose sur les calculs, formels, et bien interprétés.
S'acharner à comprendre le monde. Tentative désespérée. Mais l'on ne peut répondre qu'aux questions que l'on se pose. On constatera un fait: la résolution de problèmes provoque l'émergence de conjectures nouvelles. C'est ainsi que progressent les connaissances. Nous nous trouvons dans la situation de celui qui, ayant décodé un système, pénètre un espace nouveau, qu'il faut explorer, espace borné à son tour par de multiples portes, et bien qu'il faille faire preuve d'imagination et de persévérance pour en dévoiler tour à tour les nouveaux mystères, rien ne garantit le résultat. Chaque fois que l'on a l'illusion de toucher au but, celui-ci s'éloigne, tel un mirage.

Il n'y a pas de théories closes -lesquelles, se voulant une explication définitive, ne seraient qu'une conception naïve- mais seulement des hypothèses transitoires et incertaines, dont nous nous efforçons de tirer des conséquences momentanées.
Quoi qu'il en soit, comme ce que l'on sait se perd dans l'océan de notre ignorance, il ne s'agit ici que de présenter, dans un désordre certain, quelques problèmes que l'on croit savoir résoudre ou apprivoiser, en demeurant muet sur le reste, dont nous sommes probablement même inconscients, que nous ne savons pas même formuler.
La science se nourrit du mystère qu'elle tente d'éclaircir, bien que celui-ci s'épaississe au fur et à mesure qu'elle progresse. Être capable de s'interroger sur quelques questions pertinentes, à la frontière, c'est déjà beaucoup. C'est dire que la science est inévitablement simplificatrice, ou, comme l'on dit, réductrice. Et c'est précisément là sa force.
Quelques rares exemples de squelettes programmés agrémentent aléatoirement le texte. Ces programmes sont simplifiés à l'extrême, et, arbitrairement, construits sans passer de paramètres. Les identificateurs sont toujours globaux, et, par mauvais esprit, c'est tout à fait intentionnel, particulièrement lors de l'écriture des procédures récursives, ce qui contribue d'ailleurs à en accélérer l'exécution.

Il y a deux standards principaux, deux styles de programmation: composer des fonctions qui absorbent des entrées, afin de produire des résultats en sortie, ou faire évoluer des automates dans quelque environnement, qu'ils modifient, -et l'on qualifiera de Lamarkiens ceux de ces automates que l'on autorise à être en retour modifiés par l'environnement dans lequel ils évoluent.

Un programme n'est pas une quelconque suite de caractères. Ce doit être un texte intelligent, dont l'interprétation par un méta-programme simule un automate abstrait significatif. Un tel texte est construit dans le but d'engendrer des objets, voulus ou attendus par les observateurs curieux que nous sommes, si bien que les plus petites modifications le rendent généralement inopérant -mais pas toujours, car l'on peut, tel l'expérimentateur distrait, parfois observer des effets inattendus.
Comme en art, comme en science, en programmation aussi le style est important.
Le sens esthétique est un fil conducteur.
Les programmeurs écrivent désormais leur texte comme le font les écrivains: directement, face à l'outil, l'écran et le clavier, pas si mal adaptés à notre vue et nos appendices manuels, car la conception des machines doit tenir compte des capacités des humains, et non le contraire. Bien sûr, il faut préalablement avoir l'idée d'un calcul automatisable, puis maîtriser tel algorithme que l'on désire traduire dans tel langage de programmation, via l'indispensable découpage en procédures fonctionnelles.
On accordera une attention particulière aux langages interprétés -et même sans déclarations- éventuellement spécialisés, permettant une écriture directe, fournissant une réponse rapide, et l'on s'attardera aux découpages astucieux en petites procédures indépendantes.
Chacun sait que la mise au point de programmes se fait ainsi, par succession de modifications, vérifications, exécutions, rectifications, ébauches parmi lesquelles nous abandonnons celles qui ne produisent pas ce que l'on en espère. Si le Darwinisme se révélait exact, et plus encore sous sa forme moderne de copie de texte, dédoublement de l'information, copie et recopie, recombinaisons et production d'erreurs, processus si typiquement informatique, il pourrait s'interpréter comme l'existence d'une nature cruelle, mais pas pressée, expérimentant des combinaisons nouvelles, et, par le jeu des lois de la sélection, observant la cruelle élimination compétitive de celles qui ne fonctionnent pas.

Le darwinisme fut un choc par l'élimination de dieu comme principe causal, il lui substitue le hasard, mais évidemment sans plus de preuve, considérer le hasard comme un principe causal est aussi arbitraire que l'invocation d'un dieu, et tout aussi inprouvable. Le monde est régi par des principes formels hypothétiques, il s'y conforme ou ne s'y conforme pas, nous ne pouvons rien dire de plus, la réalité expérimentale seule permet de trancher, le reste est affaire de conjectures, la biologie n'y échappe pas, même si quelques dogmes simplistes ont eu du succès, parce que compréhensibles aux esprits simples, qui croyaient en dieu et croient maintenant au hasard. Le darwinisme est constitué de deux axiomes qui résument tout, l'un trivial (ce qui n'est pas compétitif disparaît), l'autre inprouvable (le hasard est le moteur de l'évolution). Il n'y a pas de théorie digne de ce nom.

Rien n'empêche de concevoir le monde comme un énorme programme.

Les principales qualités de sélection d'un programme informatique sont: 1) ça fait ce que l'on veut que ça fasse 2) il n'y a pas trop d'erreurs dissimulées -ça ne plante pas trop!- 3) c'est esthétique, commode à utiliser, confortable, intuitif 4) ça peut évoluer, par greffe de fonctions supplémentaires 5) c'est peu coûteux -voir gratuit-.

Il est utile de conserver au signe d'égalité (=) une signification traditionnelle, statique, qui est celle-ci: l'objet placé à gauche est identique à celui placé à droite. C'est une affirmation, à moins d'être incorporée dans un texte stipulant une question du genre "peut-on trouver deux objets a et b tels que a=b", ou une hypothèse de travail, "si a=b, alors...". Le symbole dit "d'identité", composé de trois traits, est utilisé pour les équivalences et congruences. Tandis que le rangement d'un objet dans un magasin de stockage se représente traditionnellement par le signe d'affectation (:=). C'est une action de substitution (remplacer le contenu du magasin de stockage nommé à gauche par l'objet défini à droite), laquelle substitution, dynamique, fait perdre la mémoire de l'objet préalablement stocké sous l'identificateur figurant à gauche. La programmation est un jeu d'adresse(s) qui doit souvent trancher entre deux exigences fréquemment opposées, l'économie de mémoire et l'économie de temps.

Alors que la suite mathématique c(i)=f(c(i-1)), habituellement initialisée par la donnée d'un point de départ, c(0), considère en fait un ensemble infini d'objets, pris dans leur totalité, d'où le temps est idéalement évacué, la notation informatique (le programme itératif C:=f(C) sous l'initialisation C:=c(0)) est un palimpseste: la mémoire est gommée, afin de pouvoir y inscrire une information nouvelle, sans cesse modifiée: un seul objet y réside, mais de manière transitoire.

Il existe deux types particulièrement importants, distincts par leurs effets, mais non sans lien, respectueux d'une structure donnée, d'actions sur des collections d'objets, que l'on peut sommairement résumer ainsi:
-agir simultanément sur tous (ce sont ce que l'on appellera des morphismes -et non pas orphismes comme me l'a proposé un correcteur orthographique):
il en va ainsi des structures en abîme, dites autosimilaires, tellement à la mode
-ou énumérer, dans un certain ordre, toutes les manières d'itérer une action qui n'agit que sur un seul objet -au sens algébrique, ce sont des dérivations-: il en va ainsi, par exemple, des grammaires génératives algébriques, dites "de Chomsky".

Les méthodes de calcul se transmettent en dessinant le moins possible d'organigrammes. Une méthode de calcul, c'est initialement une idée, qu'il est préférable d'exprimer tout d'abord en utilisant une langue naturelle, bien qu'il faille ensuite formaliser. Désormais, la forme (mathématique) ne peut plus être indépendante de toute programmation, bien qu'il soit toujours irritant de se plier au style qu'imposent l'état de la technique et les langages dont nous disposons.
Plus rigoureusement encore qu'en mathématique, si c'est possible -et ça l'est vraiment- l'informatique est le lieu où règne la forme et la rigueur, et, du moins pour l'instant, le déterminisme. C'est d'ailleurs le fondement même de la démarche scientifique que de proposer des modèles strictement formels (ils n'expliquent rien: ils se contentent de décrire, et parfois, miracle, de prévoir), de les confronter aux faits expérimentaux, avec lesquels on espère qu'ils soient compatibles, du moins à une certaine échelle.
L'informatique est désormais, au coeur de cette démarche, omniprésente.

Évolution.

Il est cependant de fait que les langages de programmation et de manipulation de systèmes, ainsi que ceux de description de documents, deviennent de plus en plus des conventions aux mains de firmes dont les positions de monopoles s'accentuent.
Ainsi se précise le danger pour la masse des informaticiens d'être réduits à l'état de techniciens, servants stériles de puissances commerciales. Je ne vise pas là seulement le mercantilisme, mais ce que l'on observe, plus profondément: cette difficulté croissante à distinguer les conventions techniques des faits scientifiques.

Simultanément, le temps de la sérénité se perd, du fait de l'inflation d'échanges d'informations insignifiantes et manipulables, en proportion de leur volume croissant, au détriment de la réflexion, laquelle demande approfondissement, beaucoup de temps perdu, effort, persévérance, détachement des modes. Facilité et rapidité, qui caractérisent les moyens de communication nouveaux, ne font pas bon ménage avec la réflexion nécessaire à l'acquisition de compétences scientifiques.
Un moyen pour contourner cet écueil: continuer, dans l'enseignement, à privilégier le support traditionnel qu'est le livre, et ne pas se contenter d'y avoir recours dans un but strictement utilitaire. La civilisation est naturellement conservatrice.
Elle s'appuie sur son histoire, et c'est la seule manière de la renouveler, tandis que la barbarie détruit, nie l'histoire, la trafique. Bibliothèques spécialisées et musées demeurent le support honnête et nécessaire de notre mémoire.
Que vivent les suports qui résistent au temps! Il se trouve que l'impression sur papier, technique dit-on inventée en chine, a perduré en europe de Gutenberg - milieu du xv-ième siècle- à maintenant, soit durant environ cinq siècles. Cette pérennité est remarquable, tandis que le support informatique, comme nous l'avons constaté, ne dure que quelques années; le temps que la technique évolue, que les appareils viellisssent, et le tout finit dans les poubelles. On peut parier que cela va continuer. La pérennité, pour l'instant, c'est encore le papier.

Les scientifiques utilisent désormais beaucoup d'outils techniques, tandis que les développements scientifiques entraînent, en retour et souvent sans délai, des applications. Durant la seconde moitié du vingtième siècle, informatique et biologie en furent de parfaites illustrations.
La connaissance et la compréhension structurée du monde permettent d'agir et de produire des outils, eux-même ensuite indispensables à l'approfondissement des connaissances. Ce mouvement de va-et-vient s'est accéléré.
Entre science et technique, deux jumelles de la modernité, l'informatique a un temps occupé une place ambigüe. Perçue tout d'abord, bien à tort, par ceux dont la vue était si courte, comme simple outil technique, elle se constitue en science majeure, proposant un modèle formel, d'abord utile, puis nécessaire, et finalement indispensable à la compréhension du monde.
En ce sens, elle induit une philosophie purement spéculative, même si tous les informaticiens ne sont pas alignés sur les mêmes positions.

Curieusement, fait qui fut si tardivement perçu par les mathématiciens eux-mêmes, et non sans résistances -hélas, ce fut le cas surtout en France- l'ordinateur est un outil puissant, permettant des investigations expérimentales dont nous commencons seulement à entrevoir les possibilités.

Comment ne pas voir que ce modèle n'est pas contraire aux idéaux hypothético-déductifs de l'antiquité grecque, ni à ceux de Hilbert (et non pas Gilbert comme le propose un correcteur orthographique), Gödel, ou même du monstre polycéphale, Bourbaki. Tout au contraire, outil d'une continuité, il en est le produit, les précise, les prolonge d'une manière magistrale, permettant enfin de les mettre en oeuvre.
Nous avons donc fait l'hypothèse réductrice que l'utilisation des machines à calculer et de leurs périphériques à venir appartient au domaine des mathématiques déterministes, fussent-elles considérées comme appliquées.
C'est dire que se développe aussi une science expérimentale au sein même du corps des mathématiques, ce qui finalement nous occupe, ce que nos maîtres, hier, ont aveuglément méprisé, ouvrant une voie royale à des dominations très américaines, qui n'avaient pas les même scrupules.
Grâce aux moyens de calcul, et face aux insuffisances criantes de la théorie, les programmes de simulation se sont développés. Vint alors le moment où ceux-ci permirent de mettre en évidence des phénomènes devant lesquels bien des mathématiciens, même français, demeurèrent muets, souvent incrédules, méprisants même. Vous constaterez que les premiers programmeurs eurent un peu plus d'humour. Pourvu que ça doure!

Il est par ailleurs frappant de constater que

non seulement les techniques et les sciences du calcul -par exemple la théorie des automates et des langages formels, initialement érigée par des probabilistes- se sont développées de manière concomitante aux techniques et sciences de la biologie,

mais encore que les fondements de la biologie moderne, le décryptage, dans les années cinquante, du code génétique comme support strictement typographique de l'information nécessaire à la reproduction, au développement, et au fonctionnement des êtres vivants, et ce qui s'en est suivi, c'est-à-dire le modèle de la glorieuse cellule vivante comme stupéfiante et minuscule usine, complexe automatisé,

avec ses centrales énergétiques, les mitochondries, ses usines d'assemblages, les ribosomes, ses stations d'épuration, les lysosomes- obéissant à un programme intégré, quasi-auto-reproducteur, et même, ce n'est pas le moindre, mais c'est ce qui pose le plus de questions, générateur de nouveautés si imprévues qu'elles en paraissent aléatoires,

font que le cadre formel à l'intérieur duquel la biologie se construit est, depuis, spectaculairement calculatoire et informatique. Par exemple, déjà des dizaines de maladies génétiques identifiées concernant les seuls lysosomes, perturbant de diverse manière le fonctionnement de ces automates complexes que sont les cellules.
Il est faux que l'humanité progresse en copiant la nature. Conception bien naïve. L'humanité ne progresse qu'en s'opposant à l'inhumaine nature.
Pas de roue dans la nature, pas de métallurgie, pas de moteur à explosion, ni ordinateur ni téléviseur, pas d'avion qui tienne l'air en copiant le vol des oiseaux, aucune mine de théorèmes. Copier ne mène à rien, il faut inventer.
Il a fallu procéder de manière axiomatique, imaginer des hypothèses, en déduire des conséquences, les confronter aux résultats d'astucieuses expériences, si ambigües et si malaisées à interpréter, fonder des théories, formelles et, surtout, jetables.
Lorsque Pasteur fabrique un vaccin contre la rage, dont il n'a jamais vu l'agent causal (qui ne fut identifé, grâce au microscope électronique, que vers le milieu du vingtième siècle, par un japonais), c'est le produit d'intuitions exceptionnelles converties en hypothèses simples et formelles, étayées d'expériences itérées, sans cesses imaginées, tellement il se méfie de ce qu'il voit. Il étaye ses convictions, les axiomatise, et finalement, il en résulte miraculeusement une capacité de prévision.
Cependant, lorsqu'il démontre, en 1881, à Pouilly-le-fort, en deux jours, l'efficacité de la vaccination des moutons contre la maladie du charbon, c'est dû au travail d'une collectivité, c'est que Emile Roux a préparé le vaccin, selon les méthodes utilisées par Greenfield et Toussaint l'année précédente, et l'histoire ne retient que le nom de Pasteur, car l'on ne prête qu'aux riches, et seule la médiatisation compte.

La géométrie n'est pas la simple description de l'espace physique, l'algèbre s'est séparée des nombres concrets, et les infinis qui gouvernent les mathématiques ne se rencontrent pas au coin de la rue. Bizarrement, si les mathématiques ont induit si peu d'applications pratiques, des siècles durant, il n'en va plus de même.
Désormais, elles ne cessent de régner sur les techniques.

Vous ne pourrez éviter que l'on vous pose la question du rapport au calcul formel informatisé de mystérieuses notions très floues, comme celle d'intelligence. Si vous faites de l'informatique, vous ne pourrez éviter de vous heurter à des questions sans réponse qui concernent aussi la biologie. La stupidité consiste à imposer de choisir entre deux hypothèses méthaphysiques, celle de l'existence des dieux, et celle des philosophes darwiniens, postulant que seul le hasard est le moteur de l'évolution. Deux hypothèses, au fond équivalentes, et d'ailleurs également invérifiables. Devant l'improbable émergence de la vie sur la terre, certains essaient de mesurer cette faible probabilité. Tentative vaine, car nous pouvons postuler à notre tour qu'elle est rigoureusement nulle, que la réalité est de probabilité strictement nulle.
Alors que nos machines à calculer sont des automates finis, la réalité peut se concevoir comme un complexe immergé, et réalisé, dans quelque infini des possibles.

Pas de réponse, non plus, à propos de constructions mathématiques, à la lancinante et naïve question: "à quoi cela sert-il ?". Nous n'en savons rien.

Bien que les programmes de simulation se multiplient, dans tous les domaines, ils se heurtent à des difficultés considérables, dès la représentation même des objets dont on veut simuler la forme et l'évolution. En biologie moléculaire, par exemple, la représentation spatiale non-ambigüe des molécules -et spécialement celle des protéines- géométrie dont on sait l'importance depuis le cristallographe qu'était Louis Pasteur tentant la synthèse de la vie, c'est un problème très actuel.
Les techniques du moment font un grand usage de suites de caractères, et des omniprésentes structures arborescentes. Cette contrainte radicale, de devoir tout représenter, matériellement -ou abstraitement- par des suites de caractères typographiques, a induit une école d'informatique théorique qui est précisément centrée sur l'étude des propriétés combinatoires des suites de caractères.
Ce qui suit peut être considéré comme une douce incitation en direction de ces disciplines, formellement de tendance linguistique, au sens large.

Bien que les structures mathématiques utilisées soient dans l'ensemble simples et même, peut-il sembler, très primitives, les problèmes soulevés n'en sont pas moins extraordinairement difficiles. Autrefois, les combinatoriciens se préoccupaient, de temps à autre, de compter.

Désormais, sous l'aiguillon de la technique informatique, cela ne suffit pas, il faut préalablement engendrer. C'est la mission première confiée à la linguistique combinatoire: représenter (coder), ordonner, et énumérer, avant même que de dénombrer et transformer. Voilà un état d'esprit exigeant et relativement nouveau, et aussi une manière d'aborder les probabilités et les statistiques. Nous nous plaçons là résolument dans une perspective où le hasard n'existe pas. En postulant délibérément que tout est déterminé, nous supposons que l'aléatoire physique ou biologique est soit l'effet de processus dont nous ignorons le déterminisme, soit la propriété de fonctions suffisamment chaotiques pour que nous ne sachions pas vraiment les analyser. C'est une position métaphysique.

Les machines à calculer digitales ont un gros avantage: les programmes sont en général déterministes: soumises aux mêmes données initiales, les récurrences définies par tel programme calculent la même suite d'états, à condition toutefois de procéder avec rigueur, le même nombre de chiffres significatifs, les mêmes procédures de service, telles les troncatures et arrondis, etc...
Les bons programmes se devraient d'être portables, universels, en ce sens que le résultat ne devrait pas dépendre du calculateur sur lesquels ils sont exécutés. Au minimum, qu'ils s'adaptent, automatiquement, à la résolution de la machine sur laquelle ils sont exploités. Le calcul digital étant d'un déterminisme absolu, les pseudos-hasards engendrés risquent d'être perçus comme des artefacts.

Nous l'avons déjà souligné: la croyance au Hasard comme moteur de phénomènes physiques, chimiques, ou biologiques est une position métaphysique. Ces concepts sont hors du champ scientifique, et ce serait un postulat improductif que de considérer le hasard comme une cause. D'ailleurs, les probabilités et statistiques ne disent rien sur le hasard: elles se contentent d'évaluer les tailles relatives des parties d'un ensemble, classées selon quelque propriété. C'est de cette manière que nous considérerons, modestement, par exemple, le classement, l'énumération, le dénombrement statistique de permutations et d'arborescences.

Le fait que la technologie actuelle privilégie un système de numération particulier n'est pas sans effet sur certains résultats produits. C'est une des raisons pour laquelle on observera avec circonspection les résultats produits par des calculs menés en représentation flottante.

Insistons: ne pas perdre de vue qu'un programme déterministe n'est en principe, si l'on n'y introduit pas de phénomène pseudo-aléatoire, que l'itération, à partir d'un état initial, d'une application d'un ensemble fini dans lui-même. Si aucun phénomène physique perturbateur, accidentel -imprévisible ou qualifié d'aléatoire- n'intervient au décours du calcul automatisé (comme, par exemple, la lecture d'une tension électrique erratique), toute suite calculée est ultimement périodique, et l'observation de cette période par un méta-programme signe nécessairement la limite du calcul (la période est souvent le résultat même du dit calcul).
En ce sens, toute exécution de programme converge vers un ensemble fini.

Il n'est guère traité ici de la structure des ordinateurs.
Ce n'est pas notre propos, bien que l'on convienne qu'il soit tout aussi important de connaître ce qui constitue les machines que de savoir les utiliser. De même que l'entomologiste peut disséquer les insectes, ou se contenter d'observer leur comportement, vous pouvez réduire les machines à calculer à leurs composants, ou observer l'usage qui en est fait. Il y a d'ailleurs une éthologie de l'informatique -et des informaticiens-.

Quelques dégâts.
On se méfiera de l'usage d'anglicismes mal compris, si fréquent désormais, et même source d'égarements épistémologiques. Je ne puis m'empêcher de penser à l'utilisation du mot "falsifiable", emprunté à Karl Popper. Dans ce méchant jargon, on qualifie une théorie de "non falsifiable" pour signifier qu'elle n'est pas scientifique parce qu'elle qu'elle n'est pas réfutable. On enfonce des portes ouvertes. En effet, chacun sait que le propre des théories scientifiques est d'être transitoires: on convient qu'elles peuvent être démenties à tout moment, et, de fait, elles le sont à un moment ou un autre. Le destin des dogmes est de s'effondrer.

En biologie les dogmes s'effondrent constamment.Tandis que les croyances ne se réfutent pas. Il a été dit que la science exigeait l'expérimentation, et qu'elle devait prédire. Elle a aussi soif de rigueur, plus que de bons sens. Parce que des théories imaginées et confrontées aux faits expérimentaux produisent des résultats contraires au sens commun. C'est pourquoi la démarche rationnelle cherche à étayer nos convictions, par des preuves, et les prédictions sont confrontées à la réalité. C'est son honneur, de ne pas se satisfaire de croyance voulues irréfutables.

Constater que les dogmes évoluent, c'est souligner le fait que les preuves et prédictions produites par les sciences n'ont de valeur qu'à l'intérieur d'un système formel que l'on peut convoquer ou révoquer, plus distinct de la réalité qu'il n'en serait la copie.
Les disciples de Freud expliquent le monde par la sexualité, ceux de Marx par l'argent, ceux de Darwin par le hasard, les religions par les dieux, les informaticiens par les automates. Tous les dogmes ont engendré, et engendreront sans doute, leur lot d'abominations.

Jusqu'à ce jour, les mathématiques dépendaient peu de l'expérimentation mécanique; l'émergence de puissantes machines à calculer change cela.
Bien que les explications scientifiques soient tout aussi mystérieuses et miraculeuses que les explications mythologiques, elles ont l'avantage -ou l'inconvénient, c'est selon- d'être jetables, du fait que, confrontées d'une part à l'expérimentation et d'autre part à la cohérence de systèmes formels, elles évoluent sous cette double impulsion. Leur puissance réside dans ce fait qu'elles ne sont des vérités ni révélées ni absolues, mais, répétons le, relatives et transitoires.

On réfléchira à la curieuse corrélation qui peut exister entre la conception du droit dans telle société et l'état de l'esprit scientifique. En ce qui concerne ces deux domaines -que l'on pourrait imaginer sans lien- on peut cependant comparer la rigueur de la recherche de la preuve à la rigueur des efforts pour éliminer les contradictions sociales et les injustices. Dans les deux cas, on se préoccupe d'hypothèses et de vérité, on recherche des preuves afin d'étayer des certitudes rongées par le doute. Le défaut de rigueur, le mépris dans l'application des lois, s'accompagnent de l'arbitraire administratif ordinaire, générateur de haine, lequel est le signe le plus sûr du retour de tyrannies qui toujours nous menacent. Hélas, les ordinateurs sont un puissant moyen au service d'un pouvoir gestionnaire, destructeur de consensus, si bien que la corruption des esprits peut apparaître comme le seul moyen d'y échapper. Nous voici incertains: peut-être sommes nous menacés par le règne de la sauvagerie technique et bureaucratique, qui est l'exclusion de la science et de l'ordre légal. A cette époque où nous voyons des politiciens automatisés incapables d'exposer sans lire leurs papiers, nous ne sommes plus que des numéros.

Devons nous, fuite en avant, placer quelque espoir dans le règne des ordinateurs, désormais également capables eux aussi de lire et de parler ? Certes non; puisqu'ils sont plus périssables que toute autre technique, nos fichiers digitalisés ne traverseront pas les siècles. Tandis qu'à Versailles une horloge construite en 1746 fonctionne sans discontinuer. En ce temps où il devient si difficile de dialoguer avec des bureaucrates autistes, qui usent de pouvoirs administratifs arbitraires, irresponsables, désordonnés et dysfonctionnants, la tentation est forte de préférer être gouvernés par des machines. Celles-ci ne se révéleraient-elles pas encore plus obtuses? Ou, d'une certaine manière, ne gouvernent-elles pas, déjà ? Les informaticiens en sont en tout cas, pour une part, responsables, eux qui sont les servants des machines. Ils ne sont pas dispensés d'une réflexion sur l'état du monde, et de l'usage qui est fait, par ceux qui prétendent gérer au nom de tous, du puissant outil qu'ils servent.

Comme disait Léo Ferré, Einstein s'amuse avec des équations, et nous les prenons sur la gueule. De la manière même que les biologistes ne peuvent se désintéresser de l'usage qui est fait de leurs trouvailles. Or, nous sommes à l'ère où le pouvoir de contrôle, d'oppression, de délation, dont disposent les états, devient considérable, du fait de ces moyens techniques confisqués, dont ils useront et abuseront inévitablement, soyons en sûrs, aux mains de partis constitués en mafias qui se parent de la loi. Comme le dit l'écrivain italien Claudio Magris, nous sommes les premiers à avoir le sentiment de vivre mieux que les générations passées, mais également mieux que les générations à venir.

Le qualificatif scientifique a été interprété, détourné, dévoyé par des disciplines qui n'en relèvent nullement. On s'interrogera avec profit sur le statut scientifique de la mathématique et de l'informatiques, à l'aune de la formalisation, de l'expérimentation, de la rigueur, de la prévision. Sur la valeur et la portée des preuves. Une discipline dite scientifique ne consiste pas exclusivement en la méthode: encore faut-il que l'objet même de nos préoccupations soit susceptible d'étude rigoureuse, car les charlatans peuvent appliquer quelque méthode stricte et formelle à tout, et à n'importe quoi, à l'ésotérisme et à la divination.

Terminons.

L'investigation du monde physique devient plus en plus éloignée de nos intuitions au fur et à mesure de son exploration en direction du tout petit (la mécanique quantique) ou du très grand (la cosmologie).
Nous demeurons à un niveau d'intuition bien plus banal.
Ces trois parties, trace de ce qui ne fut qu'un support de cours à l'usage de futurs informaticiens, représentent un ensemble serré d'environ huit cent pages. On voudra bien me pardonner d'éventuelles répétitions -lesquelles peuvent malgré tout avoir un intérêt pédagogique- mais surtout les inévitables erreurs, fussent-elles d'inattention.
J'insiste sur le fait qu'il ne s'agit pas d'un livre structuré avec rigueur, mais plutôt d'une collection hétéroclite de sujets utilisés en cours, d'exercices, de suggestions, anacoluthes entremêlés, qui ne remplaceront nullement un cours rigoureux, ni de mathématiques, ni de combinatoire, ni de linguistique, ni d'informatique pratique. Le prendre comme un outil de travail, au carrefour de ces disciplines.

Initialement saisi et programmé avec des moyens minimaux sur une machine Atari, une part de ce texte a ensuite été artisanalement et malaisément porté, puis augmenté, sur une machine Apple-Macintosh. Bien que relue, cette première transcription a bien dû laisser passer des erreurs. S'il n'y a pas de table des matières, c'est que ce support fut un objet vivant constamment évolutif, constitué de sédiments successifs, et sans doute criblé d'erreurs en tous genres.
En voici la trace, chiasmes par endroit cohérents, et à d'autres erratiques.
Finalement, du vrac, à l'usage de ceux qui aiment, avec des exercices, très mélangés, et de difficultés extrèmement variable, du plus simple au plus compliqué. Un outil de travail, désordonné. Certains thèmes sont largement développés, d'autres à peine effleurés, ou seulement suggérés. Beaucoup d'exercices, divers, sont souvent totalement résolus, parfois seulement esquissés ou suggérés, d'autres étant seulement l'occasion de faire état de conjectures qui résisteront encore longtemps

Les deux acronymes suivants seront utilisés, et éventuellement rappelées dans le cours du texte:
- càd signifiera "*c'est-à-dire*" (en place de la locution latine i.e.)
- ssi signifiera "*si et seulement si*"

Enfin, attirons l'attention sur ceci:

(i,j) sera souvent la simple notation *du coefficient binomial* n! / (i!j!), nombre de bipartitions d'un ensemble de n=i+j éléments en un couple de deux parties de i et j élément, nombre interprété comme comptant les mots du mélange d'un mot de i lettres et d'un mot de j lettres;

les nombres de catalan seront généralement initialisés par c(1)=1=c(2), lorsqu'ils dénombrent les arbres binaires ou les mots polonais, et parfois par c(0)=1=c(1) lorqu'ils comptent les mots de parenthèses. Il aurait certainement été utile d'introduire les apocopes Cat(1)=1=Cat(2) et Bin(i,j)=(i+j)! / (i!j!).

[n] notera l'ensemble (1,2...,n) naturellement ordonné des entiers de 1 à n.
[0,n] notera l'ensemble (0,1,2...,n) naturellement ordonné des entiers de 0 à n.

Par exemple la notation D=(e, r, srr, rr....) désignera un ensemble ordonné
et D=e+ r+ srr+ rr.... une série formelle.

En ce qui concerne les suites d'entiers, si présentes,
vous consulterez avantageusement, à chaque occasion, la référence imprimée

"The encyclopedia of integer sequences",
le dictionnaire de Sloane et Plouffe de 1995, suite du livre de 1973 de N.J.A.Slaone
"A Handbook of Integer Sequences"
et surtout, désormais, la référence électronique,
" **the On-Line Encyclopedia of Integer Sequences**",

l'impressionnante, volumineuse bible structurée de données en ligne, accessible à tous de par le monde, que nous livre Neil Sloane (est-il Prométhée ou Sisyphe ?), qui y a consacré sa vie, laquelle base enfle journellement, et dangereusement peut-être, mais stimule la réflexion, et incite à un constant travail de synthèse,
puisque la quantité finit par en modifier la qualité.

Cette base de données était hébergée par la compagnie américaine American Telephone and Telegraph. En cette fin d'année 2001, nous apprenons que ce relatif mécénat est menaçé. Nous sommes dans l'attente de ce qui va advenir de cette base...et de Sloane lui-même.

Les personnes curieuses de propriétés baroques des nombres (particulièrement des entiers) consulteront au moins une fois avec profit quelques vieilleries comme le petit catalogue précurseur édité en 1983, et rédigé en français, ce qui devient rare, des remarquables François Le Lionnais et Jean Brette, "Les nombres remarquables", compilation d'une vie. Les vieux livres d'Edouard Lucas (vers 1890, dont la postérité est principalement américaine, Lucas a été "notoirement méconnu"), également des vieilleries en bon français, livres relatifs à l'arithmétique, à la combinatoire, et aux distractions mathématiques, n'ont rien perdu de leur fraicheur, et bien que le monde ait changé, ils demeurent utiles à l'enseignement, du fait même, sans doute et surtout, de leur style obsolète. Si vous vous voulez plus moderne, consulter des sites comme Mathworld (sorte d'encyclopédie mathématico-combinatoire), ou Mathpuzzle (journal d'actualités bizarres et variées), et bien d'autres, référencés par ceux-ci, évidemment quasi-exclusivement, hélas, en langue anglaise. Adressons nous cependant à ceux qui n'ont pas encore abandonné la langue française, scientifiquement en voie de disparition. Ils avaient une belle langue, et ils l'ont trahie. Si la colonisation est d'abord culturelle, c'est qu'elle sonne le glas d'une civilisation qui ne croit plus en elle. A l'heure de la paradoxale promotion des langues régionales, comment penser que la France soit capable de défendre ses intérêts vitaux, puisqu'elle n'est pas même capable de défendre sa propre langue chez elle, puisque ses scientifiques ne publient pas en français, puisque certaines de ses régions prétendent exclurent la langue française de leurs écoles.

Les élites ne pouvent servir leur peuple qu'en s'incorporant la science, de manière quasi obsessionnelle, ce qui ne peut se faire pour chacun qu'en la pensant dans sa langue maternelle, en instruisant son peuple tout d'abord dans sa langue maternelle; c'est particulièrement facile en ce qui concerne les concepts mathématiques, dont les idées sont universelles, dont le vocabulaire peut et doit se recréer, avec imagination, en toute langue. Seul le langage ordinaire permet d'exprimer et d'enchaîner les idées, de transmettre les algorithmes au plus grand nombre.

Seule une langue maîtrisée et polie au contact des bons auteurs permet une bonne mise en forme, préalable nécessaire à la bonne automatisation des calculs.

Mes remerciements vont à ceux qui m'ont encouragé dans ces rédactions.
Je me suis toujours efforcé à la simplicité.
Que risquent les idées compliquées, sinon d'être tout simplement inutiles ?
Que risquent les idées simples, sinon d'être simplement fausses ?

Claude Lenormand.

The Number Of M-Sequences And f-Vectors (Make Corrections)

Svante Linusson
Combinatorica

Abstract: . We give a recursive formula for the number of M-sequences (a.k.a. f-vectors for multicomplexes or O-sequences) given the number of variables and a maximum degree. In particular, it is shown that the number of M-sequences for at most 2 variables is a power of two and for at most 3 variables is equal to the Bell numbers. The recursive formula is generalized to the number of f-vectors for general Clements-Lindstrom complexes and then specialized to the number of f-vectors for simplicial... (Update)

Abstract

The task of constructing the subsets of a set grows exponentially with the size of the set. The two most common methods of enumerating the subsets of a set, lexicographic ordering and Gray codes, in practice are sub-optimal when the sets become large. An algorithm is presented for rapidly finding the smallest subset $T_{\min} \subseteq S$ satisfying some condition P. The algorithm generates a sequence of all subsets of a set of n elements in which the number of elements in each subset is monotonically increasing. Time complexity of the algorithm is only slightly greater than that of lexicographic ordering. The algorithm will find the smallest subset containing up to $k < n$ items before either lexicographic ordering or a binary reflected Gray code sequence have even looked at all n elements in the set.

1 Introduction

The task of constructing the subsets of a set grows exponentially with the size of the set. We describe a method for generating a sequence of subsets in which the number of elements in each subset increases monotonically. No other known method of enumerating subsets generates a monotonic sequence. The method we present will find the smallest subset $T_{\min} \subseteq S$ satisfying some condition P

in much less time than either lexicographic or Gray code ordering. An algorithm is given for efficiently generating sequences of this type. The technique is applicable to the solution of Constraint Satisfaction Problems (CSP).

1.1 Paper Organization

The first part of this paper introduces the idea of enumerating the subsets of a set by means of a sequence of binary numbers. The known systematic methods of enumerating the subsets of a set, lexicographic ordering and Gray codes, are described, along with their drawbacks when sets become large. Then a new method is described, one that generates the subsets of a set in monotonically increasing order of size. An algorithm is presented for efficiently generating sequences of this type.

2 Enumerating Subsets

We can express the idea of a k-subset (T_k) of a set S having n elements by means of a n-digit binary number in which exactly k of the digits are 1 [4]. If a given element of the set $s_i \in T_k$, then the ith most-significant bit of the n-digit binary number is 1. The total number of subsets is 2^n. Thus, to enumerate $\mathcal{P}(S)$, the set of all subsets of S, it suffices to count from 0 to $2^n - 1$ in binary.

There are $2^n!$ possible sequences. As n becomes large, the order in which we construct the subsets becomes significant. A good solution must have the following characteristics:

- It must be computationally efficient.
- All subsets containing k elements should be enumerated before any subsets containing $k+1$ elements; and furthermore, the number of elements in each subset should be monotonically increasing.

The two most commonly used methods of enumerating the subsets of a set are lexicographic ordering and Gray codes [2]. Unfortunately, neither of these methods satisfies the second requirement. We will shortly describe a new method that does.

2.1 Lexicographic Ordering

Lexicographic ordering is simply the familiar counting sequence

$$1, 2, 3, \ldots, 2^n - 1.$$

Table 1 shows a lexicographic sequence, and Figure 1 illustrates how the size of the subset varies over time. The problem with lexicographic ordering is that it never considers the last element in the set until halfway through the sequence. If you have a set of n items, you must construct 2^{n-1} permutations of the first $n - 1$ items before even considering the nth item in the set. The performance of this sequence for large values of n is poor.

Table 1: Subsets in lexicographic order. The last item in the set, represented by the most significant bit of the binary representation, is not even considered until halfway through the sequence. If the number of elements in the set is large, this could take a very long time.

Binary Number	*Subset of* { ∘, ◇, ⋆, ● }
0000	ϕ
0001	{ ∘ }
0010	{ ◇ }
0011	{ ∘, ◇ }
0100	{ ⋆ }
0101	{ ∘, ⋆ }
0110	{ ◇, ⋆ }
0111	{ ∘, ◇, ⋆ }
1000	{ ● }
1001	{ ∘, ● }
1010	{ ◇, ● }
1011	{ ∘, ◇, ● }
1100	{ ⋆, ● }
1101	{ ∘, ⋆, ● }
1110	{ ◇, ⋆, ● }
1111	{ ∘, ◇, ⋆, ● }

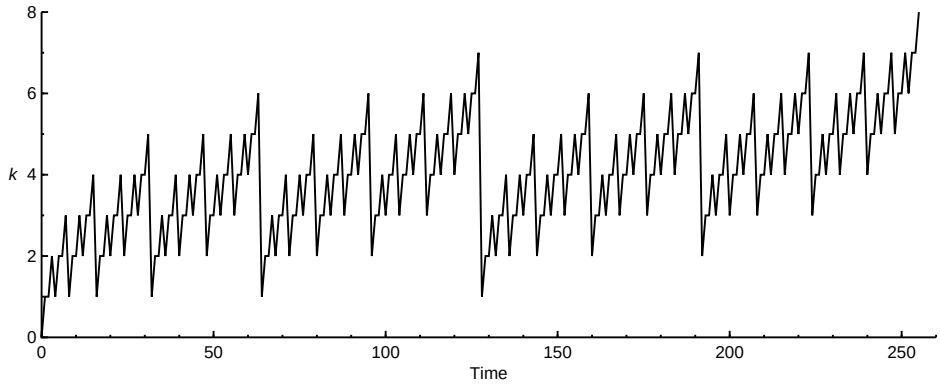

Figure 1: Lexicographic ordering amounts simply to counting in binary.

2.2 Gray Codes

Gray codes are a rearrangement of the binary numbers such that adjacent values differ in exactly one bit position[1]. There are many such sequences; the one shown here is called a *binary reflected Gray code*. A Gray code sequence is computationally optimal in the sense that it minimizes the number of set operations required. Any subset in $\mathcal{P}(S)$ can be constructed from its immediate predecessor in the sequence merely by adding or removing one item. But Table 2 shows that the Gray code sequence is no better than lexicographic ordering when it comes to constructing a reasonable sequence of subsets. (Figure 2 shows this behavior geometrically.) As in lexicographic ordering, the nth element in the set is not even considered until 2^{n-1} subsets have already been constructed. The performance of this method for large values of n is also poor.

Table 2: Subsets in Gray code order. Just as was the case with a lexicographic sequence, the last item in the set, represented by the most significant bit of the binary representation, is not even considered until fully half of all possible subsets have been examined.

Binary Number	*Subset of* { ∘, ◇, ⋆, • }
0000	ϕ
0001	{ ∘ }
0011	{ ∘, ◇ }
0010	{ ◇ }
0110	{ ◇, ⋆ }
0111	{ ∘, ◇, ⋆ }
0101	{ ∘, ⋆ }
0100	{ ⋆ }
1100	{ ⋆, • }
1110	{ ◇, ⋆, • }
1111	{ ∘, ◇, ⋆, • }
1101	{ ∘, ⋆, • }
1001	{ ∘, • }
1011	{ ∘, ◇, • }
1010	{ ◇, • }
1000	{ • }

2.3 Banker's Sequence

If n is large, then systematically constructing all 2^n subsets of S can take a while. If the problem is to find the smallest subset $T_{\min} \subseteq S$ that satisfies some

[1] One way of constructing an n-bit Gray code is to find a Hamiltonian path through adjacent vertices of an n-dimensional hypercube with sides of length 1.

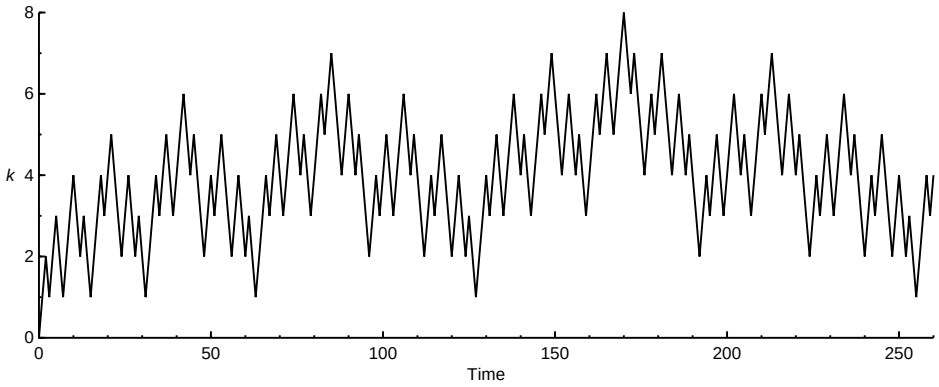

Figure 2: Gray codes are computationally optimal, but they share the weakness of lexicographic ordering that not all members of the set are examined until the sequence is half finished.

predicate P, then we would like to examine subsets in monotonically increasing order by size.

Consider the ordering presented in Table 3, in which we examine the subsets of S in order by the number of elements in each subset. Ideally we would like to examine all k-subsets before considering any subsets of size $k+1$ or larger. So we first construct all the subsets consisting of a single element. Then we examine all 2-subsets, all 3-subsets, and so on, until $k \rightarrow n$ and we have constructed all 2^n subsets.[2]

The new sequence, being a permutation of the numbers between 0 and 2^n-1, depends on n; for $n = 6$, one such sequence (in decimal) is:

$$\begin{aligned} B_6 \quad = \quad & \{0, 32, 16, 8, 4, 2, 1, \\ & 48, 40, 36, 34, 33, 24, 20, 18, 17, 12, 10, 9, 6, 5, 3, \\ & 56, 52, 50, 49, 44, 42, 41, 38, 37, 35, 28, 26, 25, 22, 21, 19, 14, 13, 11, 7, \\ & 60, 58, 57, 54, 53, 51, 46, 45, 43, 39, 30, 29, 27, 23, 15, \\ & 62, 61, 59, 55, 47, 31, 63\}. \end{aligned} \tag{1}$$

No reference to this sequence was found in the literature [1, 3]. We refer to this ordering as a Banker's sequence, because it was discovered while looking for a solution to the problem of matching "adjustments" in a bank's books at the end of the day. Figure 3 illustrates how the sequence proceeds systematically through increasingly larger subsets of S.

[2]or until we find a solution, or until we run out of time.

Table 3: Banker's sequence. Every element of the set is examined within the first n iterations. Correspondingly larger subsets are constructed in monotonically increasing order of size.

Binary Number	*Subset of* { ○, ◇, ⋆, ● }
0000	ϕ
1000	{ ○ }
0100	{ ◇ }
0010	{ ⋆ }
0001	{ ● }
1100	{ ○, ◇ }
1010	{ ○, ⋆ }
1001	{ ○, ● }
0110	{ ◇, ⋆ }
0101	{ ◇, ● }
0011	{ ⋆, ● }
1110	{ ○, ◇, ⋆ }
1101	{ ○, ◇, ● }
1011	{ ○, ⋆, ● }
0111	{ ◇, ⋆, ● }
1111	{ ○, ◇, ⋆, ● }

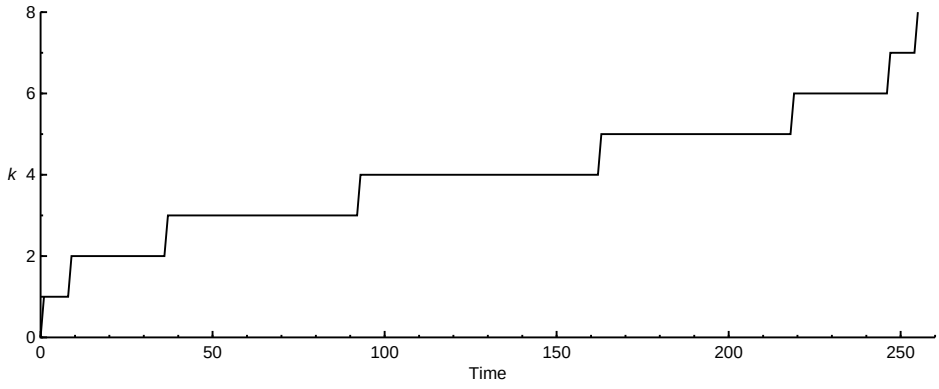

Figure 3: The banker's sequence looks at the smaller subsets first.

3 Efficiently Enumerating Subsets

Neither lexicographic ordering nor Gray codes are particularly well suited to looking for a *minimum* subset. Both sequences will eventually enumerate $\mathcal{P}(S)$, but they tend to waste a lot of time up front constructing large subsets. For $n = 100$, there are 2^{100} subsets, about 10^{30}. Assuming a computer capable of checking 10^8 subsets per second, a Gray code solution would require about 10^{22} seconds, or about 4×10^{14} years to complete. The running time of a lexicographic ordering is about twice that. The problem is computationally intractable without an intelligent method of ordering.

Table 4 shows the number of set operations (bit transitions) required to completely search a smaller set of $n = 30$ elements. The running time of the banker's sequence is comparable to that of a lexicographic ordering. However, the banker's sequence is guaranteed to find the smallest subset of up to $k \leq 29$ items before either of the other two orderings have even finished examining all $n = 30$ items in the set.

Table 4: Comparison of the running times of three different algorithms for a set of $n = 30$ elements.

Method of Ordering	*Total Bit Transitions*
Gray Code	1,073,741,824
Lexicographic	2,147,483,617
Banker's Sequence	2,863,311,486

4 Generating a Banker's Sequence

There are many ways to generate a banker's-type sequence. The following algorithm, which generates a Banker's sequence for a set of n items, implements it in one possible way.

```
#include <iostream.h>
#include <stdlib.h>

void output(int string[], int position);
void generate(int string[], int position, int positions);

int length;

// This function takes "string", which contains a description
// of what bits should be set in the output, and writes the
// corresponding binary representation to the terminal.
// The variable "position" is the effective last position.
```

```
void
output(int string[], int position)
{
  int * temp_string = new int[length];
  int index = 0;
  int i;

  for (i = 0; i < length; i++)
  {
    if ((index < position) && (string[index] == i))
    {
      temp_string[i] = 1;
      index++;
    }
    else
      temp_string[i] = 0;
  }

  for (i = 0; i < length; i++)
    cout << temp_string[i];

  delete [] temp_string;
  cout << endl;
}

// Recursively generate the banker's sequence.

void
generate(int string[], int position, int positions)
{
  if (position < positions)
  {
    if (position == 0)
    {
      for (int i = 0; i < length; i++)
      {
        string[position] = i;
        generate(string, position + 1, positions);
      }
    }
    else
    {
      for (int i = string[position - 1] + 1; i < length; i++)
      {
         string[position] = i;
         generate(string, position + 1, positions);
```

```
      }
    }
  }
  else
    output(string, positions);
}

// Main program accepts one parameter: the number of elements
// in the set.  It loops over the allowed number of ones, from
// zero to n.

int
main (int argc, char ** argv)
{
  if (argc != 2)
  {
    cout << "Usage: " << argv[0] << " n" << endl;
    exit(1);
  }
  length = atoi(argv[1]);

  for (int i = 0; i <= length; i++)
  {
    int * string = new int[length];
    generate(string, 0, i);
    delete [] string;
  }
  return (0);
}
```

4.1 How the Algorithm Works

The algorithm works by... (*need table from Jano for explanation*).

Interestingly, the sequence generated by Algorithm 1, expressed in binary, is bitwise symmetric about the middle, sort of like a binary reflected Gray code.

5 Conclusions and Future Work

We presented a method for generating a sequence of subsets in which the number of elements in each subset increases monotonically. There is no other known method of enumerating subsets that generates a monotonic sequence. The method we presented is useful for finding the smallest subset $T_{\min} \subseteq S$ that satisfies some condition P. It will find a solution much faster than either lexicographic or Gray code ordering, because it avoids generating reams of large subsets until it has examined all of the smaller possible subsets first.

An algorithm was presented for efficiently generating sequences of subsets in monotonically increasing order by size. The technique is applicable to the solution of Constraint Satisfaction Problems (CSP).

In the future it would be nice to have a direct mapping from the natural numbers $\mathcal{N}$ such that if $a_{\in\mathcal{N}} < b_{\in\mathcal{N}}$ then the number of 1's in the binary representation of a is less than the number of ones in the binary representation of b.

I

In al hun verscheidenheid zijn wiskundigen op één punt tamelijk eensgezind, namelijk in hun, wat Freud omschreef als, "narcisme van het kleine verschil".

II

[1, 2, 3] Beschouw het vierkant rooster $\mathbb{Z}^2$, en verbind horizontaal of verticaal aangrenzende punten met weerstanden van 1Ω. De vervangingsweerstand tussen de punten $(0,0)$ en (n,m) is dan

$$R(n,m) \;=\; \frac{1}{2} \sum_{\substack{\text{Alle paden be-}\\ \text{ginnend in } (0,0)}} \frac{1}{4^{\text{padlengte}}} \times \begin{cases} 1 \text{ als het pad eindigt in } (0,0) \\ -1 \text{ als het pad eindigt in } (n,m) \\ 0 \text{ in alle andere gevallen} \end{cases}$$

$$= \frac{1}{\pi^2} \int_0^\pi \int_0^\pi \frac{1 - \cos nt \cdot \cos ms}{2 - \cos t - \cos s} \mathrm{d}t\mathrm{d}s$$

$$= \frac{1}{2\pi i} \int_{-i}^{i} \frac{2}{1+u^2} - \frac{(u+1)^n u^n}{(1+u^2)(u-1)^n} \left\{ \frac{u^m (1-u)^m}{(1+u)^m} + \frac{(1+u)^m}{u^m (1-u)^m} \right\} \mathrm{d}u.$$

(De pad-som convergeert voorwaardelijk; de termen dienen gegroepeerd te worden naar padlengte. De laatste integraal geldt voor $n \geq 0$, en het integratiepad dient het punt $u = 0$ links te passeren indien $m > n$.)

In het bijzonder is $R(1,0) = \frac{1}{2}$, en $R(n,n) = \frac{2}{\pi}\left(\, 1 + \frac{1}{3} + \cdots + \frac{1}{2n-1} \,\right)$.

III

[4] Maak twee vergissingen, en je hebt de nijlpaarden aan het dansen.

IV

[5] Voor elke n reële getallen $b_1, \ldots, b_n$, niet allemaal nul, geldt de volgende ongelijkheid:

$$\left(2\sin\frac{\pi}{2(n+1)}\right)^4 \leq \frac{\sum_{k=1}^{n}(b_{k-1}-2b_k+b_{k+1})^2}{\sum_{k=1}^{n}b_k^2} \leq \left(2+2\cos\frac{\pi}{n+1}\right)^2,$$

waarbij $b_0 = b_{n+1} = 0$. Deze ongelijkheid kan niet worden aangescherpt.

V

[6] Niet alleen wiskundigen abstraheren met plezier.

VI

[7, 8] Zij a_n het n-de getal in Peter Hendriks' binaire variant van Conway's audioaktieve reeks, ook bekend als de *look-and-say sequence*, die begint met

a_0:	1	1 één,
a_1:	11	2 enen,
a_2:	101	1 één, 1 nul, 1 één,
a_3:	111011	3 enen, 1 nul, 2 enen,
a_4:	11110101	4 enen, 1 nul, 1 één, 1 nul, 1 één,
a_5:	100110111011	(etc.)

Het aantal cijfers waaruit a_n bestaat is gelijk aan

$$\left(\frac{8}{9}+\frac{1}{18}\sqrt[3]{748-36\sqrt{93}}+\frac{1}{18}\sqrt[3]{748+36\sqrt{93}}\right)\times$$
$$\left(\frac{1}{3}+\frac{1}{6}\sqrt[3]{116-12\sqrt{93}}+\frac{1}{6}\sqrt[3]{116+12\sqrt{93}}\right)^n,$$

naar beneden afgerond op een geheel getal, behalve voor $n = 2$ en $n = 3$.

VII

[9] Zij $B_n := (\mathbb{Z}/2\mathbb{Z}) \oplus (\mathbb{Z}/2\mathbb{Z}) \oplus \cdots \oplus (\mathbb{Z}/2\mathbb{Z})$ (n termen); $B_n \subset B_m$ $(n < m)$ door rechts toevoegen van nullen; $B := \cup_{n\in\mathbb{N}} B_n$.
Zij $\pi_n : B \to B_n$ de canonieke projectie.
Zij P_n de groep van permutaties van B_n; $P_n \subset P_m$ $(n < m)$ door rechts als de identiteit te laten werken; $P := \cup_{n\in\mathbb{N}} P_n$.
Zij $L_k := \{\sigma \in P | \exists n : \sigma \in P_{n+k}$ en $\forall \beta \in B : \pi_n \sigma \beta = \pi_n \beta\}$ (k-lokale permutaties).
Zij $c_k(\sigma) := \min\{m \in \mathbb{N} | \exists(\sigma_1, \ldots, \sigma_m) \in L_k^m : \sigma_1\sigma_2\cdots\sigma_m = \sigma\}$ (k-complexiteit).
Zij $N_k(\sigma) := \{\tilde{\sigma} \in P | \forall \beta \in B : \pi_k\sigma\pi_k\tilde{\sigma}\pi_k\sigma\pi_k\beta = \pi_k\sigma\pi_k\beta\}$ (k-nepinverses).
Dan:
1. $\forall n \geq 4\ \forall \sigma \in P_n, \sigma$ een 2-cykel : $c_3(\sigma) \leq 18(n-2)^4$
2. $\forall n \geq 4\ \forall \sigma \in P_n : c_3(\sigma) \leq (2^n!)18(n-2)^4$
3. $\forall n \geq 1\ \forall k \leq n : \max_{\sigma\in P_n} c_k(\sigma) \geq \log(2^n!)/\log(2^k!(2k-1))$
4. $\forall n \geq 4 : \max_{\sigma\in P_n} c_3(\sigma) \geq n2^{n-5}$
5. $\forall n \geq 1\ \forall \sigma \in P_n\ \forall k \geq 1 : N_k(\sigma) \neq \emptyset$
6. P=NP $\Rightarrow\ \forall a \in \mathbb{N}\ \exists b \in \mathbb{N} : \max\limits_{\substack{\sigma\in P_{2n},\\ c_3(\sigma)<n^a}} \min\limits_{\tilde{\sigma}\in N_n(\sigma)} c_3(\tilde{\sigma}) = O(n^b) \qquad (n \to \infty)$

VIII

Onder invloed van het Engels worden samengestelde woorden steeds vaker los geschreven. Het gebruik van deze Engelse Spatie is besmettelijk, en met name hoger opgeleiden, onder wie velen die normaal gesproken prat gaan op een verzorgd taalgebruik, vormen vanwege hun wisselende linguïstische contacten een risicogroep.

Test by R. Jonasson : Logima Strictica : 176
Test by K. Langdon : LAIT : 173 (before 1994)
Test by N. Lygeros, Ph.D. : G-Test : 176

Is Consciousness Physical?

G. Fogleman

Many people have the intuition that consciousness cannot be merely physical. This insight can be phrased as follows: There is something about subjective conscious experience that cannot be explained by physical laws. By physical laws I mean all that we know, in a broad sense, about the laws of physics, including relativity and quantum mechanics, and all that in principle can be built up from these fundamental laws: chemistry, biology, neurophysiology. A number of present-day philosophers believe that consciousness can be fully and satisfactorily explained in terms of physical mechanisms. Others disagree and believe that there must be something non-physical about consciousness. In *The Conscious Mind*, David Chalmers reports that he conducted an informal survey and found that the ratio is about two or three to one in favor of the physicalist description.

Proponents of the view that consciousness is not physical have had great difficulty coming up with a satisfactory argument for their case. In this article I review Frank Jacksons attempt, known as the knowledge argument, and discuss some of the rebuttals that have followed.

In his 1980 article What Mary Didnt Know, Frank Jackson attempts to refute the version of physicalism that states that the world is *entirely* physical. He considers a scientist named Mary who is confined to a black-and-white environment but who has learned everything there is to know about the physics, neurophysiology, associated functional states, etc. of color. If physicalism is true, then Mary knows everything there is to know about color. However, it cannot be the case that Mary knows all there is to know about color. When she is let out of the black-and-white room or given a color television, she will learn what it is like to see something red, say. Thus, from her subjective experience of the color red she acquires new knowledge about the world, and physicalism must be false. Jackson points out that the knowledge that Mary initially lacked was knowledge about the experience of others and not about her own. After Mary is let out of her black-and-white environment, she will realize that there was something about other peoples understanding of color that she was quite unaware of. Jackson says that knowledge about this feature is knowledge about a fact, but not a physical fact.

Laurence Nemirow and David Lewis disagree. They point out that the knowledge argument assumes that knowledge of what its like must be knowledge of the way things are. This identification is wrong and results from the confusion of knowledge with ability. Knowledge of what it is like to see a color is, in effect, the ability to imagine seeing that color. Referring back to Jacksons argument, Mary does not acquire new knowledge, but only new abilities. Thus the completeness of the physicalist description is not threatened. Some abilities are not expressible linguistically (e.g., how to wiggle your ears or ride a bicycle) and can only be learned by, say, trial and error, after having the basic idea pointed to through use of related concepts that are already available. There are some cases, e.g. the case of trying to explain the sensation of red to a blind person, where no related concepts are available and the attempts to express the new concept linguistically are doomed to failure. This does not appear, however, to cause any problems for physicalism. The argument of Nemirow and Lewis is known as the ability hypothesis.

In a 1995 article, Martine Nida-Rümelin attempts to explicitly separate the knowledge-how and the knowledge-that acquired by Mary when she is released from her black-and-white environment. Nida-Rümelin introduces a character named Marianna who, like Mary, has always lived in a black-and-white environment. She is not required to have detailed physicalist knowledge about color. Marianna is presented with four samples of color – say pieces of paper that are blue, red, green and yellow. She is asked which of these colors does she believe to be the color of the sky. Having always heard that the sky is beautiful, and personally finding the red paper particularly pretty, she points to the red paper and says I believe the sky is this color. Marianna correctly believes that she is normally sighted.

To explicitly state what it is that Marianna believes, we must distinguish between two uses of the concept of color. There is a linguistic, non-phenomenal meaning of color, denoted by blue(np) and red(np), that Marianna understands. Marianna believes that (1) the sky is blue(np) and not red(np). After being shown the colored papers, Marianna also knows the phenomenal sensations corresponding to blue and red, called blue(p) and red(p). Marianna incorrectly believes that (2) the sky appears red(p) and not blue(p) to normally sighted people. Mariannas beliefs (1) and (2) are beliefs about something that may or may not be the case, and thus these beliefs should have propositions as their content.

Nida-Rümelin points out the following about Jacksons Mary argument: When Mary is finally released she acquires new knowledge about the experiences of others (She learns, e.g., that the sky appears blue(p) to people with normal color perception). But Mary does not gain this item of knowledge simply by gaining sight and thereby acquaintance with colors. A disadvantage of Jacksons example is that it fails to distinguish two steps of epistemic progress that can be distinguished clearly in Mariannas case. There are two steps involved. First, Mary acquires epistemic access to color through personal experience of what it is like to see color. Second, Mary gains knowledge about things like how the sky appears to normally-sighted people.

Nida-Rümelin concludes that the above considerations provide a counter argument to the ability objections to Jacksons knowledge argument: I hope to have convinced the reader that the ability objection loses its intuitive appeal once one accepts that Marys epistemic progress is adequately described in the way here proposed (as an acquisition of phenomenal knowledge and not as an acquisition of knowing what its like) and that it certainly is not obvious how the claim that phenomenal knowledge too is nothing but a bundle of practical abilities could be argued for in a convincing manner.

I have only provided a very brief summary of these recent philosophical arguments, but I hope I have been able to give a little of the flavor of the discussion. Anyone interested in working through the full details of these arguments should take a look at the original papers.

The Hofstadter Sequence: A Paradigm for Non-uniform Reasoning

N. Lygeros

translated from french by Q. Jackson and the author

The Douglas Hofstadter sequence is, to some extent, a deformation of Fibonacci's. It represents a generic case of the existence of an abstracted relation between the immediate future and the remote past. With the opposition to the mentality generated by the theory of differential equations, we find in this sequence a fractal aspect whose complexity is interpreted a priori as indeterminism because this recursive process seems to have a chaotic behavior. Our goal is to show that this process, ultimately deterministic and understandable, constitutes a paradigm for non-uniform reasoning.

One of the characteristics of the reasoning described as intelligent is the synchronic synthesis of knowledge to solve a given problem. It seems that for relatively elementary problems - for example, exercises or fast tests - this characteristic is amply sufficient for their resolution. The really difficult problems, however, require the use of diachronic synthesis. This method, although very expensive in terms of memory, is essential. Indeed, its power not only makes it possible to overcome the difficulties encountered, but also to completely understand the complexity of the problems.

Within this framework, let us attempt to analyze the surprising character of the fast resolution of a complex problem. It is obvious that this type of resolution can come from a preliminary knowledge of a problem and an analogous resolution. Let us therefore exclude this case from our study, a choice which all the more highlights the surprising character of the resolution. Let us propose, then, a possible explanation of this phenomenon: fast resolution appears surprising for one observing the solver because the observer first carries out an implicit inference, knowing the continuity of the reasoning in cognitive space. This inference implies for the observer that there is no essential phase shift in the reasoning of the solver. Thus, for the observer, the immediate outcome of the intellectual advance could even depend only on the present. Nevertheless, we now consider a type of problem whose heuristic model corresponds to the Douglas Hofstadter sequence. It is clear that the value sought for a given row does not depend on those of immediately close rows. In this type of problem, a local knowledge proves to be insufficient and only a diachronic synthesis, and thus, in a certain total way, allows the determination of the required value. And it is precisely this method of the solver that surprises the observer: the solver was not locally fast but different in an essential way.

Thus our paradigm of non-uniform reasoning explicitly shows that the difference between a reasoning based on a diachronic synthesis and another is qualitative rather than quantitative. Moreover, when the solver belongs to one of the fundamental categories (cf our article: M-classification) this qualitative difference leads to a concept incomparable in cognitive space.

L'enfant surdoué et l'école

M. Heremans

psychologue de Mensa Youth Foundation Belgium-Luxemburg

La science n'a pas dit son dernier mot, loin s'en faut, sur les questions relatives à la cognition humaine. Les considérations idéologiques supplantent trop souvent les réflexions scientifiquement fondées, y compris chez les " défenseurs " du QI et de la surdouance. Je sais parfaitement bien qu'en prenant fait et cause pour la reconnaissance et la défense des enfants surdoués je tombe partiellement dans le piège idéologique que je dénonce. Le militantisme fait rarement bon ménage avec la science. De plus,la " réalité " est souvent très difficile à modéliser en sciences humaines ; les généralisations propres au discours scientifique s'avèrent facilement abusives. Considérez donc les assertions qui suivent avec les nuances qui s'imposent...(remarques, critiques,...bienvenues !)

Pourquoi l'école actuelle est-elle inadaptée aux enfants intellectuellement précoces?

L'ennui

* Les programmes scolaires sont conçus en fonction du rythme d'apprentissage moyen des élèves.

* Or, dès leur entrée en première primaire, les enfants surdoués ont, intellectuellement s'entend, au moins un an et demi d'avance par rapport aux enfants d'intelligence moyenne.

* Ils sont dans une situation plus ou moins comparable à celle d'un enfant d'intelligence moyenne qui serait contraint de suivre un enseignement dans une école fréquentée par des déficients mentaux !

* L'hétérogénéité croissante des classes, due à une série de mesures politiques récentes (cabinet Onckelinckx) visant à retarder, voire éliminer, toute forme de sélection (interdiction de redoublement avant la fin de la deuxième primaire (CE1), passage automatique de la première à la deuxième secondaire (en France, passage de 6ème en 5ème), etc.), aggrave encore le décalage que vit l'enfant surdoué.

* Selon Jean-Charles Terrassier, spécialiste français des enfants surdoués, on assiste ainsi à une augmentation artificielle du nombre d'élèves surdoués!

* Des propos qui précèdent, il ne faudrait pas conclure de façon hâtive que le redoublement est à mes yeux une mesure nécessaire et efficace. Mais sa suppression, sans autre forme de procès, nous fait tomber de Charybde en Scylla !

La dyssynchronie intellectuelle (au sens de Jean-Charles Terrassier)

* L'école, organisée en classes d'âge est adaptée à un enfant purement virtuel qui serait moyen dans tous les secteurs (mathématiques, orthographe, raisonnement verbal ou logico-mathématique, capacités d'attention etc.)

* Or, les enfants surdoués polyvalents sont l'exception plutôt que la règle. Pourquoi un élève très doué en mathématiques, par exemple, devrait-il être freiné dans sa progression au sein de sa branche de prédilection sous prétexte qu'il a moins de facilités en orthographe ou que son écriture ne correspond qu'à son âge chronologique ?

* Le regroupement des enfants surdoués dans des classes spéciales ne résout que partiellement ce problème.

Pédagogie inadaptée

* Si les enfants " légèrement " surdoués (QI 130 - Perc. 98) s'accommodent parfois de solutions consistant à accélérer ou renforcer le programme (saut de classe, choix d'une école élitiste, par exemple) il en va différemment des enfants modérément (QI 150 - Perc. 99.9) et surtout sévèrement (QI 160/170 - Perc. 99.99) surdoués qui sont qualitativement trop différents des enfants ordinaires, même motivés et travaillant beaucoup.

* L'approche artificiellement encyclopédique des écoles élitistes, la quantité de matière prévalant sur l'intégration des connaissances (" tête bien pleine ") et le caractère trop dirigiste et conformiste de leur " pédagogie " (discours magistral, rôle passif de l'élève) ne parviennent pas à satisfaire la curiosité intellectuelle propre au surdoué.

* Les écoles à pédagogie dite " nouvelle " (Montessori,Freinet, Decroly) sont en ce sens plus adaptées puisque les élèves y sont considérés comme acteurs plutôt que comme spectateurs des apprentissages. Par ailleurs, l'importance que ces écoles accordent à l'intégration des connaissances (" tête bien faite ") convient bien à l'approche cognitive de l'élève surdoué. Malheureusement les connaissances proprement dites (connaissances déclaratives telles que définies en psychologie cognitive) y occupent souvent une place vraiment trop réduite. L'enfant n'est pas suffisamment entraîné à mémoriser.

Difficultés d'intégration

* L'enfant surdoué a des difficultés à communiquer avec les enfants de son âge parce qu'il ne partage pas leurs centres d'intérêts. Et s'il les partage, il les aborde de manière qualitativement différente.

* Philippe Gouillou, autre spécialiste français des enfants surdoués, dit à ce sujet, reprenant un concept utilisé en P.N.L., que l'enfant intellectuellement précoce est dans l'incapacité de réussir ses " tests de similarité " avec les enfants de son âge.

* Afin d'établir coûte que coûte un contact avec leurs pairs, certains enfants essayent d'adopter les comportements les plus normalisés possibles . Ils jouent en quelque sorte un rôle de composition en " singeant " les autres. La personnalité ainsi construite se révèle tellement artificielle qu'elle est rapidement démasquée par les autres enfants d'où, isolement progressif; risques de phobie scolaire, de dépression, voire de suicide.

Mauvaises habitudes de travail

En référence à la théorie de Piaget concernant l'adaptation, on peut considérer que l'enfant surdoué est doté de telles capacités d'assimilation que les schèmes d'accommodation sont insuffisamment mis à contribution. Il n'apprend pas à travailler, à se dépasser, à faire preuve de persévérance. Dès lors, la moindre " vraie " difficulté le déconcerte, voire l'angoisse. Il abandonne parfois prématurément une tâche dont la solution ne lui apparaît pas de façon immédiate. Dans l'enseignement secondaire (surtout à partir de la troisième année) il peut être confronté à des difficultés d'apprentissage et de mémorisation lorsque les matières deviennent plus complexes !

Que faire ?

* Le principe général à suivre est identique à celui qui devrait prévaloir à l'éducation de tout enfant : lui assurer un épanouissement intellectuel et socio-affectif optimal.

* Il est donc nécessaire de veiller à ce que l'enfant :

- puisse progresser à son rythme, nécessairement différencié selon les secteurs puisque, comme je l'ai dit plus haut, la précocité polyvalente est l'exception

- ait la possibilité de réussir ses tests de similarité avec d'autres enfants

* En Belgique il n'existe malheureusement pas de structure scolaire adaptée aux enfants surdoués. Le " syndrome " de la précocité intellectuelle est en effet superbement ignoré dans notre pays . Le décret " Onckelinckx " du 31/5/1999 (ce fut le cadeau d'adieu de notre ministre de l'éducation !) modifiant la réglementation relative aux jurys de la communauté française compétents pour l'enseignement secondaire, m'a ôté l'une des rares possibilités d'orientation qui restait à ma disposition pour ces enfants, à savoir, l'admission anticipée aux examens du jury (l'autre possibilité est le saut de classe, en primaire, du moins). En effet, ce décret interdit (aucune dérogation n'est prévue), à tout élève suivant des cours par correspondance - en France, à distance- (auxquels les surdoués ont souvent recours) de terminer ses humanités avec plus d'un an d'avance. Il s'agit d'une mesure très injuste si l'on sait que le taux de réussite des enfants admis précocement à ces examens est très supérieur à la moyenne ! (en France, une mesure identique avait été proposée - j'ignore si elle est toujours d'application -concernant le baccalauréat

Echec scolaire chez l'enfant surdoué

Contrairement à une opinion répandue parmi le grand public, les enfants surdoués rencontrent parfois de graves difficultés scolaires. Parmi les raisons qui expliquent l'échec, citons les causes d'origine :

- Conative : démotivation due à l'ennui ;

- Socio-affective : inhibitions liées à l'impossibilité de nouer des contacts enrichissants avec ses pairs.(et souvent aussi, malheureusement avec les enseignants) Or l'équilibre affectif favorise l'investissement intellectuel. ;

- Cognitive : consécutives à la dyssynchronie intellectuelle. Ces dernières passent très souvent inaperçues à l'école primaire parce que l'enfant camoufle, grâce à son potentiel élevé, certaines difficultés plus ou moins spécifiques, par ex. :

- Syndrome ADHD (ou " hyperkinésie ") : caractérisé par des troubles intensifs de l'attention sélective souvent associés à une instabilité motrice excessive. (à ne surtout pas confondre avec la suractivité de l'enfant qui s'ennuie);

- Dyslexie : difficultés sévères en lecture liées à l'impossibilité d'automatiser les processus de décodage (des graphèmes en phonèmes). La lecture à voix haute de l'enfant dyslexique est, si on la compare à celle des normolecteurs du même âge, trop lente, hachée et fautive. La dyslexie peut passer longtemps inaperçue chez l'enfant surdoué parce que ses capacités de compréhension et sa culture générale suppléent partiellement aux difficultés de décodage.

Temps de travail, Machines et Chomage

A. Frank

Les machines (robots, ordinateurs,...) ont été conçues pour aider l'homme, et non pour lui poser un tas de problèmes. Or , que se passe-t-il? Dans le contexte actuel, elles sont génératrices de chômage!! Ce n'est évidemment nullement leur "faute", mais la cause de ce sinistre état de fait est à chercher dans un système aberrant.

Pour effectuer une tâche déterminée, il fallait il y a vingt ans (à titre d'exemple) 10h. Maintenant, avec l'aide des machines, il n'en faut plus que 5. Donc, pour une même productivité, au lieu de 38 h (par semaine), il n'en faut plus que 19 (un peu plus, globalement, vu la maintenance des machines). C'est magnifique : Grâce aux machines, il faut travailler deux fois moins pour obtenir le même résultat. Ce devrait être une grande réussite! (nous n'entrerons pas ici dans le problème de la civilisation des loisirs) . Que ce passe-t-il en pratique? "ON" a fixé des "temps de travail" (le nombre d'heures à prester par semaine - et non pas ce qui doit être fait) , et comme, grâce aux machines, deux personnes peuvent maintenant, pendant ce temps, faire ce qu'une faisait avant, on licencie l'autre, au nom du rendement! Dès lors, les machines sont devenues des ennemies de l'homme. Cette vision peut sembler simpliste, mais les exemples pullulent : Faire une facture, émettre un billet d'avion, imprimer un article,...

Et cela ne semble en rien devoir s'arrêter : la "compétitivité" à tout prix, le "tabou" du nombre d'heures à respecter, la peur (!) de pouvoir être remplacé par une machine "plus rapide et plus efficace". Combien de gens auraient un "rendement" (je n'aime pas ce terme) meilleur s'ils pouvaient travailler à leur rythme et à leur convenance, pour exécuter des tâches données.

Je terminerai en donnant un exemple que j'ai agréablement vécu : Il y a 25 ans, j'étais responsable des horaires à l'Université Nationale du Zaïre, Campus de Kisangani. L'emploi du temps annuel demandait la prise en considération de beaucoup de données (déplacements des visiteurs, regroupements, locaux...) En une semaine, je réalisai l'emploi du temps de tout le monde, pour un an. Les quelques centaines de professeurs et représentants d'étudiants se trouvèrent satisfaits. Le Secrétaire général de l'université, m'ayant convoqué, me dit " tu as réalisé un travail qui prend "normalement" deux mois" , donc tu reprendras tes activités dans sept semaines... en attendant, amuse-toi bien! Que la vie serait belle s'il en était toujours ainsi.

Champion of 54 digits
484061254276878368125726870789180231995964870094916937 (N. Lygeros, M. Mizony 12/99)

On December 26, 1999, we found a prime factor of 54 digits of a 127-digit composite number with GMP-ECM, a free implementation of the Elliptic Curve Method (ECM) of Paul Zimmermann based on T. Granlund's GMP multiprecision library. According to the table maintained by Richard Brent this is the largest prime factor ever found by ECM.

The number we factored was a cofactor from $(6^{43}-1)^{42}+1$, more precisely $n = b^4 - b^2 + 1$ where $b = 6^{43} - 1$. It was known that $n = 13 * 733 * 7177 * c127$ where c127 is a 127-digit composite number. We discovered that this number factors into $c127 = p54 * p73$ where $p54 = 484061254276878368125726870789180231995964870094916937$ is the factor found. This search was done in a huge factoring project started a year ago about generalized Sloane's sequences. Those generalize sequences A003504, A005166 and A005167 from The Encyclopedia of Integer Sequences.

The Elliptic Curve Method was discovered by H. W. Lenstra in 1985. The lucky curve was of the form $b * y^2 * z = x^3 + A * x^2 * z + x * z^2$
with A =42252164565182179790842156574398525292951923168424966 6 mod p, and group order $2^3*3^2*13*53*283*337*29077*837283*1164803*3978523*7613819*8939393*13323719$. Very surprisingly, the 54-digit prime was found in step 1 of ECM! The first limit used was B1=15,000,000. The probability of finding a 54-digit prime in step 1 with such parameters is about one over three million. We just did 1300 curves. The lucky curve took 454 seconds to compute on a 500Mhz Dec Alpha EV6 from the Center for the Development of Parallel Scientific Computation.

Au bord du ciel et de la mer

N. Lygeros

Par son insupportable légèreté, la Grèce tient du ciel.
Une légèreté que nous pourrions qualifier de socratique.
Devant la gravité permanente du contexte historique,
la légèreté représente une sorte de survie.
Un moyen d'affonter le destin.
Le destin d'un peuple en quête d'absolu.
Un absolu nécessaire, celui de l'existence.
Chez nous l'existence diachronique est synonyme d'éternité de l'instant,
d'où la conscience de détenir un trésor lorsque nous parlons d'histoire.
Nous marchons avec légèreté afin de ne pas écraser nos vestiges.

Par la profondeur de son histoire, la Grèce tient de la mer.
Une histoire qui a la beauté de l'invisible.
Son caractère invisible n'est pas dû à l'obscurité
mais à l'accumulation de lumière ; un paradoxe alexandrin.
Comment voir dans la multitude du visible ?
Chaque parcelle de notre pays est chargée d'histoire.
Alors que vaut l'essentiel lorsque tout est important ?
Chez nous l'existence synchronique est synonyme d'omniprésence de l'histoire,
d'où la conscience de détenir un trésor lorsque nous vivons l'instant.
Nos pas sont profonds afin de toucher notre mémoire.

La force de la Grèce c'est d'être une frontière entre le ciel et la mer.
Un point de contact entre deux mondes bleus.
Les îles dans la mer, les cimes dans le ciel.
Une terre gorgée de lumière qui réchauffe son peuple.
Un peuple attaché à sa terre comme le langage à la pensée.
Notre langue est comme ce marbre antique
que nous retrouvons dans les églises byzantines et les forts vénitiens,
elle appartient à la structure fondamentale du Grec.
Le Grec qui, depuis des siècles,
contemple le ciel et la mer.

Ordinateurs et Démonstration

N. Lygeros

PRÉLUDE À DÉMONSTRATION

Nous allons analyser la structure logique des implications reliant les théorèmes et les lemmes de l'article [9]. Ceci dans le but de déceler une des premières interventions de l'ordinateur dans une démonstration de théorie des nombres.

Initialement l'intervention de l'ordinateur se situe dans la démonstration du lemme 3. En effet pour démontrer ce dernier, si l'on suit la méthode adoptée par Newman, on est amené à montrer par un calcul numérique standard que le polynôme suivant :
$r^8-134r^7+6496r^6-147854r^5+1709659r^4-10035116r^3+28014804r^2-29758896r+6531840$
n'a aucune racine dans $\mathbf{Z}$. J.-P. Serre remarque alors que pour effectuer cela, l'ordinateur est indispensable. Ce qui est selon lui «désagréable».

Cela constitue un jugement assez général parmi les mathématiciens qui utilisent l'ordinateur avec la même réticence que l'axiome du choix et qui se sentent bien aise lorsqu'ils peuvent s'en passer. Mais du fait que l'ordinateur intervient dans une des extrémités du graphe des implications et que donc l'aspect «désagréable» se propage dans quasiment toute la démonstration, il est important d'éliminer son rôle.

Le mot désagréable utilisé à propos de l'ordinateur et surtout dans la définition de J.-P. Serre (correspondance personnelle) de la qualité d'une démonstration qui n'est pas sans rappeler des arguments à la Hermann Weyl - qui disait que dans son travail il avait toujours essayer d'unifier la vérité avec le beau et que quand il avait à choisir entre l'une ou l'autre habituellement il choisissait le beau.

En fait tout cela peut être considéré comme du purisme esthétique démodé ; tel Pierre Deligne qui répond à une question sournoise de David Ruelle en finissant par dire que ce qui l'intéressait personnellement c'étaient les résultats qu'il pouvait lui-même, et tout seul, comprendre dans leur entièreté. L'époque antique où les mathématiques représentaient la science du beau est totalement révolue. La beauté est un luxe que certains théorèmes ne peuvent s'offrir ; d'ailleurs peu nous importe la beauté seule la vérité compte.

Et que faire d'un théorème comme celui de Paris-Harrington, obtenu en 1977, qui est prouvable dans le cadre ensembliste usuel mais ne l'est pas dans le cadre seul des ensembles finis ? Si l'on reste sur des positions classiques l'on risque de se retrouver dans la même situation qu'André Weil lorsqu'il pensait que la mathématique courait le danger d'être étouffée par la foison des travaux médiocres et qui doit à présent avouer que celle-ci risque d'être étouffée par l'abondance de très bons travaux.

Des théorèmes qui n'obéissent pas à ces critères de qualité, il y en aura de plus en plus car nous avons besoin de savoir la vérité et non de voir la beauté.

Mais revenons aux conséquences que va impliquer l'attitude de J.-P. Serre quant à la démonstration du lemme. Repartant de l'énoncé du lemme, il explicite le fait qu'il s'agit de prouver que $p_r(10) \neq 0$ lorsque $r \equiv 2\ (mod 11)$. En remarquant alors que «le polynôme $r \to p_r(10)$ est à coefficients 11-entiers», J.-P. Serre réduit la difficulté calculatoire en utilisant une connaissance placée plus haut dans la hiérarchie de la complexité démonstrative. Ainsi

le polynôme est «constant (mod 11) sur toute la classe modulo 11, et l'on a : $p_r(10) \equiv p_2(10)\ (mod 11)$».

Jusqu'à ce stade tout mathématicien normalement constitué en aurait fait de même. Cependant J.-P.Serre n'est pas n'importe quel mathématicien, aussi non content d'avoir trouvé une méthode qui élimine le rôle de l'ordinateur, il va s'efforcer de montrer que cette méthode est simple et surtout sans calculs. Et c'est là qu'il va aller trop loin - on ne peut tout de même pas l'accuser de ne pas en être conscient puisque c'est à ce moment précis qu'il va exploiter la puissance de la rhétorique.

En effet J.-P. Serre écrit : «il est immédiat que $p_2(10) = 1$» - tout en s'empressant à l'aide d'une parenthèse, d'en donner la raison ! Comme si un énoncé trivial avait besoin d'être justifié. De plus l'utilisation qu'il fait par la suite de l'expression «par exemple» implique l'existence de plusieurs raisons capables d'expliquer un fait immédiat.

Le problème de l'utilisation du mot «immédiat» provient sans doute du fait qu'en mathématiques ce mot comporte un aspect très subjectif. Pour la plupart des mathématiciens il convient d'utiliser ce mot lorsque ce que l'on affirme ne doit pas son existence à diverses théories très techniques. Ce qui est gênant dans cette approche c'est que l'utilisation du mot immédiat va dépendre de la connaissance mathématique culturelle de l'utilisateur. Ainsi voulant pallier ce manque d'universalité nous nous plaçons dans le cadre axiomatique de la théorie des nombres (si l'on suit jusqu'au bout ce raisonnement il faudrait partir des axiomes de Peano). De cette façon, ce qui est immédiat dépend directement des axiomes de la théorie considérée et d'eux seuls.

Et à présent le point d'orgue ; la raison : $p_2(10) = 1$ résulte «de la détermination explicite de $p_2(n)$». Cependant que peut bien signifier le mot «explicite» dans ce contexte ? Que la détermination de $p_1(n)$ et $p_3(n)$ le soit c'est évident, puisque l'on a les identités d'Euler et Jacobi :

$$\prod_{m=1}^{+\infty}(1-q^m) = \sum_{-\infty}^{+\infty}(-1)^n q^{(3n^2+n)/2} = \sum_{n=0}^{+\infty} p_1(n)q^n$$

$$\prod_{m=1}^{+\infty}(1-q^m)^3 = \sum_{-\infty}^{+\infty}(-1)^n(2n+1)q^{(n^2+n)/2} = \sum_{n=0}^{+\infty} p_3(n)q^n$$

mais l'on ne connait aucune formule de la sorte pour $p_2(n)$. Tout ce que l'on sait sur $p_2(10)$ c'est qu'il est différent de zéro (puisque d'après un résultat de J.-P. Serre on a : $p_2(10) \Leftrightarrow$ il existe un nombre premier $p \not\equiv 1(mod 12)$ dont l'exposant dans $1 + 12n$ est impair) et à part faire le produit suivant :

$$((1-q)(1-q^2)(1-q^3)(1-q^4)(1-q^5)(1-q^6)(1-q^7)(1-q^8)(1-q^9)(1-q^{10}))^2$$

que l'on peut difficilement ne pas considérer comme un calcul, et regarder le 11ème coefficient du polynôme obtenu, on ne voit pas comment obtenir la valeur de $p_2(10)$ de façon immédiate.

Bien sûr, l'on peut utiliser l'identité d'Euler - connaissance mathémathique - et alors on doit développer le produit suivant : $(1 - q - q^2 + q^5 + q^7)^2$ qui bien que peu compliqué n'en demeure pas moins un calcul. Les autres méthodes que J.-P. Serre propose (correspondance personnelle) abondent dans ce sens puisqu'elles nécessitent soit la connaissance de la série de Dirichlet (avec en plus la compréhension de l'extension galoisienne associée), soit la connaissance des formes de types CM. Mais bien sûr, il n'est pas vraiment étonnant qu'un spécialiste

de théorie des nombres comme J.-P. Serre considère l'utilisation de toutes ces notions comme élémentaire.

Et donc pour parvenir au but initial que s'était proposé J.-P. Serre c'est-à-dire obtenir la valeur de $p_2(10)$ sans calcul il faut être capable à partir de l'explicitation des exposants dans l'identité d'Euler de dire que l'équation diophantienne suivante : $(m, n) \in \mathbf{Z}^2$, $3m^2 + 3n^2 + m + n = 20$ n'admet qu'une unique solution à savoir $n = m = -2$. Procédure que l'on ne peut pas qualifier d'immédiate.

De cette analyse de l'approche de J.-P. Serre apparaît l'idée suivante. Du point de vue de la théorie de la démonstration - pour des problèmes finis - un calcul ne peut être éliminé ni par un autre calcul même si ce dernier est plus simple, ni par une procédure élémentaire dépourvue de calcul. La réduction de la difficulté calculatoire nécessite une augmentation de la complexité de la démonstration. Or cette augmentation ne peut être infinie, ainsi la capacité calculatoire détermine en quelque sorte les limites de la démonstration mathématique. On peut alors se poser la question suivante : de quelle façon l'introduction de l'ordinateur va modifier la notion de démonstration ? Ou plus simplement encore que signifie, DÉMONSTRATION ?

DÉMONSTRATION

Cette fois c'est un article de O. Lanford [7], que nous allons analyser pour comprendre une situation où le rôle de l'ordinateur bien qu'encore auxiliaire est plus important.

Ce qui est tout à fait remarquable dans l'énoncé des théorèmes de cet article c'est que l'on ne voit pas du tout comment O. Lanford est parvenu à s'aider de l'ordinateur pour les démontrer. En effet les théorèmes semblent indépendants de tout calcul et à part les bornes μ_∞ fournies dans le théorème 5, on ne trouve aucune indication de type numérique. La situation est même plus délicate encore car une lecture attentive des énoncés permet de voir qu'il s'agit de théorèmes de type existentiel : le théorème 1 sur l'existence d'une fonction, la proposition 2 sur celle d'un voisinage, le théorème 4 sur celle d'un entier et d'un élément d'une variété instable, enfin le théorème 5 sur celle d'un entier et d'une valeur paramétrique.

Ce cas de figure constitue un exemple caractéristique d'une des trois familles les plus naturelles de notre objet d'étude, la DÉMONSTRATION, qui sont : la Transformation, la Structuration, la Classification. Ici évidemment l'on a à faire à une démonstration de genre transformation, c'est-à-dire que la phase qui précède l'intervention proprement dite de l'ordinateur consiste en une transformation des énoncés mathématiques dépourvus de calculs en estimations calculatoires certes complexes pour l'homme mais immédiates pour l'ordinateur.

Cette transformation s'obtient au prix d'une explicitation des objets sur lesquels s'appuient les énoncés considérés. Ainsi on fait exprimer aux théorèmes le maximum d'informations qu'ils puissent posséder afin de pouvoir s'aider de l'ordinateur qui ne peut manipuler que des êtres concrets même s'ils ne le sont quelquefois que de manière implicite. Donc l'on décompresse l'information dense des théorèmes de mathématiques mais alors la conséquence immédiate de cette action est que la quantité d'informations ainsi obtenues dépasse de loin les capacités humaines et rend nécessaire l'assistance de l'ordinateur pour les gérer, les trier, puis les sélectionner. Bien sûr ces procédures sont élémentaires - du point de vue de l'ordinateur - cependant leurs manipulations ne le sont pas forcément. Néanmoins dans

notre exemple qui est plus intermédiaire - entre les démonstrations classiques et celles où l'ordinateur intervient - qu'une véritable DÉMONSTRATION ce n'est pas le cas.

Pour conclure O. Lanford remarque que les calculs nécessaires à la démonstration des résultats annoncés sont justes à la limite de ce qui est vérifiable à la main. Plus exactement il considère qu'un ensemble minimal d'estimations choisi attentivement serait suffisant pour prouver les théorèmes 1 et 3 à l'aide seulement d'une calculatrice programmable en quelques jours. Cette justification de son approche est tout à fait significative ; en effet elle permet de déduire les ressentiments des mathématiciens d'alors envers des DÉMONSTRATIONS de ce genre. D'ailleurs le fait que Campanino, Epstein et Ruelle aient pu démontrer (c'est donc qu'ils ont essayé de le faire !) le théorème 1 par une autre méthode confirme cette opinion négative. Pourtant à l'instar du 19ème siècle avec les fonctions monstrueuses, le 20ème verra sans aucun doute une révolution conceptuelle provoquée par les DÉMONSTRATIONS qui bouleversera l'Empire Mathématique.

DÉMONSTRATION et empire mathématique

On appelle poset (partially ordered set) un ensemble P muni d'un ordre partiel. Lorsqu'il a n éléments et r relations de comparaison, c'est encore un graphe simple à n sommets et r arètes, orienté et transitif. On obtient son dual en inversant ses arêtes, et lorsque c'est possible un conjugué en enlevant les r arètes et en orientant transitivement les $(n(n-1)/2-r$ autres arêtes. Quant à sa dimension elle est égale au nombre minimum d'extensions linéaires dont il représente l'intersection. On dit qu'un poset est représentable par cercles si l'on peut lui associer une famille de cercles munie de l'ordre partiel d'inclusion dont les relations entre les éléments s'identifient avec celles que définit le poset.

Se pose alors la question de savoir dans quels cas un poset est représentable par cercles. Depuis longtemps, on sait que tout poset de dimension inférieur ou égale à deux est représentable par cercles. Mais l'on a aussi un résultat de Brightwell et Winkler [3] qui permet de déduire l'existence explicite d'un poset à 14 éléments qui n'est pas représentable par cercles. Dans ce chapitre nous allons nous attarder sur la démonstration du théorème suivant : tous les posets d'au plus 7 éléments sont représentables par cercles.

La contribution de l'ordinateur, quoique fondamentale, n'est pas évidente à localiser dans la démonstration, et pour cause elle est omniprésente ! Lorsque l'auteur écrit «Pour $n = 6$, après avoir utilisé le théorème [de Dushik et Miller] [...] il suffit d'étudier 2 posets...» il n'explique pas en quoi consiste réellement l'utilisation de ce théorème. Or une simple remarque numérique permet de constater le rôle primordial de cette utilisation. En effet pour $n = 6$ on a 318 posets non isomorphes or après cette mystérieuse, pour l'instant, utilisation de ce théorème il n'en reste plus que 2 à étudier.

Voici à présent la méthode utilisée. D'après le théorème de Dushnik et Miller on a : $(dimP \leq 2) \Leftrightarrow (P$ a un ordre conjugué), et par ailleurs l'on sait que les posets P de $(dimP \leq 2)$ sont représentables par cercles. Donc plutôt que de tester directement si un poset donné est représentable par cercles, l'on regarde s'il a un conjugué. Seulement cette procédure a du être appliquée aux 318 posets à 6 éléments et c'est l'ordinateur qui s'est chargé de ce travail. Il a agi de même pour $n = 7$, et cette fois il a traité 2045 posets en laissant 49 posets à étudier à la main.

Le lecteur curieux pourrait se demander pourquoi l'auteur n'a pas poursuivi sa méthode jusqu' à $n = 8$. Voici la réponse : lorsque $n = 8$ on a affaire à 16999 posets et une fois l'ordinateur utilisé il en reste encore 1141 à étudier. Or l'auteur a mis 2 jours pour traiter à la main les 49 posets qui restaient pour $n = 7$. Donc même en considérant que la difficulté est la même pour 8 sommets (ce qui est faux je vous l'assure !) il lui aurait fallu environ 46 jours de travail fastidieux ! (pour 9 sommets il en faudrait 532).

Ainsi pour faire mieux dans ce domaine si l'on conserve la même approche, qui est la seule jusqu'à présent à avoir donné des résultats, il faut soit découvrir de nouveaux théorèmes soit construire un algorithme performant qui permette de trouver lorsqu'elle existe une représentation par cercles d'un poset donné. Il est bien évident que le rôle de l'ordinateur sera encore plus grand que dans la deuxième possibilité, même si après une recherche forcément finie d'une représentation il faudra utiliser une autre méthode pour prouver que le poset considéré n'est pas représentable par cercles.

Néanmoins je pense que l'on peut aller plus loin si l'on change notre approche du problème et si l'on accepte bien sûr de donner à l'ordinateur un rôle encore plus grand. L'inconvénient principal de cette méthode - mais c'est aussi son originalité - c'est que malgré l'utilisation de l'ordinateur elle n'offrira qu'un résultat existentiel ! Voyons un peu de quoi il s'agit :

Il est évident qu'un ensemble de cercles dans le plan, une fois considéré par la relation d'inclusion constitue un poset et ce de façon univoque lorsque l'on regarde le problème à isomorphie près. Par ailleurs d'après le théorème de Brightwell et Winkler on sait qu'il existe des posets non représentables par cercles. Notons C_n le cardinal de l'ensemble des configurations non isomorphes en termes d'inclusion que peuvent avoir n cercles. On a alors l'inégalité suivante : $C_n \leq P_n$ et l'on sait que $C_k = P_k$ pour $k \in [1, ..., 7]$ et $C_{14} < P_{14}$.

Ainsi si l'on crée un programme qui calcule C_n, il suffira alors de comparer C_n avec P_n et l'existence de posets à m éléments non représentables découlera directement de : $C_m < P_m$.

Seulement si l'on regarde les valeurs de P_n pour $1 \leq n \leq 13$ ([4],[5],[6],[8]) à savoir : 1, 2, 5, 16, 63, 318, 2 045, 16 999, 183 231, 2 567 284, 46 749 427, 1 104 891 746, 33 823 827 452, on constate qu'elles deviennent vite énormes et en tout cas trop grandes pour un traitement à la main. Et si de plus il s'avère que pour les valeurs considérées C_n soit proche de P_n l'on se retrouvera devant une situation assez inconfortable. Car, par exemple, si C_n diffère pour la première fois de P_n et de peu pour $n = 13$ on saura qu'il existe parmi les milliards de posets possibles quelques posets non représentables par cercles sans pour autant pouvoir les déterminer du moins par cette méthode ! La seule chance que l'on pourrait avoir et donc où cette situation n'aurait pas lieu serait que $C_k = P_k$ pour $k \in [1, ..., 13]$, ce qui après tout n'est pas impossible.

Il faut tout de même pour finir cette partie, préciser que l'obtention d'un algorithme qui génère les C_n semble actuellement extrêmement difficile et ce même si l'on se contente de performances médiocres - qu'il faudrait de toute façon améliorer si l'on désire résoudre complètement ce problème.

Dans la partie précédente nous avons analysé une démonstration du genre «structuration» c'est-à-dire que la phase qui précède l'intervention proprement dite de l'ordinateur consiste à générer des structures à l'aide d'un calculateur - ce dernier peut être humain mais il semble évident que dans la plupart des cas ce sera une machine. Il est sans doute bon de préciser la nuance que nous utilisons entre les termes ordinateur et calculateur, au moins dans le présent

article. Un calculateur ne fait que compter dans le sens classique du terme c'est-à-dire que même s'il dénombre des structures plus complexes que des nombres, il n'en retient que le nombre qui vérifiera une certaine propriété alors que l'ordinateur va conserver l'ensemble des nombres qui caractérisent les structures qu'il a générées de façon globale. Et à présent il doit sembler évident au lecteur que dans notre travail c'est bien à la notion d'ordinateur et non de calculateur que nous nous intéressons.

Essayons maintenant de comprendre pourquoi dans l'état actuel des connaissances dans ce domaine il est nécessaire d'avoir recours à l'ordinateur pour démontrer le théorème étudié. Du point de vue mathématique (classique) cette démonstration découle de seulement deux théorèmes celui de Dushnik et Miller et celui d'Hiraguchi qui semblent être du même genre mais nous allons voir que ce n'est pas le cas.

Dans les deux théorèmes intervient la notion de dimension. Mais comme le calcul de cette dernière lorsqu'elle est supérieure ou égale à 3 est un problème NP-complet ([10]) nous allons nous intéresser uniquement au cas où elle est inférieure ou égale à 2. Dans ce cas le théorème d'Hiraguchi nous apprend que les posets P à 4 ou 5 éléments vérifient : $dimP \leq 2$. Même si cela peut sembler être un piètre résultat il faut voir que du point de vue numérique il permet de savoir la dimension de (16 + 63) posets en ne nécessitant pour ainsi dire aucun calcul puisqu'il suffit de connaitre la cardinalité du poset. Tandis que le théorème de Dushnik et Miller s'il est utilisé pour obtenir le même résultat est bien plus coûteux au niveau calculatoire puisque l'on est dans l'obligation de tester chacun des (16 + 63) posets pour savoir s'ils ont un conjugué. La différence entre ces deux théorèmes provient de la connaissance du poset plus ou moins grande qu'il faut avoir pour les appliquer. Dans le premier il suffit d'avoir le nombre d'éléments alors que dans le second il faut non seulement connaitre les relations qui lient ces éléments mais aussi déterminer si le complémentaire (avec ses sommets et arêtes) est un conjugué. Cette différence apparait dans l'utilisation : celle du premier est immédiate - on dira que c'est un théorème effectif - alors que celle du deuxième fait rapidement intervenir l'ordinateur.

De manière plus générale l'on peut affirmer le principe suivant :

Si un théorème dépend de toute la structure de l'objet étudié alors pour rendre son utilisation effective il faudra sans doute l'ordinateur.

Il est bien évident que la véracité de ce principe dans le cas général est contestable, pour le voir il suffit de considérer un problème qui ne concerne que peu d'objets. Par contre si l'on a affaire à un grand nombre d'objets et s'ils sont un tant soit peu compliqués alors la puissance du principe devient flagrante. De sorte qu'il est préférable de l'énoncer sous une forme plus précise - mais un peu plus formelle :

Si une démonstration d'un théorème sur n objets (pour n suffisamment grand mais fini) nécessite l'utilisation d'un théorème qui dépend de toute la structure (suffisamment complexe) des objets auxquels il s'applique alors l'ordinateur sera nécessaire à sa réalisation.

Il semble que l'on puisse aller encore plus loin dans cette idée en augmentant soit le nombre n d'objets soit leur complexité car alors on en arrive à l'énoncé qui est inaccessible même à l'aide de l'ordinateur, du moins dans sa totalité. Par exemple l'on pourrait se retrouver dans la situation suivante qui représente bien sûr un cas particulier du précédent principe :

Si le problème général est indécidable alors le problème partiel rend l'ordinateur indispensable.

Il est bien évident qu'en se restreignant à des préoccupations générales comme nous l'avons fait l'on ne saurait obtenir comme résultats autre chose que des principes. De toute façon le but que nous désirons atteindre ici n'est pas de construire une théorie complétement axiomatisée du rôle de l'ordinateur au sein de la théorie de la démonstration. Nous nous contentons, du moins pour l'instant, seulement d'écrire les prémices de cette théorie de la DÉMONSTRATION.

Seconde DÉMONSTRATION

En ce qui concerne le théorème des 4 couleurs Appel et Haken ([1],[2]) sont convaincus par des analyses probabilistes qu'un ensemble inévitable beaucoup plus petit et contenant des configurations de beaucoup plus petite taille n'existe pas. De récents développements dans la démonstration du théorème des 4 couleurs qui ont simplifié la partie traitée par l'humain et non par l'ordinateur vont dans ce sens. Appel et Haken ont employé 1000 heures de temps de calcul à prouver la réductibilité des 1880 configurations de leur ensemble. Ils croient qu'il est possible de produire un ensemble qui exige seulement 200 heures pour la vérification. Mais ils sont sûrs qu'il est impossible de produire une telle preuve vérifiable à la main. Jean Mayer, un des grands experts en matière de réductibilité, ne croit pas que la tâche de vérifier un tel ensemble à la main soit praticable. Ainsi, si personne ne trouve une preuve plus simple sans utiliser d'ordinateur, il faudra admettre que le théorème des 4 couleurs exige une preuve que personne ne peut vérifier à la main même en y passant toute sa vie.

La solution exige une étude combinatoire d'autant plus complexe que les données logiques sont plus simples et peu susceptibles d'engendrer des théorémes généraux. Pour les mêmes raisons, l'ensemble inévitable de configurations réductibles ne peut se réduire à un petit nombre d'éléments. Enfin, la plupart des réductions auxquelles on aboutit sont impraticables à la main, vu le grand nombre de coloriages mis en jeu : on voit donc en quoi la démonstration du théorème, quoiqu'accessible à notre logique, dépasse par son ampleur les capacités de l'intelligence individuelle.

Elle illustre l'avènement d'un nouveau type de preuve mathématique. En effet, c'est la première fois, à notre connaissance, qu'un théorème impliquant par sa nature un nombre infini de cas se trouve ramené à une étude combinatoire finie, mais d'une ampleur telle que la preuve a nécessité plusieurs centaines d'heures d'ordinateur et que, même a posteriori, une vie d'homme ne suffirait pas à la rendre explicite.

Réflechissons un peu sur ce dernier point et analysons l'idée sur laquelle il est basé. Tout d'abord le problème initial concerne deux infinités, le nombre de cartes et le nombre de couleurs, qui ont bien sûr un rôle dissymétrique. Le problème est de trouver le plus petit nombre possible de couleurs tel que la propriété soit vérifiée. Il est trivial de montrer que ce nombre est supérieur ou égal à 4 et il est facile de montrer que ce nombre est inférieur ou égal à 5. Il s'agit donc d'un problème où l'on peut aisément obtenir une borne supérieure et une borne inférieure de la valeur recherchée. Par contre il n'est absolument pas trivial de montrer que la valeur est précisément 4. Pourquoi une telle différence de complexité ? Du point de vue théorique il est naturel que la minoration soit plus facile à obtenir puisque somme toute il ne s'agit que de trouver une carte qui nécessite un nombre donné de couleurs

pour la colorier. Par ailleurs dans le cas présent la facilité d'obtenir une majoration provient non pas d'un raisonnement symétrique mais des contraintes imposées sur le graphe associé à la carte considérée par la formule d'Euler. Ainsi pour la valeur recherchée, la difficulté consiste bien à prouver l'égalité avec l'une des deux bornes, seulement ce problème concerne une infinité de cartes même en les traitant à isomorphie près. La méthode utilisée, du point de vue de la mathématique pure, va consister à rendre fini le nombre de cartes à étudier. Ce passage de l'infini au fini représente une étape fondamentale ; c'est sans aucun doute l'une des situations où l'on peut le mieux prendre conscience de la puissance de l'outil mathématique - on a d'ailleurs le même genre de finitisation pour la conjecture de Catalan grâce au résultat de Terjanian qui a été rendu explicite par Langevin.

Une fois cette étape cruciale franchie un autre problème apparait : le nombre de cas à traiter. Bien sûr si ce nombre est très petit, la gêne causée devient dérisoire. Mais qu'en est-il lorsqu'il est grand ? S'il est vraiment très grand et qu'il appartient aux nombres métaphysiques comme dirait F. Le Lionnais, l'on ne peut guère en dire quoi que ce soit puisqu'il est par définition inaccessible à toute méthode raisonnable. Par contre si ce nombre est accessible, cela dépend bien sûr du problème, et alors plusieurs difficultés méthodologiques apparaissent :

Tout d'abord comment faire pour réduire ce nombre ? Dans les cas les plus favorables il faut réitérer la méthode, cependant ils ne représentent pas la majorité. Dans les cas plus difficiles seul le changement de la méthode utilisée permet de réduire ce nombre. Mais dans les cas les plus difficiles on ne sait pas faire mieux, alors si cela est possible on fait appel à l'ordinateur. Ce qui a pour conséquence directe de donner un rôle important à ce dernier. Si celui-ci permet d'obtenir un contre-exemple, son rôle est effacé et l'on n'en parle plus que laconiquement. S'il permet de compléter la démonstration du théorème conjecturé alors dans un ultime effort l'on essaye a posteriori et en utilisant les résultats de ses calculs d'éliminer sa contribution. Pourtant dans le cas du théorème des 4 couleurs cette dernière tentative a échoué et l'on s'est retrouvé avec un résultat démontré grâce à l'ordinateur. Signalons à ce propos que les spécialistes omettent volontairement ou non de souligner la part euristique jouée par l'ordinateur dans ce problème, nous espérons d'ailleurs qu'avec notre article nous avons effectué une mise au point à ce sujet.

Ensuite lorsque l'on se trouve dans une situation où l'ordinateur a été indispensable, l'on est en droit de se demander si en utilisant une autre méthode (dans le futur) il aurait encore été nécessaire. En ce qui concerne le problème des 4 couleurs on sait grâce aux analyses probabilistes d'Appel et Haken que des variantes de la méthode utilisée seraient obligées d'employer l'ordinateur. Seulement cela n'est pas convaincant car il s'agit de méthodes trop proches pour résoudre le cas général.

C'est à ce niveau là que nous prenons le contre-pied de l'opinion majoritaire. Nous nous plaçons dans la problématique qu'aurait eue un épistémologue prégödelien fictif. Car si à l'époque de Gödel les mathématiciens n'ont point trouvé son théorème, cela ne provient pas tellement de la difficulté technique mais plutôt conceptuelle. En fait de façon plus concise l'on peut dire qu'ils ne réfléchissaient pas au bon problème. Ils s'étaient tous mis dans l'idée de chercher à unifier les mathématiques en les ramenant à une structure dont ils espéraient démontrer la cohérence sans se poser un seul instant la question de savoir si cela était seulement possible !

À notre époque certains mathématiciens s'acharnent à trouver des démonstrations où l'intervention de l'ordinateur est éliminée. Mais après tout il ne peut s'agir là que d'un acte de foi car l'on ne sait pas si cette procédure est possible dans le cas général.

Car de la même façon que l'on ne peut lutter contre les lois physiques, l'on ne peut guère lutter contre un fait mathématique (comme c'est le cas lorsque l'on a affaire à des structures indépendantes). Par exemple une des grandes réussites du 20ème siècle sur le plan mathématique a été la classification des groupes finis simples et donc aussi l'explicitation des groupes sporadiques, l'oeuvre de nombreux mathématiciens, qui ont travaillé pendant plusieurs décennies, dont la démonstration comporte actuellement plus de 15000 pages ! (Précisons à son propos que ce résultat est objectivement plus contestable que le théorème des 4 couleurs puisque plus sujet à l'erreur étant donné l'importance du rôle social entre les mathématiciens. Alors qu'aucun mathématicien n'émet de doute quant à la validité de sa preuve. Comme quoi le jugement des mathématiciens est extrêmement subjectif malgré la prétendue appartenance de leur domaine au monde des idées.) Mais que se serait-il passé si au lieu de 26 groupes sporadiques, il y en avait eu 260 ou 2600 ? Car l'esprit humain, et par conséquent les mathématiques qui en sont un des honneurs, a toujours tendance à unifier, à synthétiser les objets qu'il étudie pour mieux les comprendre, mais comment faire s'il y a à faire face à des structures véritablement indépendantes ? Comme c'est le cas avec P_{13} qui est égal à 33 823 827 452 ni plus ni moins !

Ainsi si l'on arrivait à démontrer qu'un problème comporte un grand nombre de structures indépendantes on montrerait du même coup la nécessité d'utiliser un ordinateur, si le nombre est accessible évidemment. Pour cela il faudrait montrer que quelque que soit la méthode utilisée, la donnée des structures à considérer est incompressible. Peut-être d'ailleurs que le théorème, qui démontrera la nécessité de l'utilisation de l'ordinateur pour démontrer un théorème sera lui-même démontré à l'aide de l'ordinateur ? Après tout lorsque l'on parle de fondements l'autoréférence est souvent au rendez-vous.

Pour finir essayons d'expliciter ce que nous avons voulu démontrer tout au long de ce cycle DÉMONSTRATION constitué de quatre parties. Nous avons examiné des problèmes où le rôle de l'ordinateur était croissant ce qui nous a amené à considérer le problème de la vérification qui lui-même nous a conduit à l'un des deux paramètres fondamentaux de la démonstration à savoir la longueur, l'autre étant la complexité.

Par ailleurs nous avons voulu mettre en évidence que du point de vue de la théorie de la démonstration, l'action de l'ordinateur intervenait de la même façon que l'utilisation d'un axiome. En effet l'alternative est simple : soit on utilise l'axiome de l'ordinateur c'est-à-dire que l'on se permet d'employer une procédure mécanique qui détermine si un ensemble fini, mais grand, de cas à considérer vérifie ou pas une certaine propriété, soit on exclut la possibilité et dans certains cas - comme celui du théorème des 4 couleurs - l'on n'arrive pas à prouver la vérité d'une conjecture.

An Exegesis of Promethean Myth

N. Lygeros, J.D. Martinez

Myths, legends and the like serve the purpose of kindling the flame of oral, cultural transmission by facilitating its conveyance from one generation to another. Myths helped illuminate and render Greek religion intelligible to worshippers by furnishing a wealth of religious background detail conceived in simple and picturesque terms. The Romans' functionally perceived deities had their counterparts in the more fully anthropomorphized oral and literary tradition of Greek mythology; including Greek epic poetry, theogony ("Divine Genealogy"), cosmogony, and allegory. One should bear in mind that Greek epic poetry is much more than a mere catalogue of matings and births of gods, rivers, planets, winds, and other abstract phenomena.

In the Greek language one of the etymological meanings of the name Prometheus is 'prometheia' or 'prnoia', which literally means pre-vision and is translated into English as 'forethought'. Prometheus is the one who reflects beforehand and he is sometimes referred to as the maker of mankind and a god of fire. He has also been referred to as the supreme trickster.

In Greek mythology Prometheus was the son of Iapetus (ΙΑΠΕΤΟΣ) and the ocean-nymph, Clymene. At this point there is already a difference between Hesiod and Eschyle. Prometheus had a double who can be considered to have been a kind of alter ego embodied in his brother, Epimetheus, who later became Pandora's husband. Epimetheus is translated as 'afterthought' or 'hindsight', i.e. the one who reflects a posteriori. They had another

brother named Atlas. Prometheus and Epimetheus are like the two halves of a unique Janus-faced personage. As far as humanity is concerned, 'prometheia' is just one aspect of our complete ignorance of the future. Prometheus is 'poiklos and 'aiolmetis', whereas Epimetheus is 'harmartnoos'.Prometheus supported Zeus against his brother Titans. The Titans were one race of giant gods, the offspring of Uranus and Gaea, who were conquered and succeeded by the gods of Olympus. The latter imprisoned the former in Tartarus and also in Etna.

It is said that Zeus employed Prometheus to make men out of mud and water. Prometheus created mortals from clay, while Athena had breathed life into them. These mortals suffered from the pains of hunger and cold. Prometheus felt sorry for the plight of humanity, so he decided to steal fire from Heaven in order to give humanity this precious gift. This allowed our ancestors to use fire to keep warm and to build instruments hence enabling them to soften the impact of nature's harsh climate. In this way Prometheus tried to be more astute than Zeus by attempting to outwit and deceive him.

Zeus retaliated by sending Pandora to earth with her box of evils- but Prometheus understood the real reason for this 'poisoned' gift; the victim was Epimetheus and in this way Zeus took revenge on humanity. This was to counterbalance the gift of fire that Prometheus had previously made to mankind. Furthermore, Zeus punished Prometheus by chaining him to a rock on Mount Caucasus. An eagle daily devoured Prometheus' liver, which was made whole again at night so that the same thing could continue the following day. Prometheus endured this torment until he was released by Herakles (the Romans called him Hercules) who slew the eagle. Thus, Prometheus' punishment for stealing fire and defying the gods was their curse that has since then been passed on to the creatures (mortals) whom he created from mud and water in the first place.

In Homer's epic Odyssey, the mortals sailed the ship of Odysseus in a violent sea during Odysseus'(Ulyses') wandering after the war of Troy. The sailors passed by the seashores where seductive sirens sang to attract them to land, and amongst others they landed on the island of the witch-goddess. This would represent the journey of the universal wanderer seeking immortality and trying to escape the destiny-bound cycle of life and death. During the wandering the Promethean man is highlighted, seeking to refute Heaven and destiny, while sailing over the tumultuous waters of life and defiantly trying to escape from human suffering! A philosophical paradigm may be employed within which human life and health can be regarded as being like the existence of an abandoned,directionless vessel that is trying to establish a course while standing up to the adverse elements of nature en route.

Within this myth the eagle would appear to be associated with a nocturnal register rather than a diurnal kind of symbolism. There is no real association with eagles' habits but rather with the idea of darkness during the night being equated with negative thoughts, feelings, emotions, fear, and the dark side of human nature. As a matter of fact in Hesiodus' Theogony (v.523-524), we find the following sentence : "Et sur lui il lacha aussi un aigle aux longues ailes - et l'aigle mangeait le foie immortel, mais celui-ci s'accroissait d'une quantité en tout point égale,pendant la nuit, à ce que, durant le jour, mangeait l'oiseau aux longues ailes". Moreover "l'aigle est né d'ECHIDNA, la Vipère monstrueuse" (cf. Pierre Grimal). And its symbol is so negative that some authors prefer the expression : "vorace vautour". Thus Robert Graves writes : "De plus en plus irrité, Zeus fit enchainer Prométhée, nu, à une colonne dans une montagne du Caucase ou un vorace vautour lui dévorait le foie toute

la journée, du début à la fin de l'année". Therefore, a solar interpretation does not appear to correspond to the eagle. On the other hand, people would often consider Prometheus' liver to be a solar symbol par excellence. The liver is considered immortal not only because it belongs to Prometheus but because the sun that is associated with Prometheus' liver is considered to be immortal, i.e. an everlasting source of energy or existing from the beginning of time and/or the universe.

We are aware of the importance attached to the liver by our ancestors (cf. heliocentric idea of the solar system). In a certain sense the essential thing is not so much the choice of the devoured organ but rather its acknowledged importance in the eyes of humanity. In other words, if the myth had been created after Michael Servetus' (1511-53) pioneering study and description of the pulmonary circulation of blood the devoured organ would most likely have been the lungs whereas after William Harvey's (1578-1657) discoveries concerning the circulation of the blood around the body, the chosen devoured organ would probably have been the heart. Without doubt the organ of choice nowadays would be the brain (cf. for example, the tale of the man with a golden brain by Alphonse Daudet).

In effect, the relevance of the organ that is considered to be of vital importance to human beings can be traced back to, and associated with, the moment in history in question and its concomitant scientific development. Galen of Pergamum, also known as Claudios Galenos (b.AD 129 d. circa AD 199) was the distinguished physician of antiquity who founded experimental physiology. Galen believed that the four bodily humours; blood, phlegm, yellow bile, and black bile were supposed to give rise to the sanguine, phlegmatic, choleric, and melancholic temperaments, respectively. Thus, human health was thought to require an equilibrium between these four humours. This constituted a continuation of the earlier Hippocratic conception of the unity of the organism(cf. atomic view).There was also an epoch when the stomach was considered to be a fundamental organ, the seat of all human emotions, i.e. the temper or spirit.Thus, chronologically-speaking the order of scientific importance attached to various human organs could be as follows:

$Liver- > gall - bladder- > stomach- > lungs- > heart- > brain- > mind- > consciousness.$

The inhabitants of the Greek Islands still transport fire from one place to another on a giant fennel and Prometheus chained on Mount Caucasus is perhaps a legend that the Hellenic people keep alive or they emigrated from the Caspian Sea in order to give themselves up in Greece: "that gigantic ice cap lying in the snow of the mountain peaks and surrounded by vultures" (cf. Robert Graves).

Another possible interpretation of the myth of Prometheus is that he is said to have been an astronomer who went up Mount Caucasus and stayed there all night in order to make some observations. The myth came about due to the lack of understanding of his close friends and relatives in an attempt to search for the etymological meaning of man. As a matter of fact, one of the plausible etymologies of the Greek word for man (ΑΝΘΡΩΠΟΣ) is; 'the one who looks up'(an implicit reference to the sky) and above all, an "acte gratuite", in other words, not indispensible to humanity's survival and yet an act that distinguishes human beings from other animals. Within this alternative framework we can observe the same type of amalgamation that led to the creation of the myth of the centaurs. In sum, the centaurs (ΚΕΝΤΑΥΡΟΣ) were veteran knights who lived in the Pelion, a mountain located

near Mount Ossa in Thessaly, Greece.

The compelling image of Prometheus, the astronomer looking up to observe the sky at the summit of Mount Caucasus, could be taken to represent the human race. It is our feeble attempt to comprehend the immensity of the far-away space and heavens and the vast universe that exists in relation to our nearby terrestrial world and mundane existence on this planet.

Prometheus loved humankind and this is evinced by displays of hyper altruistic behaviour and he is the symbol of the well-minded and good-spirited (ΑΚΑΚΗΤΑ ΠΡΟΜΗΘΕΥΣ; Prométhée sans malice ΗΣΙΟΔΟΣv. 614).

Aristotelian duality provides us with a clear inter-relationship between the two states represented by the psyche and the material world. The conceptualization of the Physis and the marked influence of Pre-Socratic thought(involving the four elements; earth,wind,fire,and water) tend to provide a vision of the universe that is constantly changing, whereby these changes both originate from and are fuelled by the Physis itself.

Orozco (1883-1949) portrayed Prometheus as a monumental pseudo- Michelangelesque giant, straining his powerful muscles against the burden of his fate. Prometheus was the self-sacrificing, creative man ("Man of Fire") providing humanity with fire which enlightens,liberates, and purifies but also consumes!

Cooperative phenomena in crystals and social choice theory

Thierry Marchant*
Ghent University

May 15, 2000

Abstract

In 1960, C. Domb published a paper entitled *On the theory of cooperative phenomena in crystals* in which he presented an expression for the number of cycles of length l in a triangular lattice. This expression was erroneous. We present a correct expression and we show that it is linked, in social choice theory, to the probability that all candidates are tied in an election with the Borda rule.

Keywords: Borda, probability of ties

1 Introduction

In 1960, C. Domb published a massive paper (212 pages) entitled *On the theory of cooperative phenomena in crystals* [Domb 60]. In this paper, he addressed many different problems. One of them, related to the magnetic properties of crystals, was the following. Consider the lattice[1] presented in Fig. 1.

A cycle in this lattice is a path starting from some node, travelling along some edges and coming back to the same node. The length of a cycle is the number of edges contained in it. E.g., the shortest cycle has length 2; it starts from some node, travels along one edge and directly comes back along the same edge. The next shortest cycle has length 3. It travels along the 3 edges delimiting a small triangle. How many different cycles, with length l, starting from a given node, are there?

The answer given by C. Domb (page 344) was

$$\sum_{s,t} \frac{1}{s!t!} \sum_{q=0}^{s} 2^{s-q} \frac{(t+q)!}{((t+q)/2!)^2} \frac{1}{q!(s-q)!}, \tag{1}$$

*The research presented in this paper was done while the author was working at the Service de Mathématiques de la Gestion, Université Libre de Bruxelles.

[1] In classical graph theory, lattice has a different meaning. We use it here in its cristallography meaning which is close to the concept of pavement in geometry

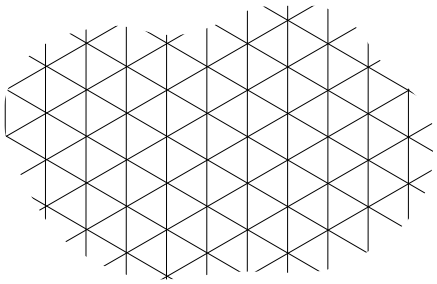

Figure 1: Triangular lattice

with $s, t = 0, 1 \ldots l$, satisfying the conditions $(2s + t) = l$ and $(t + q)$ even. He called this number r_l. On page 345, he also computed some values of r_l for $l = 2$ through 9. Unfortunately expression (1) for r_l is incorrect although numerical values given on page 345 are correct. In Section 2, we present a correct expression for r_l. In the last section, we present some links with social choice theory.

2 A correct expression for the number of cycles

At each node, there are 6 possible edges. Let us call them $x, -x, y, -y, z, -z$ as in Fig. 2.

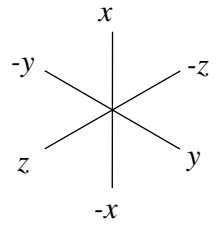

Figure 2: Names of the edges

In a cycle, an edge of any kind can be compensated by a corresponding edge of the opposite sign. E.g., a x edge can be compensated by a $-x$ edge; a $-z$ edge by a z edge, and so on. But an edge of any kind can also be compensated by two other edges of different kinds and same sign. E.g., a y edge can be compensated by a x edge and a z edge; a $-z$ edge by a $-x$ edge and a $-y$ edge and so on.

Hence, in any cycle, we can sort the edges into two parts: (a) those compensating 2 by 2 and (b) those that do not compensate 2 by 2 (thus compensating 3 by 3). In (a), we necessarily have $2s$ edges (s integer between 0 and $l/2$). In (b), we necessarily have $3t$ edges (t integer between 0 and $l/3$) and they have the same sign, otherwise some of them could could compensate 2 by 2. Obviously,

$2s + 3t = l$. In (a), s edges are positive, while s edges are negative. Among the s positive edges, there is any repartition between x, y and z. Among the s negative edges, there is the same repartition between $-x, -y$ and $-z$. Hence, if $2s$ edges among l are chosen, the number of possible configurations of these $2s$ edges, such that they all compensate 2 by 2 (case (a)), is given by

$$\binom{2s}{s} \sum_{q=0}^{s} \sum_{r=0}^{s-q} \frac{(s!)^2}{((s-q-r)!r!q!)^2}. \tag{2}$$

In this expression, q represents the number of x edges, r the number of y edges and $(s - q - r)$ the number of z edges. Let us come back to (b). Among the $3t$ edges, we necessarily have the same number of x, y, z or (exclusive) $-x, -y, -z$. Thus, if we choose $3t$ edges, the number of possible configurations such that they compensate 3 by 3 and not 2 by 2, is given by

$$2^{[t>0]} \frac{(3t)!}{(t!)^3}, \tag{3}$$

where $[t > 0]$ equals 1 if $t > 0$ and 0 otherwise.

For given s and t, the number of possible cycles is not just the product of expressions (2) and (3). It would be equivalent to considering as different some cycles just because we arbitrarily separated some edges of the same kind and sign in the (a) and (b) parts. Thus we have to take into account the number of ways to choose t edges of kind x (or $-x$) among the whole number of x edges. And there are $q + t$ such edges. The number of ways to make this choice is thus $\binom{q+t}{t}$. For y and z edges, we must consider $\binom{r+t}{t}$ and $\binom{s-q-r+t}{t}$.

Hence, for given s and t, the number of possible cycles is given by

$$\binom{l}{2s} \binom{2s}{s} \sum_{q=0}^{s} \sum_{r=0}^{s-q} \frac{\frac{(s!)^2}{((s-q-r)!r!q!)^2} \frac{2^{[t>0]}(3t)!}{(t!)^3}}{\binom{q+t}{t} \binom{r+t}{t} \binom{s-q-r+t}{t}}. \tag{4}$$

Finally, letting vary s and t so that $2s + 3t = l$, we obtain the following expression:

$$r_l = \sum_{2s+3t=l} \binom{l}{2s} \binom{2s}{s} \sum_{q=0}^{s} \sum_{r=0}^{s-q} \frac{\frac{(s!)^2}{((s-q-r)!r!q!)^2} \frac{2^{[t>0]}(3t)!}{(t!)^3}}{\binom{q+t}{t} \binom{r+t}{t} \binom{s-q-r+t}{t}}. \tag{5}$$

After some simplification, r_l is given by

$$l! \sum_{2s+3t=l} 2^{[t>0]} \sum_{q=0}^{s} \sum_{r=0}^{s-q} \frac{1}{q!r!(s-q-r)!(q+t)!(r+t)!(s-q-r+t)!}. \tag{6}$$

Shortly after we found this expression, Domb (personal communication) found the error in his expression: a multiplicative factor $l!$ had disappeared

from his formula during the typing process ! Therefore, an alternate expression for (5) is

$$\sum_{s,t} \frac{l!}{s!t!} \sum_{q=0}^{s} 2^{s-q} \frac{(t+q)!}{((t+q)/2!)^2} \frac{1}{q!(s-q)!}, \tag{7}$$

whith $s, t = 0, 1 \ldots l$, satisfying the conditions $(2s + t) = l$ and $(t + q)$ even. So, Domb knew the right expression in 1960. But, due to the fact that a proof of this expression has never been published and that this result finds some new applications in social choice theory (see next section), we tkink that it is worth publishing our proof.

3 Some links with social choice theory

A very classical problem in social choice is the following. Suppose that l voters $\{1, 2 \ldots, l\}$ must elect a president and there are k candidates $\{a, b, c, \ldots\}$. Each voter expresses his preferences about the candidates by mean of a complete ranking, from best to worst. We call profile a vector containing the rankings of each voter. E.g.,

$$\begin{pmatrix} a{>}b{>}c \\ b{>}c{>}a \\ c{>}b{>}a \end{pmatrix} \tag{8}$$

is a profile with 3 voters and 3 candidates such that voter 1's most preferred candidate is a, voter 1's last candidate is c and voter 2's most preferred candidate is b. How shall we derive from a profile which candidate should be elected? This question has been at the heart of social choice theory since the end of the 18th century. Many methods have been proposed. For example,

- choose the candidate with most first positions,
- or the candidate with least last positions,
- or compute the ranking which is at minimum distance of the l rankings in the profile (a metric needs to be defined over the set of the rankings). Then choose the candidate in first position in this new ranking.
- A very popular method is the Borda method. A candidate receives one point for each first position in the profile, 2 points for each 2nd position, 3 points for each 3rd position, ... and k points for each last position. The candidate who has the fewest points is elected.

Let us illustrate the Borda method by an example. In the profile shown in (8), a has 7 points, b, 5 points and c, 6 points. Hence, b is elected. In some cases the Borda method doesn't help much as all candidates have the same number of points and are tied, as in profile (9) where they all have 6 points.

$$\begin{pmatrix} a{>}b{>}c \\ b{>}c{>}a \\ c{>}a{>}b \end{pmatrix}. \tag{9}$$

Of course, most methods that have been devised lead to different results. Which one should we choose? Many criteria have been proposed to assess the merits of a method. Hundreds of axiomatic studies have been conducted, characterizing the various methods by a set of axioms.

A possible criterion to compare different methods, is the probability that a method yields a tie (by this, we mean a complete tie of all candidates). A method with a high probability of tie might be considered as less interesting than a method with a low probability because it more often fails to designate a winner. Of course, if the difference of the probabilities is not very large, this disadvantage might be compensated by other advantages. Hence, this criterion should be taken into account only for very large differences of probabilities. We are going to show now that the probabilty that the Borda method yields a tie is related to r_l.

3.1 The case of three candidates

For three candidates, there are $3! = 6$ possible rankings and each voter can choose any of the 6 rankings. Let us associate each ranking to one of the 6 different kinds of edges of our triangular lattice (see Fig. 2).

$$\begin{array}{rcr} a>b>c & : & x \\ b>c>a & : & y \\ c>a>b & : & z \\ c>b>a & : & -x \\ a>c>b & : & -y \\ b>a>c & : & -z \end{array} \tag{10}$$

Then any profile corresponds to a path in the triangular lattice. For example, the profile in (9) corresponds to a path x, y, z. Remark that this path is in fact a cycle. It is not difficult to see that it is not a coincidence. A profile will yield all candidates tied (under the Borda method) if and only if the corresponding path in the triangular lattice is a cycle. Hence, the number of profiles yielding all candidates tied under the Borda method is r_l. And the probability we were looking for is just r_l divided by the number of different profiles, i.e. $(3!)^l$. Some numerical values of the probability of ties are given in table 1.

l	2	3	4	5	6	7	8

l	9	19	29	39	49		
Pr. of ties	.0288	.0141	.0093	.0070	.0056		
Pr. of Condorcet paradox	.0780	.0832	.0848	.0856	.0860		

Table 1: Numerical values of the probability of ties for three candidates

The Condorcet method selects the candidate that beats every other candidates in pairwise comparisons. It is well known that the Condorcet method can

also fail to produce a winner (Condorcet paradox) but for very different reasons: the candidates are not tied, the method just doesn't work. Nevertheless, from a practical point of view, if all candidates win (tied), using the Borda method, or no candidate wins, using the Condorcet one, the president of the committee where such an election happens is very embarassed: he doesn't know what to choose. Therefore, it seems interesting to us to compare the probabilities of ties for the Borda method to those of Condorcet paradox for the Condorcet method (see table 1), taken from [Gehrlein 83]. The proportion of profiles such that the president of the committee is not helped is larger with the Condorcet method. Furthermore, the probability of ties decreases with l while the probability of Condorcet paradox increases with l. From this viewpoint, the Borda method seems more interesting that the Condorcet one. In fact, for very large number of voters and candidates, the probability that the Condorcet method designates no winner approaches 1 [Bell 81].

3.2 The case of two candidates

Let us consider the lattice of Fig. 3 , consisting of edges aligned on a straight line.

Figure 3: Linear lattice

At each node of this lattice, there are 2 possible edges. Let us call them x and $-x$. It is clear that we can describe any profile with two candidates by a path in our linear lattice. We just need to associate $a > b$ rankings to an edge, say x, and $b > a$ rankings to the other edge, i.e. $-x$. It is obvious as well that all profiles such that a and b are tied correspond to cycles in the linear lattice and the number of different cycles of length l is given by $\begin{pmatrix} l \\ l/2 \end{pmatrix}$ for l even and 0 for l odd. Some values of the probability of ties are given in table 2.

l	2	4	6	8	10	20	50	∞
Pr. of ties	.5000	.3750	.3125	.2734	.2461	.1762	.1123	0

Table 2: Numerical values of the probability of ties for two candidates

For larger number of candidates, other lattices must be used but they can no longer be represented in two dimensions. Derivation of explicit formulas for r_l is much more difficult.

In our computations of the probabilities, we considered that any profile is as likely as any other one (this condition is known as the *impartial culture condition*). Therefore, it is obvious that our results must be taken with a pinch of salt for, in reality, such an assumption is clearly questionable [Fishburn and Gehrlein 80]. Nevertheless, they provide some hint.

Note that I discovered the similarity between the two problems thanks to the amazing *Encyclopedia of integer sequences* [Sloane and Plouffe 95], sequence M4101.

Counting 1324-Avoiding Permutations

We consider permutations that avoid the pattern 1324. By studying the generating tree for such permutations, we obtain a recurrence formula for their number. A computer program provides data for the number of 1324-avoiding permutations of length up to 20.

FARMER TED GOES NATURAL

GREG MARTIN

1. Setting the Stage

We've all been given a problem in a calculus class remarkably similar to the following one:

> Farmer Ted is building a chicken coop. He decides he can spare 190 square feet of his land for the coop, which will be built in the shape of a rectangle. Being a practical man, Farmer Ted wants to spend as little as possible on the chicken wire for the fence. What dimensions should he make the chicken coop?

By solving a simple optimization problem, we learn that Farmer Ted should make his chicken coop a square with side lengths $\sqrt{190}$ feet. And that, according to the solution manual, is that.

But the calculus books don't tell the rest of the story:

> So Farmer Ted went over to Builders Square and told the salesman, "I'd like $4\sqrt{190}$ feet of chicken wire, please." The salesman, however, replied that he could sell one foot or two feet or a hundred feet of chicken wire, but what the heck was $4\sqrt{190}$ feet of chicken wire? Farmer Ted was taken aback, explaining heatedly that his family had been buying as little chicken wire as possible for generations, and he really wanted $4\sqrt{190}$ feet of chicken wire measured off for him immediately! But the salesman, fearing more irrational behavior from Farmer Ted, told him, "I don't want to hear about your roots. We do business in a natural way here, and if you don't like it you can leave the whole store." Well, Farmer Ted didn't feel that this treatment was commensurate with his request, but he left Builders Square to rethink his coop from square one.

At first, Farmer Ted thought his best bet would be to make a $10' \times 19'$ chicken coop, necessitating the purchase of 58 feet of chicken wire—certainly this was better than 86 feet of chicken wire for a $5' \times 38'$ coop, say. But then he realized that he could be more cost-effective by not using all of the 190 square feet of land he had reserved for the coop. For instance, he could construct an $11' \times 17'$ coop (187 square feet) with only 56 feet of chicken wire; this would give him about 3.34 square feet of coop space per foot of chicken wire purchased, as opposed to only 3.28 square feet per chicken-wire-foot for the $10' \times 19'$ coop. Naturally, the parsimonious farmer wondered: could he do even better?

2. Posing the Problem

Jon Grantham posed the following problem at the 1998 SouthEast Regional Meeting On Numbers in Greensboro, North Carolina: given a positive integer N, find the dimensions of the rectangle with integer side lengths and area at most N whose area-to-perimeter ratio is largest among all such rectangles. In the story above, Farmer Ted is trying to solve this problem for $N = 190$.

Let's introduce some notation so we can formulate Grantham's problem more precisely. For a positive integer n, let $s(n)$ denote the least possible semiperimeter (length plus width) of a rectangle with integer side lengths and area n. (Since the area-to-semiperimeter ratio of a rectangle is always twice the area-to-perimeter ratio, it doesn't really change the problem

if we consider semiperimeters instead of perimeters; this will eliminate annoying factors of 2 in many of our formulas.) In other (and fewer) words,

$$s(n) = \min_{cd=n}(c+d) = \min_{d\mid n}(d+n/d),$$

where $d \mid n$ means that d divides n.

Let $F(n) = n/s(n)$ denote the area-to-semiperimeter ratio in which we are interested. We want to investigate the integers n such that $F(n)$ is large, and so we define the set $\mathcal{A}$ of "record-breakers" for the function F as follows:

$$\mathcal{A} = \{n \in \mathbb{N} \colon F(k) \le F(n) \text{ for all } k \le n\}. \tag{1}$$

(Well, the "record-tiers" are also included in $\mathcal{A}$.) Then it is clear after a moment's thought that to solve Grantham's problem for a given number N, we simply need to find the largest element of $\mathcal{A}$ not exceeding N.

By computing all possible factorizations of the numbers up to 200 by brute force, we can make a list of the first 59 elements of $\mathcal{A}$:

$\mathcal{A} = \{1, 2, 3, 4, 6, 8, 9, 12, 15, 16, 18, 20, 24, 25, 28, 30, 35, 36, 40, 42, 48, 49, 54, 56, 60, 63, 64, 70, 72, 77, 80, 81, 88, 90, 96, 99, 100, 108, 110, 117, 120, 121, 130, 132, 140, 143, 144, 150, 154, 156, 165, 168, 169, 176, 180, 182, 192, 195, 196, \dots\}$

If we write, in place of the elements $n \in \mathcal{A}$, the dimensions of the rectangles with area n and least semiperimeter, we obtain

$\mathcal{A} = \{1\times1, 1\times2, 1\times3, 2\times2, 2\times3, 2\times4, 3\times3, 3\times4, 3\times5, 4\times4, 3\times6, 4\times5, 4\times6, 5\times5, 4\times7, 5\times6, 5\times7, 6\times6, 5\times8, 6\times7, 6\times8, 7\times7, 6\times9, 7\times8, 6\times10, 7\times9, 8\times8, 7\times10, 8\times9, 7\times11, 8\times10, 9\times9, 8\times11, 9\times10, 8\times12, 9\times11, 10\times10, 9\times12, 10\times11, 9\times13, 10\times12, 11\times11, 10\times13, 11\times12, 10\times14, 11\times13, 12\times12, 10\times15, 11\times14, 12\times13, 11\times15, 12\times14, 13\times13, 11\times16, 12\times15, 13\times14, 12\times16, 13\times15, 14\times14, \dots\},$

a list that exhibits a tantalizing promise of pattern! The interested reader is invited to try to determine the precise pattern of the set $\mathcal{A}$, before reading into the next section in which the secret will be revealed. One thing we immediately notice, though, is that the dimensions of each of these rectangles are almost (or exactly) equal. For this reason, we will call the elements of $\mathcal{A}$ *almost-squares*. This supports our intuition about what the answers to Grantham's problem should be, since after all, Farmer Ted would build his rectangles with precisely equal sides if he weren't hampered by the integral policies of (the ironically-named) Builders Square.

From the list of the first 59 almost-squares, we find that 182 is the largest almost-square not exceeding 190. Therefore, Farmer Ted should build a chicken coop with area 182 square feet; and indeed, a $13' \times 14'$ coop would give him about 3.37 square feet of coop space per foot of chicken wire purchased, which is more cost-effective than the options he thought of back in Section 1. But what about next time, when Farmer Ted wants to build a supercoop on the 8,675,309 square feet of land he has to spare, or even more? Eventually, computations will need to give way to a better understanding of $\mathcal{A}$.

Our specific goals in this paper will be to answer the following questions:

1. Can we describe $\mathcal{A}$ more explicitly? That is, can we characterize when a number n is an almost-square with a description that refers only to n itself, rather than all the numbers smaller than n? Can we find a formula for the number of almost-squares not exceeding a given positive number x?

2. Can we quickly compute the largest almost-square not exceeding N, for a given number N? We will describe more specifically what we mean by "quickly" in the next section, but for now we simply say that we'll want to avoid both brute force searches and computations that involve factoring integers.

In the next section, we will find that these questions have surprisingly elegant answers.

3. Remarkable Results

Have you uncovered the pattern of the almost-squares? One detail you might have noticed is that all numbers of the form $m \times m$ and $(m-1) \times m$, and also $(m-1) \times (m+1)$, seem to be almost-squares. (If not, maybe we should come up with a better name for the elements of $\mathcal{A}$!) This turns out to be true, as we will see in Lemma 3 below. The problem is that there are other almost-squares than these—3×6, 4×7, 5×8, 6×9, 6×10—and the "exceptions" seem to become more and more numerous . . . . Even so, it will be convenient to think of the particular almost-squares of the form $m \times m$ and $(m-1) \times m$ as "punctuation" of a sort for $\mathcal{A}$. To this end, we will define a *flock* to be the set of almost-squares between $(m-1)^2+1$ and $m(m-1)$, or between $m(m-1)+1$ and m^2, including the endpoints in both cases.

If we group the rectangles corresponding to the almost-squares into flocks in this way, indicating the end of each flock by a semicolon, we obtain:

$\mathcal{A} = \{1\times1;\ 1\times2;\ 1\times3,\ 2\times2;\ 2\times3;\ 2\times4,\ 3\times3;\ 3\times4;\ 3\times5,\ 4\times4;\ 3\times6,\ 4\times5;\ 4\times6,\ 5\times5;\ 4\times7,\ 5\times6;$
$5\times7,\ 6\times6;\ 5\times8,\ 6\times7;\ 6\times8,\ 7\times7;\ 6\times9,\ 7\times8;\ 6\times10,\ 7\times9,\ 8\times8;\ 7\times10,\ 8\times9;\ 7\times11,\ 8\times10,\ 9\times9;$
$8\times11,\ 9\times10;\ 8\times12,\ 9\times11,\ 10\times10;\ 9\times12,\ 10\times11;\ 9\times13,\ 10\times12,\ 11\times11;\ 10\times13,\ 11\times12;\ 10\times14,$
$11\times13,\ 12\times12;\ 10\times15,\ 11\times14,\ 12\times13;\ 11\times15,\ 12\times14,\ 13\times13;\ 11\times16,\ 12\times15,\ 13\times14;\ 12\times16,$
$13\times15,\ 14\times14;\ \ldots\ \}$

It seems that all of the rectangles in a given flock have the same semiperimeter; this also turns out to be true, as we will see in Lemma 4 below. The remaining question, then, is to determine which rectangles of the common semiperimeter a given flock contains. At first it seems that all rectangles of the "right" semiperimeter will be in the flock as long as their area exceeds that of the last rectangle in the preceding flock, but then we note a few omissions—2×5, 3×7, 4×8, 5×9, 5×10—which also become more numerous if we extend our computations of $\mathcal{A}$ . . . .

But as it happens, this question can be resolved, and we can actually determine exactly which numbers are almost-squares, as our main theorem indicates. Recall that $\lfloor x \rfloor$ denotes the greatest integer not exceeding x.

Main Theorem. *For any integer $m \geq 2$, the set of almost-squares between $(m-1)^2+1$ and m^2 (inclusive) consists of two flocks, the first of which is*

$$\{(m+a_m)(m-a_m-1), (m+a_m-1)(m-a_m), \ldots, (m+1)(m-2), m(m-1)\}$$

where $a_m = \lfloor(\sqrt{2m-1}-1)/2\rfloor$, and the second of which is

$$\{(m+b_m)(m-b_m), (m+b_m-1)(m-b_m+1), \ldots, (m+1)(m-1), m^2\}$$

where $b_m = \lfloor\sqrt{m/2}\rfloor$.

The Main Theorem allows us to easily enumerate the almost-squares in order, but if we simply want an explicit characterization of almost-squares without regard to their order, there turns out to be one that is extremely elegant. To describe it, we recall that the *triangular numbers* $\{0, 1, 3, 6, 10, 15, \ldots\}$ are the numbers $t_n = \binom{n}{2} = n(n-1)/2$ (Conway

and Guy [1] describe many interesting properties of these and other "figurate" numbers). We let $T(x)$ denote the number of triangular numbers not exceeding x. (Notice that in our notation, $t_1 = \binom{1}{2} = 0$ is the first triangular number, so that $T(1) = 2$, for instance.) Then an alternate interpretation of the Main Theorem is the following:

Corollary 1. *The almost-squares are precisely those integers that can be written in the form $k(k+h)$, for some integers $k \ge 1$ and $0 \le h \le T(k)$.*

It is perhaps not so surprising that the triangular numbers are connected to the almost-squares—after all, adding t_m to itself or to t_{m+1} yields almost-squares of the form $m(m-1)$ or m^2, respectively (Figure 1 illustrates this for $m = 6$). In any case, the precision of this characterization is quite attractive and unexpected, and it is conceivable that Corollary 1 has a direct proof that doesn't use the Main Theorem. We leave this as an open problem for the reader.

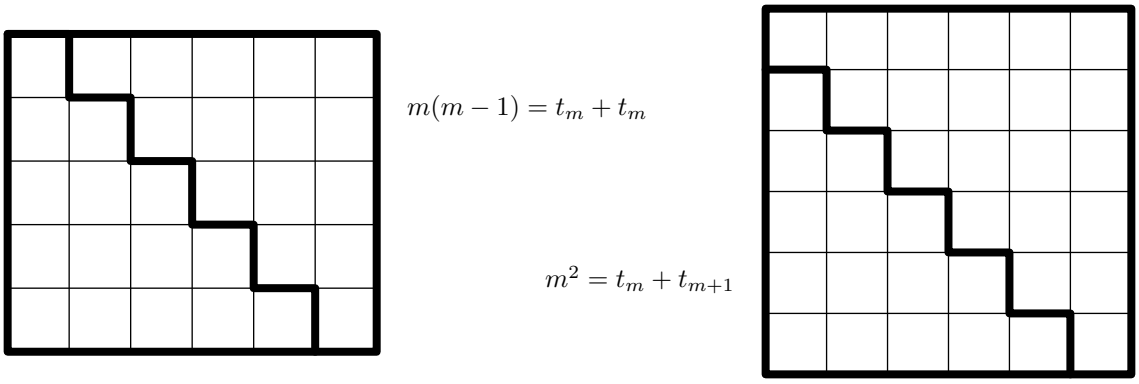

FIGURE 1. Two triangular integers invoke an almost-square

In a different direction, we can use the Main Theorem's precise enumeration of the almost-squares in each flock to count the number of almost-squares quite accurately.

Corollary 2. *Let $A(x)$ denotes the number of almost-squares not exceeding x. Then for $x \ge 1$,*

$$A(x) = \frac{2\sqrt{2}}{3}x^{3/4} + \frac{1}{2}x^{1/2} + R(x),$$

where $R(x)$ is an oscillating term whose order of magnitude is $x^{1/4}$.

A graph of $A(x)$ (see Figure 2) exhibits a steady growth with a little bit of a wiggle. When we isolate $R(x)$ by subtracting the main term $2\sqrt{2}x^{3/4}/3 + x^{1/2}/2$ from $A(x)$, the resulting graph (Figure 2, where we have plotted a point every time x passes an almost-square) is a pyrotechnic, almost whimsical display that seems to suggest that our computer code needs to be rechecked. Yet this is the true nature of $R(x)$. When we prove Corollary 2 (in a more specific and precise form) in Section 6, we will see that there are two reasons that the "remainder term" $R(x)$ oscillates: there are oscillations on a local scale because the almost-squares flock towards the right half of each interval of the form $((m-1)^2, m(m-1)]$ or $(m(m-1), m^2]$, and oscillations on a larger scale for a less obvious reason.

These theoretical results about the structure of the almost-squares address question 1 nicely, and we turn our attention to the focus of question 2, the practicality of actually

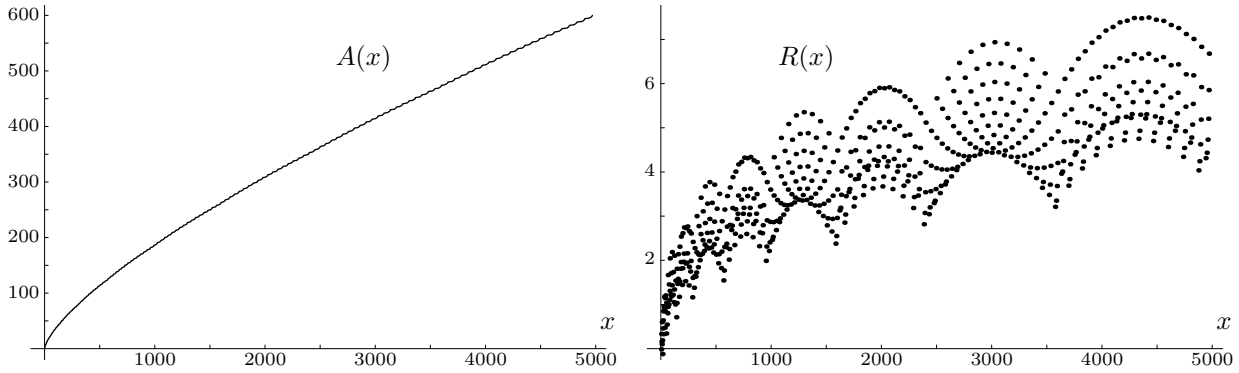

FIGURE 2. Superficial steadiness of $A(x)$, mesmerizing meanderings of $R(x)$

computing answers to questions about almost-squares. Even simple tasks like printing out a number or adding two numbers together obviously take time for a computer to perform, and they take longer for bigger numbers. To measure how the computing time needed for a particular computation increases as the size of the input grows, let $f(k)$ denote the amount of time it takes to perform the calculation on a k-digit number. Of course, the time could depend significantly on which k-digit number we choose; what we mean is the worst-case scenario, so that the processing time is at most $f(k)$ no matter which k-digit number we choose.

We say that a computation runs in *polynomial time* if this function $f(k)$ grows only as fast as a polynomial in k, i.e., if there are positive constants A and B such that $f(k) < Ak^B$. Generally speaking, the computations that we consider efficient to perform on very large inputs are those that run in polynomial time. (Because we are only concerned with this category of computations as a whole, it doesn't matter if we write our numbers in base 10 or base 2 or any other base, since this only multiplies the number of digits by a constant factor like $\log_2 10$.)

All of our familiar arithmetic operations $+$, $-$, $\times$, $\div$, $\sqrt{\cdot}$, $\lfloor\cdot\rfloor$ and so on have polynomial-time algorithms. On the other hand, performing a calculation on each of the numbers from 1 to the input n, or even from 1 to $\sqrt{n}$, etc., is definitely not polynomial-time. Thus computing almost-squares by their definition, which involves comparing $F(n)$ with all of the preceding $F(k)$, is not efficient for large n. Furthermore, the obvious method of factoring numbers—testing all possible divisors in turn—is not polynomial-time for the same reason. While there are faster ways to factor numbers, at this time there is still no known polynomial-time algorithm for factoring numbers; so even factoring a single number would make an algorithm inefficient. (Dewdney [2] writes about many facets of algorithms, including this property of running in polynomial time, while Pomerance [4] gives a more detailed discussion of factoring algorithms and their computational complexity.)

Fortunately, the Main Theorem provides a way to compute almost-squares that avoids both factorization and brute-force enumeration. In fact, we can show that all sorts of computations involving almost-squares are efficient:

Corollary 3. *There are polynomial-time algorithms to perform each of the following tasks, given a positive integer N:*

(a) *determine whether N is an almost-square, and if so determine the dimensions of the optimal rectangle;*

(b) *find the greatest almost-square not exceeding N, including the dimensions of the optimal rectangle;*
(c) *compute the number $A(N)$ of almost-squares not exceeding N;*
(d) *find the Nth almost-square, including the dimensions of the optimal rectangle.*

We reiterate that these algorithms work without ever factoring a single integer. Corollary 3, together with our lack of a polynomial-time factoring algorithm, has a rather interesting implication: for large values of N, it is much faster to compute the most cost-effective chicken coop (in terms of area-to-semiperimeter ratio) with area *at most* N than it is to compute the most cost-effective chicken coop with area *equal to* N, a somewhat paradoxical state of affairs! Nobody ever said farming was easy . . . .

4. The Theorem Thought Through

Before proving the Main Theorem, we need to build up a stockpile of easy lemmas. The first of these simply confirms our expectations that the most cost-effective rectangle of a given area is the one whose side lengths are as close together as possible, and also provides some inequalities for the functions $s(n)$ and $F(n)$. Let us define $d(n)$ to be the largest divisor of n not exceeding $\sqrt{n}$ and $d'(n)$ the smallest divisor of n that is at least $\sqrt{n}$, so that $d'(n) = n/d(n)$.

Lemma 1. *The rectangle with integer side lengths and area n that has the smallest semiperimeter is the one with dimensions $d(n) \times d'(n)$. In other words,*

$$s(n) = d(n) + d'(n).$$

We also have the inequalities

$$s(n) \ge 2\sqrt{n} \quad \text{and} \quad F(n) \le \sqrt{n}/2.$$

Proof: For a fixed positive number n, the function $f(t) = t + n/t$ has derivative $f'(t) = 1 - n/t^2$ which is negative for $1 \le t < \sqrt{n}$, and therefore $t + n/t$ is a decreasing function of t in that range. Thus if we restrict our attention to those t such that both t and n/t are positive integers (in other words, t is an integer dividing n), we see that the expression $t + n/t$ is minimized when $t = d(n)$. We therefore have

$$s(n) = d(n) + n/d(n) \ge 2\sqrt{n},$$

where the last inequality follows from the Arithmetic Mean/Geometric Mean inequality; and the inequality for $F(n)$ then follows directly from the definition of F. □

If we have a number n written as $c \times d$ where c and d are pretty close to $\sqrt{n}$, when can we say that there isn't some better factorization out there, so that $s(n)$ is really equal to $c + d$? The following lemma gives us a useful criterion.

Lemma 2. *If a number n satisfying $(m-1)^2 < n \le m(m-1)$ has the form $n = (m-a-1)(m+a)$ for some number a, then $s(n) = 2m-1$, and $d(n) = m-a-1$ and $d'(n) = m+a$. Similarly, if a number n satisfying $m(m-1) < n \le m^2$ has the form $n = m^2 - b^2$ for some number b, then $s(n) = 2m$, and $d(n) = m - b$ and $d'(n) = m + b$.*

Proof: First let's recall that for any positive real numbers α and β, the pair of equations $r+s=\alpha$ and $rs=\beta$ have a unique solution (r,s) with $r\le s$, as long as the Arithmetic Mean/Geometric Mean inequality $\alpha/2\ge\sqrt{\beta}$ holds. This is because r and s will be the roots of the quadratic polynomial $t^2-\alpha t+\beta$, which has real roots when its discriminant $\alpha^2-4\beta$ is nonnegative, i.e., when $\alpha/2\ge\sqrt{\beta}$.

Now if $n=(m-a-1)(m+a)$, then clearly $s(n)\le(m-1-a)+(m+a)=2m-1$ by the definition of $s(n)$. On the other hand, by Lemma 1 we know that $s(n)\ge 2\sqrt{n}>2(m-1)$, and so $s(n)=2m-1$ exactly. We now know that $d(n)d'(n)=n=(m-a-1)(m+a)$ and

$$d(n)+d'(n)=s(n)=2m-1=(m-a-1)+(m+a),$$

and of course $d(n)\le d'(n)$ as well; by the argument of the previous paragraph, we conclude that $d(n)=m-a-1$ and $d'(n)=m+a$. This establishes the first assertion of the lemma, and a similar argument holds for the second assertion. □

Of course, if a number n satisfies $s(n)=2m$ for some m, then n can be written as $n=cd$ with $c\le d$ and $c+d=2m$; and letting $b=d-m$, we see that $n=cd=(2m-d)d=(m-b)(m+b)$. A similar statement is true if $s(n)=2m-1$, and so we see that the converse of Lemma 2 also holds. We also remark that in the statement of the lemma, the two expressions $m(m-1)$ can be replaced by $(m-1/2)^2=m(m-1)+1/4$ if we wish.

Lemma 2 implies in particular that for $m\ge 2$,

$$s(m^2)=2m,\quad s(m(m-1))=2m-1,\quad \text{and } s((m-1)(m+1))=2m,$$

and so

$$F(m^2)=\frac{m}{2},\quad F(m^2-m)=\frac{m(m-1)}{2m-1},\quad \text{and } F(m^2-1)=\frac{m^2-1}{2m}.$$

Using these facts, we can verify our theory that these numbers are always almost-squares.

Lemma 3. *Each positive integer of the form m^2, $m(m-1)$, or m^2-1 is an almost-square.*

It is interesting to note that these are precisely those integers n that are divisible by $\lfloor\sqrt{n}\rfloor$ (see [3]), one of the many interesting things that can be discovered by referring to Sloane and Plouffe [6].

Proof: We verify directly that such numbers satisfy the condition in the definition (1) of $\mathcal{A}$. If $k<m^2$, then by Lemma 1 we have $F(k)\le\sqrt{k}/2<m/2=F(m^2)$, and so m^2 is an almost-square. Similarly, if $k<m(m-1)$, then again

$$F(k)\le\frac{\sqrt{k}}{2}\le\frac{\sqrt{m^2-m-1}}{2}<\frac{m(m-1)}{2m-1}=F(m(m-1)),$$

where the strict inequality can be verified as a "fun" algebraic exercise. Thus $m(m-1)$ is also an almost-square. A similar argument shows that m^2-1 is also an almost-square. □

Now we're getting somewhere! Next we show that the semiperimeters of the rectangles corresponding to the almost-squares in a given flock are all equal, as we observed at the beginning of Section 3.

Lemma 4. *Let $m\ge 2$ be an integer. If n is an almost-square satisfying $(m-1)^2<n\le m(m-1)$, then $s(n)=2m-1$; similarly, if n is an almost-square satisfying $m(m-1)<n\le m^2$, then $s(n)=2m$.*

Proof: If $n = m(m-1)$, we have already shown that $s(n) = 2m-1$. If n satisfies $(m-1)^2 < n < m(m-1)$, then by Lemma 1 we have $s(n) \ge 2\sqrt{n} > 2(m-1)$. On the other hand, since n is an almost-square exceeding $(m-1)^2$, we have

$$\frac{m-1}{2} = F((m-1)^2) \le F(n) = \frac{n}{s(n)} < \frac{m(m-1)}{s(n)},$$

and so $s(n) < 2m$. Therefore $s(n) = 2m-1$ in this case.

Similarly, if n satisfies $m(m-1) < n < m^2$, then $s(n) \ge 2\sqrt{n} \ge 2\sqrt{m^2-m+1} > 2m-1$; on the other hand,

$$\frac{m(m-1)}{2m-1} = F(m(m-1)) \le F(n) = \frac{n}{s(n)} \le \frac{m^2-1}{s(n)},$$

and so $s(n) < (m+1)(2m-1)/m < 2m+1$. Therefore $s(n) = 2m$ in this case. □

Finally, we need to exhibit some properties of the sequences a_m and b_m defined in the statement of the Main Theorem.

Lemma 5. *Define* $a_m = \lfloor (\sqrt{2m-1}-1)/2 \rfloor$ *and* $b_m = \lfloor \sqrt{m/2} \rfloor$. *For any integer* $m \ge 2$*:*

(a) $a_m \le b_m \le a_m + 1$*;*
(b) $b_m = \lfloor m/\sqrt{2m-1} \rfloor$*; and*
(c) $a_m + b_m = \lfloor \sqrt{2m} \rfloor - 1$.

We omit the proof of this lemma since it is tedious but straightforward. The idea is to show that in the sequences a_m, b_m, $\lfloor m/\sqrt{2m-1} \rfloor$, and so on, two consecutive terms are either equal or else differ by 1, and then to determine precisely for what values of m the differences of 1 occur.

Armed with these lemmas, we are now ready to furnish a proof of the Main Theorem.

Proof of the Main Theorem: Fix an integer $m \ge 2$. By Lemma 4, every almost-square n with $(m-1)^2 < n \le m(m-1)$ satisfies $s(n) = 2m-1$; while by Lemma 2, the integers $(m-1)^2 < n \le m(m-1)$ satisfying $s(n) = 2m-1$ are precisely the elements of the form $n_a = (m-a-1)(m+a)$ that lie in that interval. Thus it suffices to determine which of the n_a are almost-squares.

Furthermore, suppose that n_a is an almost-square for some $a \ge 1$. Then $F(n_a) \ge F(n)$ for all $n < n_a$ by the definition of $\mathcal{A}$, while $F(n_a) > F(n)$ for all $n_a < n < n_{a-1}$ since we've already concluded that no such n can be an almost-square. Moreover, $n_{a-1} > n_a$ and $s(n_{a-1}) = 2m-1 = s(n_a)$, so $F(n_{a-1}) > F(n_a)$, and thus n_{a-1} is an almost-square as well. Therefore it suffices to find the largest value of a (corresponding to the smallest n_a) such that n_a is an almost-square.

By Lemma 3, we know that $(m-1)^2$ is an almost-square, and so we need to find the largest a such that $F(n_a) \ge F((m-1)^2)$, i.e.,

$$\frac{(m-a-1)(m+a)}{2m-1} \ge \frac{m-1}{2},$$

which is the same as $2a(a+1)+1 \le m$. By completing the square and solving for a, we find that this inequality is equivalent to

$$\frac{-\sqrt{2m-1}-1}{2} \le a \le \frac{\sqrt{2m-1}-1}{2}, \tag{2}$$

and so the largest integer a satisfying the inequality is exactly $a = \lfloor(\sqrt{2m-1}-1)/2\rfloor = a_m$, as defined in the statement of the Main Theorem. This establishes the first part of the theorem.

By the same reasoning, it suffices to find the largest value of b such that $F(m^2-b^2) \geq F(m(m-1))$, i.e.,

$$\frac{m^2-b^2}{2m} \geq \frac{m(m-1)}{2m-1},$$

which is the same as

$$b^2 \leq m^2/(2m-1) \tag{3}$$

or $b \leq \lfloor m/\sqrt{2m-1}\rfloor$. But by Lemma 5(b), $\lfloor m/\sqrt{2m-1}\rfloor = b_m$ for $m \geq 2$, and so the second part of the theorem is established. □

With the Main Theorem now proven, we remark that Lemma 5(c) implies that for any integer $m \geq 2$, the number of almost-squares in the two flocks between $(m-1)^2+1$ and m^2 is exactly $(1+a_m)+(1+b_m) = 1+\lfloor\sqrt{2m}\rfloor$, while Lemma 5(a) implies that there are either equally many in the two flocks or else one more in the second flock than in the first.

5. Taking Notice of Triangular Numbers

Our next goal is to derive Corollary 1 from the Main Theorem. First we establish a quick lemma giving a closed-form expression for $T(x)$, the number of triangular numbers not exceeding x.

Lemma 6. *For all $x \geq 0$, we have $T(x) = \lfloor\sqrt{2x+1/4}+1/2\rfloor$.*

Proof: $T(x)$ is the number of positive integers n such that $t_n \leq x$, or $n(n-1)/2 \leq x$. This inequality is equivalent to $(n-1/2)^2 \leq 2x+1/4$, or $-\sqrt{2x+1/4}+1/2 \leq n \leq \sqrt{2x+1/4}+1/2$. The left-hand expression never exceeds $1/2$, and so $T(x)$ is simply the number of positive integers n such that $n \leq \sqrt{2x+1/4}+1/2$; in other words, $T(x) = \lfloor\sqrt{2x+1/4}+1/2\rfloor$ as desired. □

Proof of Corollary 1: Suppose first that $n = k(k+h)$ for some integers $k \geq 1$ and $h \leq T(k)$. Let $k' = k+h$, and define

$$\begin{cases} m = k+(h+1)/2 \text{ and } a = (h-1)/2, & \text{if } h \text{ is odd,} \\ m = k+h/2 \text{ and } b = h/2, & \text{if } h \text{ is even,} \end{cases}$$

so that

$$\begin{cases} k = m-a-1 \text{ and } k' = m+a, & \text{if } h \text{ is odd,} \\ k = m-b \text{ and } k' = m+b, & \text{if } h \text{ is even.} \end{cases}$$

We claim that

$$\begin{cases} (m-1)^2 < (m-a-1)(m+a) \leq (m-1/2)^2, & \text{if } h \text{ is odd,} \\ (m-1/2)^2 < m^2-b^2 \leq m^2, & \text{if } h \text{ is even.} \end{cases} \tag{4}$$

To see this, note that in terms of k and h, these inequalities become

$$\big(k+\frac{h-1}{2}\big)^2 < k(k+h) \leq \big(k+\frac{h}{2}\big)^2.$$

A little bit of algebra reveals that the right-hand inequality is trivially satisfied while the left-hand inequality is true provided that $h < 2\sqrt{k}+1$. However, from Lemma 6 we see that

$$T(k) = \lfloor \sqrt{2k+1/4} + 1/2 \rfloor \le \sqrt{2k+1/4} + 1/2 < 2\sqrt{k} + 1$$

for $k \ge 1$. Since we are assuming that $h \le T(k)$, this shows that the inequalities (4) do indeed hold.

Because of these inequalities, we may apply Lemma 2 (see the remarks following the proof of the lemma) and conclude that

$$\begin{cases} s(n) = 2m-1,\ d(n) = m-a-1,\ \text{and } d'(n) = m+a, & \text{if } h \text{ is odd,} \\ s(n) = 2m,\ d(n) = m-b,\ \text{and } d'(n) = m+b, & \text{if } h \text{ is even.} \end{cases}$$

Consequently, the Main Theorem asserts that n is an almost-square if and only if

$$\begin{cases} a \le a_m, & \text{if } h \text{ is odd,} \\ b \le b_m, & \text{if } h \text{ is even,} \end{cases} \tag{5}$$

which by the definitions of a, b, and m is the same as

$$\begin{cases} (h-1)/2 \le \lfloor (\sqrt{2m-1}-1)/2 \rfloor = \lfloor (\sqrt{2k+h}-1)/2 \rfloor, & \text{if } h \text{ is odd,} \\ h/2 \le \lfloor \sqrt{m/2} \rfloor = \lfloor \sqrt{k/2 + h/4} \rfloor, & \text{if } h \text{ is even.} \end{cases}$$

Since in either case, the left-hand side is an integer, the greatest-integer brackets can be removed from the right-hand side, whence both cases reduce to $h \le \sqrt{2k+h}$. From here, more algebra reveals that this inequality is equivalent to $h \le \sqrt{2k+1/4} + 1/2$; and since h is an integer, we can add greatest-integer brackets to the right-hand side, thus showing that the inequality (5) is equivalent to $h \le T(k)$ (again using Lemma 6). In particular, n is indeed an almost-square.

This establishes one half of the characterization asserted by Corollary 1. Conversely, suppose we are given an almost-square n, which we can suppose to be greater than 1 since 1 can obviously be written as $1(1+0)$. If we let $h = d'(n) - d(n)$, then the Main Theorem tells us that

$$\begin{cases} n = (m-a-1)(m+a),\ d(n) = m-a-1,\ \text{and } d'(n) = m+a, & \text{if } h \text{ is odd,} \\ n = m^2 - b^2,\ d(n) = m-b,\ \text{and } d'(n) = m+b, & \text{if } h \text{ is even} \end{cases}$$

for some integers $m \ge 2$ and either a with $0 \le a \le a_m$ or b with $0 \le b \le b_m$. If we set $k = d(n)$, then certainly $n = k(k+h)$. Moreover, the algebraic steps showing that the inequality (5) is equivalent to $h \le T(k)$ are all reversible; and (5) does in fact hold, since we are assuming that n is an almost-square. Therefore n does indeed have a representation of the form $k(k+h)$ with $0 \le h \le T(k)$. This establishes the corollary. □

We take a slight detour at this point to single out some special almost-squares. Let us make the convention that the kth flock refers to the flock of almost-squares with semiperimeter k, so that the first flock is actually empty, the second and third poor flocks contain only $1 = 1\times 1$ and $2 = 1\times 2$, respectively, the fourth flock contains $3 = 1\times 3$ and $4 = 2\times 2$, and so on. The Main Theorem tells us that a_m and b_m control the number of almost-squares in the odd-numbered and even-numbered flocks, respectively; thus every so often, a flock will have one more almost-square than the preceding flock of the same "parity". We'll let a *pioneer* be an almost-square that begins one of these suddenly-longer flocks.

For instance, from the division of $\mathcal{A}$ into flocks on page 3, we see that the 4th flock {1×3, 2×2} is longer than the preceding even-numbered flock {1×1}, so $1 \times 3 = 3$ is the first pioneer; the 9th flock {3×6, 4×5} is longer than the preceding odd-numbered flock {3×4}, so $3 \times 6 = 18$ is the second pioneer; and so on, the next two pioneers being 6×10 in the 16th flock and 10×15 in the 25th flock. Now if this isn't a pattern waiting for a proof, nothing is! The following lemma shows another elegant connection between the almost-squares and the squares and triangular numbers.

Corollary 4. *For any positive integer j, the jth pioneer equals $t_{j+1} \times t_{j+2}$ (where t_i is the ith triangular number), which begins the $(j+1)^2$-th flock. Furthermore, the "record-tying" almost-squares (those whose F-values are equal to the F-values of their immediate predecessors in $\mathcal{A}$) are precisely the even-numbered pioneers.*

Proof: First, Lemma 5(a) tells us that the odd- and even-numbered flocks undergo their length increases in alternation, so that the pioneers alternately appear in the flocks of each parity. The first pioneer $3 = 1 \times 3$ appears in the 4th flock, and corresponds to $m = 2$ and the first appearance of $b_m = 1$ in the notation of the Main Theorem. Thus the $(2k-1)$-st pioneer will equal $m^2 - k^2$, where m corresponds to the first appearance of $b_m = k$. It is easy to see that the first appearance of $b_m = k$ occurs when $m = 2k^2$, in which case the $(2k-1)$-st pioneer is

$$m^2 - k^2 = (2k^2)^2 - k^2 = (2k^2 - k)(2k^2 + k) = \frac{2k(2k-1)}{2}\frac{(2k+1)2k}{2} = t_{2k}t_{2k+1}.$$

Moreover, the flock in which this pioneer appears is the $2m$-th or $(2k)^2$-th flock.

Similarly, the $2k$-th pioneer will equal $(m-k-1)(m+k)$, where m corresponds to the first appearance of $a_m = k$. Again one can show that the first appearance of $a_m = k$ occurs when $m = 2k^2 + 2k + 1$, in which case the $2k$-th pioneer is

$$(m-k-1)(m+k) = (2k^2+k)(2k^2+3k+1) = \frac{(2k+1)2k}{2}\frac{(2k+2)(2k+1)}{2} = t_{2k+1}t_{2k+2}.$$

Moreover, the flock in which this pioneer appears is the $(2m-1)$-st or $(2k+1)^2$-th flock. This establishes the first assertion of the corollary.

Since the F-values of the almost-squares form a nondecreasing sequence by the definition of almost-square, to look for almost-squares with equal F-values we only need to examine consecutive almost-squares. Furthermore, two consecutive almost-squares in the same flock never have equal F-values, since they are distinct numbers but by Lemma 4 their semiperimeters are the same. Therefore we only need to determine when the last almost-square in a flock can have the same F-value as the first almost-square in the following flock.

The relationship between the F-values of these pairs of almost-squares was determined in the proof of the Main Theorem. Specifically, the equality $F((m-1)^2) = F((m-a-1)(m+a))$ holds if and only if the right-hand inequality in (2) is actually an equality; this happens precisely when $m = 2a^2 + 2a + 1$, which corresponds to the even-numbered pioneers as was determined above. On the other hand, the equality $F(m(m-1)) = F(m^2 - b^2)$ holds if and only if the inequality (3) is actually an equality; but m^2 and $2m-1$ are always relatively prime (any prime factor of m^2 must divide m and thus divides into $2m-1$ with a "remainder" of -1), implying that $m^2/(2m-1)$ is never an integer for $m \geq 2$, and so the inequality (3) can never be an equality. This establishes the second assertion of the corollary. □

We know that all squares are almost-squares, and so t_j^2 is certainly an almost-square for any triangular number t_j; also, Corollary 4 tells us that the product $t_j t_{j+1}$ of two consecutive triangular numbers is always an almost-square. This led the author to wonder which numbers of the form $t_m t_n$ are almost-squares. If m and n differ by more than 1, it would seem that the rectangle of dimensions $t_m \times t_n$ is not the most cost-effective rectangle of area $t_m t_n$, and so the author expected that these products of two triangular numbers would behave randomly with respect to being almost-squares—that is, a few of them might be but most of them wouldn't. After some computations, however, Figure 3 emerged, where a point has been plotted in the (m, n) position if and only if $t_m t_n$ is an almost-square; and the table exhibited a totally unexpected regularity.

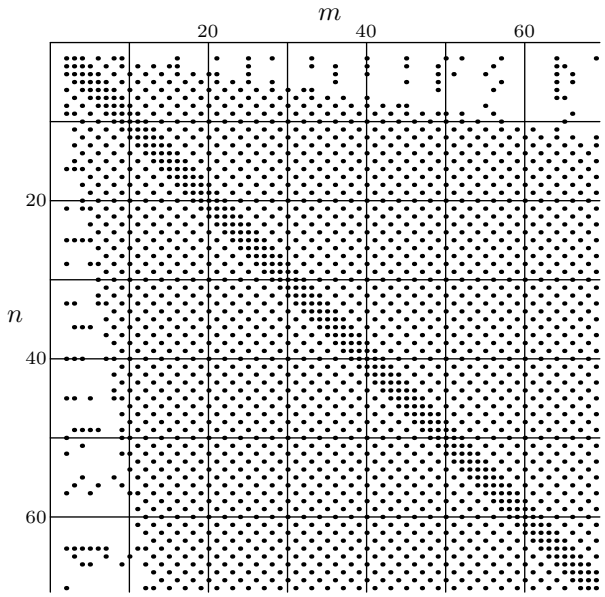

FIGURE 3. Amazing almost-square patterns in products of two triangles

Of course the symmetry of the table across the main diagonal is to be expected since $t_m t_n = t_n t_m$. The main diagonal and the first off-diagonals are filled with plotted points, corresponding to the almost-squares t_m^2 and $t_m t_{m+1}$; and in hindsight, the second off-diagonals correspond to

$$t_m t_{m+2} = \frac{m(m-1)}{2}\frac{(m+2)(m+1)}{2} = \frac{m^2+m-2}{2}\,\frac{m^2+m}{2},$$

which is the product of two consecutive integers (since m^2+m is always even) and is thus an almost-square as well. But apart from these central diagonals and some garbage along the edges of the table where m and n are quite different in size, the checkerboard-like pattern in the kite-shaped region of the table seems to be telling us that the only thing that matters in determining whether $t_m t_n$ is an almost-square is whether m and n have the same parity!

Once this phenomenon had been discovered, it turned out that the following corollary could be derived from the prior results in this paper. We leave the proof of this corollary as a challenge to the reader.

Corollary 5. *Let m and n be positive integers with $n-1 > m > 3n - \sqrt{8n(n-1)} - 1$. Then $t_m t_n$ is an almost-square if and only if $n-m$ is even.*

We remark that the function $3n-\sqrt{8n(n-1)}-1$ is asymptotic to $(3-2\sqrt{2})n+(\sqrt{2}-1)$, which explains the straight lines of slope $-(3-2\sqrt{2})\approx -0.17$ and $-1/(3-2\sqrt{2})\approx -5.83$ that seem to the eye to separate the orderly central region in Figure 3 from the garbage along the edges.

6. Counting and Computing

In this section we establish Corollaries 2 and 3. We begin by defining a function $B(x)$ that will serve as the backbone of our investigation of the almost-square counting function $A(x)$. Let $\{x\}=x-\lfloor x\rfloor$ denote the fractional part of x, and define the quantities $\gamma=\gamma(x)=\{\sqrt{2}x^{1/4}\}$ and $\delta=\delta(x)=\{x^{1/4}/\sqrt{2}\}$. Let $B(x)=B_0(x)+B_1(x)$, where

$$B_0(x)=\frac{2\sqrt{2}}{3}x^{3/4}+\frac{1}{2}x^{1/2}+\big(\frac{2\sqrt{2}}{3}+\frac{\gamma(1-\gamma)}{\sqrt{2}}\big)x^{1/4} \tag{6}$$

and

$$B_1(x)=\frac{\gamma^3}{6}-\frac{\gamma^2}{4}-\frac{5\gamma}{12}-\frac{\delta}{2}-1.$$

We remark that $\gamma=\{2\delta\}$ and that $B_1(x^4)$ is a periodic function of x with period $\sqrt{2}$, and so it is easy to check that the inequalities $-2\le B_1(x)\le -1$ always hold. The following lemma shows how the strange function $B(x)$ arises in connection with the almost-squares.

Lemma 7. *For any integer $M\ge 1$, we have $A(M^2)=B(M^2)$.*

Proof: As remarked at the end of Section 4, the number of almost-squares between $(m-1)^2+1$ and m^2 is $\lfloor\sqrt{2m}\rfloor+1$ for $m\ge 2$. Therefore

$$A(M^2)=1+\sum_{m=2}^{M}(\lfloor\sqrt{2m}\rfloor+1)=M-1+\sum_{m=1}^{M}\lfloor\sqrt{2m}\rfloor.$$

It's almost always a good idea to interchange orders of summation whenever possible—and if there aren't enough summation signs, find a way to create some more! In this case, we convert the greatest-integer function into a sum of 1s over the appropriate range of integers:

$$\begin{aligned}A(M^2)&=M-1+\sum_{m=1}^{M}\sum_{1\le k\le\sqrt{2m}}1\\&=M-1+\sum_{1\le k\le\sqrt{2M}}\ \sum_{k^2/2\le m\le M}1\\&=M-1+\sum_{\substack{1\le k\le\sqrt{2M}\\ k\text{ odd}}}\big(M-\frac{k^2-1}{2}\big)+\sum_{\substack{1\le k\le\sqrt{2M}\\ k\text{ even}}}\big(M-\big(\frac{k^2}{2}-1\big)\big).\end{aligned}$$

If we temporarily write μ for $\lfloor\sqrt{2M}\rfloor$, then

$$\begin{aligned}A(M^2)&=M-1+\mu\big(M+\frac{1}{2}\big)-\frac{1}{2}\sum_{k=1}^{\mu}k^2+\sum_{\substack{k=1\\ k\text{ even}}}^{\mu}\frac{1}{2}\\&=M(\mu+1)+\frac{\mu}{2}-1-\frac{1}{2}\frac{\mu(\mu+1)(2\mu+1)}{6}-\frac{1}{2}\lfloor\frac{\mu}{2}\rfloor,\end{aligned} \tag{7}$$

using the well-known formula for the sum of the first μ squares. Since $\lfloor \lfloor x \rfloor / n \rfloor = \lfloor x/n \rfloor$ for any real number $x \ge 0$ and any positive integer n, the last term can be written as

$$\frac12 \Big\lfloor \frac{\mu}{2} \Big\rfloor = \frac12 \left\lfloor \frac{\lfloor \sqrt{2M} \rfloor}{2} \right\rfloor = \frac12 \left\lfloor \sqrt{\frac{M}{2}} \right\rfloor = \frac12 \sqrt{\frac{M}{2}} - \frac12 \left\{ \sqrt{\frac{M}{2}} \right\} = \frac12 \sqrt{\frac{M}{2}} - \frac{\delta(M^2)}{2},$$

while we can replace the other occurrences of μ in equation (7) by $\sqrt{2M} - \{\sqrt{2M}\} = \sqrt{2M} - \gamma(M^2)$. Writing γ for $\gamma(M^2)$ and δ for $\delta(M^2)$, we see that

$$\begin{aligned} A(M^2) &= M(\sqrt{2M} - \gamma + 1) + \sqrt{2M} - \gamma - 1 \\ &\qquad - \frac12 \frac{(\sqrt{2M} - \gamma)(\sqrt{2M} - \gamma + 1)(2(\sqrt{2M} - \gamma) + 1)}{6} - \frac12 \sqrt{\frac{M}{2}} + \frac{\delta}{2} \\ &= \frac{2\sqrt2}{3} M^{3/2} + \frac{M}{2} + \Big(\frac{2\sqrt2}{3} - \frac{\gamma(1-\gamma)}{\sqrt2} \Big) \sqrt{M} + \frac{\gamma^3}{6} - \frac{\gamma^2}{4} - \frac{5\gamma}{12} - 1 - \frac{\delta}{2} = B(M^2) \end{aligned}$$

after much algebraic simplification. This establishes the lemma. □

Now $B(x)$ is a rather complicated function of x, but the next lemma gives us a couple of ways to predict the behavior of $B(x)$. First, it tells us how to predict $B(x+y)$ from $B(x)$ if y is small compared to x (roughly speaking, their difference will be $y/\sqrt2 x^{1/4}$); second, it tells us how to predict approximately when $B(x)$ assumes a given integer value.

Lemma 8. *There is a positive constant C such that:*

(a) for all real numbers $x \ge 1$ and $0 \le y \le \min\{x/2, 3\sqrt{x}\}$, we have

$$\Big| (B(x+y) - B(x)) - \frac{y}{\sqrt2 x^{1/4}} \Big| < C; \tag{8}$$

(b) if we define $z_j = \frac12 (3j)^{2/3} - \frac14 (3j)^{1/3}$ for any positive integer j, then for all $j > C$ we have $z_j > 2$ and $B((z_j - 1)^2) < j < B(z_j^2)$.

If the proof of Lemma 5 was omitted due to its tediousness, the proof of this lemma should be omitted and then buried . . . . The idea of the proof is to rewrite $B_0(x) x^{-3/4}$ using the new variable $t = x^{-1/4}$, and then expand in a Taylor series in t (a slight but easily overcome difficulty being that the term $\gamma(x)(1-\gamma(x))$ is not differentiable when $\sqrt2 x^{1/4}$ is an integer). For the proof of part (b), we also need to rewrite $z_j j^{-2/3}$ using the new variable $u = j^{-1/3}$ and expand in a Taylor series in u. We remark that the constant C in Lemma 8 can be taken to be quite small—in fact, $C = 5$ will suffice.

With these last lemmas in hand, we can dispatch Corollaries 2 and 3 in quick succession.

Proof of Corollary 2: Let $x > 1$ be a real number and define $R(x) = A(x) - 2\sqrt2 x^{3/4}/3 - \sqrt{x}/2$, as in the statement of the corollary. We will describe how to prove the following more precise statement:

$$R(x) = \Big(\frac{2\sqrt2}{3} + g(\sqrt2 x^{1/4}) - h(2\sqrt{x}) \Big) x^{1/4} + R_1(x), \tag{9}$$

where

$$g(t) = \frac{\{t\}(1 - \{t\})}{\sqrt2} \quad \text{and} \quad h(t) = \begin{cases} \dfrac{\{t\}}{\sqrt2}, & \text{if } 0 \le \{t\} \le \dfrac12, \\ \sqrt{1 - \{t\}} - \dfrac{1 - \{t\}}{\sqrt2}, & \text{if } \dfrac12 \le \{t\} \le 1 \end{cases}$$

and $|R_1(x)| < D$ for some constant D. The functions g and h are continuous and periodic with period 1, and are the causes of the oscillations in the error term $R(x)$. The expression $g(\sqrt{2}x^{1/4})$ goes through a complete cycle when x increases by about $2\sqrt{2}x^{3/4}$ (one can show this using Taylor expansions yet again!), which causes the large-scale bounces in the normalized error term $R(x)x^{-1/4}$ shown in Figure 4 below. Similarly, the expression $h(2\sqrt{x})$ goes through a complete cycle when x increases by about $\sqrt{x}$, which causes the smaller-scale stutters shown in the (horizontally magnified) right-hand graph in Figure 4.

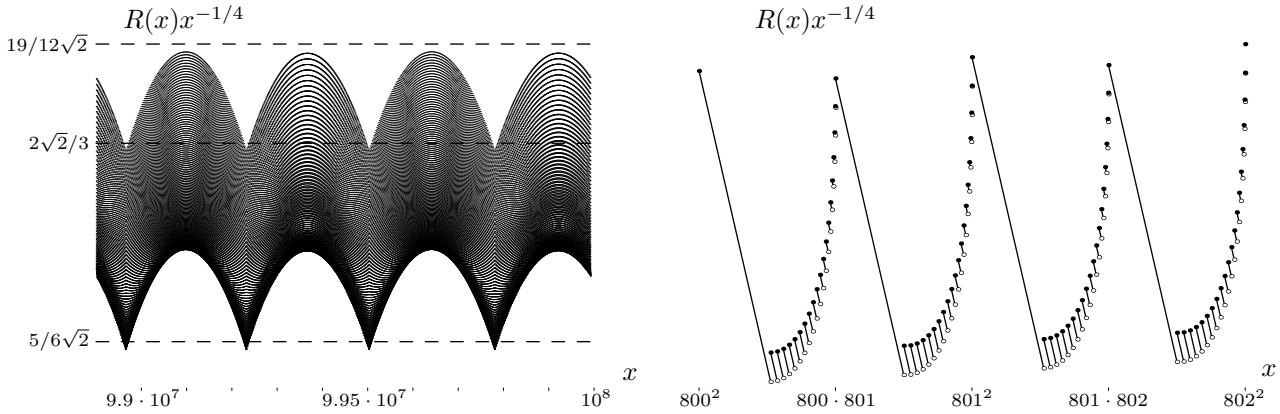

FIGURE 4. Big bounces and small stutters for $R(x)x^{-1/4}$

To establish the formula (9), we shrewdly add $B(x) - B(x)$ to the expression defining $R(x)$, which yields

$$R(x) = (A(x) - B(x)) + \big(\frac{2\sqrt{2}}{3} + \frac{\gamma(x)(1-\gamma(x))}{\sqrt{2}}\big)x^{1/4} + B_1(x)$$

from the definition (6) of $B_0(x)$. Now $B_1(x)$ is a bounded function; and since $\gamma(x) = \{\sqrt{2}x^{1/4}\}$, the expression $\gamma(x)(1-\gamma(x))/\sqrt{2}$ is precisely $g(\sqrt{2}x^{1/4})$. So what we need to show is that $B(x) - A(x) = h(2\sqrt{x})x^{1/4} + R_2(x)$, where $R_2(x)$ is another bounded function.

While we won't give all the details, the outline of showing this last fact is as follows: suppose first that $x \geq m^2$ but that x is less than the first almost-square $(m+1+a_{m+1})(m-a_{m+1})$ in the $(2m+1)$-st flock, so that $A(x) = A(m^2)$. Since $A(m^2) = B(m^2)$ by Lemma 7, we only need to show that $B(x) - B(m^2)$ is approximately $h(2\sqrt{x})x^{1/4}$; this we can accomplish with the help of Lemma 8(a).

Similarly, if $x < m^2$ but x is at least as large as the first almost-square $(m+b_m)(m-b_m)$ in the $2m$-th flock, the same method works as long as we take into account the difference between $A(m^2)$ and $A(x)$, which is $\lfloor\sqrt{m^2-x}\rfloor$ by the Main Theorem. And if x is close to an almost-square of the form $m(m-1)$ rather than m^2, the same method applies; even though $A(m(m-1))$ and $B(m(m-1))$ are not exactly equal, they differ by a bounded amount.

Notice that the functions $g(t)$ and $h(t)$ take values in $[0, 1/4\sqrt{2}]$ and $[0, 1/2\sqrt{2}]$, respectively. From this and the formula (9) we can conclude that

$$\liminf_{x\to\infty} \frac{R(x)}{x^{1/4}} = \frac{5}{6\sqrt{2}} \text{ and } \limsup_{x\to\infty} \frac{R(x)}{x^{1/4}} = \frac{19}{12\sqrt{2}}.$$

The interested reader can check, for example, that the sequences $y_j = 4j^4 + j^2$ and $z_j = (2j^2+j)^2$ satisfy $\lim_{j\to\infty} R(y_j)/y_j^{1/4} = 5/6\sqrt{2}$ and $\lim_{j\to\infty} R(z_j)/z_j^{1/4} = 19/12\sqrt{2}$. □

Proof of Corollary 3: The algorithms we describe will involve only the following types of operations: performing ordinary arithmetical calculations $+$, $-$, $\times$, $\div$; computing the greatest-integer $\lfloor\cdot\rfloor$, least-integer $\lceil\cdot\rceil$, and fractional-part $\{\cdot\}$ functions; taking square roots; and comparing two numbers to see which is bigger. All of these operations can be easily performed in polynomial time. To get the ball rolling, we remark that the functions a_m, b_m, and $B(x)$ can all be computed in polynomial time, since their definitions only involve the types of operations just stated.

We first describe a polynomial-time algorithm for computing the number of almost-squares up to a given positive integer N. Let $M = \lceil\sqrt{N}\rceil$, so that $(M-1)^2 < N \le M^2$. Lemma 7 tells us that the number of almost-squares up to M^2 is $B(M^2)$, and so we simply need to subtract from this the number of almost-squares larger than N but not exceeding M^2. This is easy to do by the characterization of almost-squares given in the Main Theorem. If $N > M(M-1)$, then we want to find the positive integer b such that $M^2 - b^2 \le N < M^2 - (b-1)^2$, except that we want $b = 0$ if $N = M^2$. In other words, we set $b = \lceil M^2 - N\rceil$. Then, if $b \le b_M$, the number of almost-squares up to N is $B(M^2) - b$, while if $b > b_M$, the number of almost-squares up to N is $B(M^2) - b_M - 1$.

In the other case, where $N \le M(M-1)$, we want to find the positive integer a such that $(M-a-1)(M+a) \le N < (M-a)(M+a-1)$, except that we want $a = 0$ if $N = M(M-1)$, In other words, we set $a = \lceil\sqrt{(M-1/2)^2 - N} + 1/2\rceil$. Then, if $a \le a_M$, the number of almost-squares up to N is $B(M^2) - b_m - 1 - a$, while if $a > a_M$, the number of almost-squares up to N is $B((M-1)^2)$. This shows that $A(N)$ can be computed in polynomial time, which establishes part (c) of the corollary.

Suppose now that we want to compute the Nth almost-square. We compute in any way we like the first C almost-squares, where C is as in Lemma 8; this only takes a constant amount of time (it doesn't change as N grows) which certainly qualifies as polynomial time. If $N \le C$ then we are done, so assume that $N > C$. Let $M = \lceil z_N\rceil$, where z_N is defined as in Lemma 8(b), so that M is at least 3 by the definition of C. By Lemma 7,

$$A(M^2) = B(M^2) \ge B(z_N^2) > N \quad \text{and} \quad A((M-2)^2) = B((M-2)^2) < B((z_N-1)^2) < N,$$

where the last inequality in each case follows from Lemma 8(b). Therefore the Nth almost-square lies between $(M-2)^2$ and M^2, and so is either in the $2M$-th flock or one of the preceding three flocks. If $0 \le B(M^2) - N \le b_M$, then the Nth almost-square is in the $2M$-th flock, and by setting $b = B(M^2) - N$ we conclude that the Nth almost-square is $M^2 - b^2$ and the dimensions of the optimal rectangle are $(M-b) \times (M+b)$. If $1 + b_M \le B(M^2) - N \le b_M + 1 + a_M$, then the Nth almost-square is in the $(2M-1)$-st flock, and so on. This establishes part (d) of the corollary.

Finally, we can determine the greatest almost-square not exceeding N by computing $J = A(N)$ and then computing the Jth almost-square, both of which can be done in polynomial time by parts (c) and (d); and we can determine whether N is an almost-square simply by checking whether this result equals N. This establishes the corollary in its entirety. □

7. Final Filibuster

We have toured some very pretty and precise properties of the almost-squares, and there are surely other natural questions that can be asked about them, some of which have already been noted. When Grantham posed this problem, he recalled the common variation on

the original calculus problem where the fence for one of the sides of the rectangle is more expensive for some reason (that side borders a road or something), and suggested the more general problem of finding the most cost-effective rectangle with integer side lengths and area at most N, where one of the sides must be fenced at a higher cost. This corresponds to replacing $s(n)$ with the more general function $s_\alpha(n) = \min_{d|n}(d + \alpha n/d)$, where α is some constant bigger than 1. While the elegance of the characterization of such "α-almost-squares" might not match that of Corollary 1, it seems reasonable to hope that an enumeration every bit as precise as the Main Theorem would be possible to establish.

How about generalizing this problem to higher dimensions? For example, given a positive integer N, find the dimensions of the rectangular box with integer side lengths and volume at most N whose volume-to-surface area ratio is largest among all such boxes. (It seems a little more natural to consider surface area rather than the sum of the box's length, width, and height, but who knows which problem has a more elegant solution?) Perhaps these "almost-cubes" have an attractive characterization analogous to Corollary 1; almost certainly a result like the Main Theorem, listing the almost-cubes in order, would be very complicated. And of course there is no reason to stop at dimension 3.

In another direction, intuitively it seems that numbers with many divisors are more likely to be almost-squares, and the author thought to test this theory with integers of the form $n!$. However, computations reveal that the only values of $n \leq 500$ for which $n!$ is an almost-square are $n = 1, 2, 3, 4, 5, 6, 7, 8, 10, 11, 13, 15$. Is it the case that these are the only factorial almost-squares? This seems like quite a hard question to resolve. Perhaps a better intuition about the almost-squares is that only those numbers that lie at the right distance from a number of the form m^2 or $m(m-1)$ are almost-squares—more an issue of good fortune than of having enough divisors.

The reader is welcome to contact the author for the Mathematica code used to calculate the functions related to almost-squares described in this paper. With this code, for instance, one can verify that with 8,675,309 square feet of land at his disposal, it is most cost-effective for Farmer Ted to build a $2{,}919' \times 2{,}972'$ supercoop ... speaking of which, we almost forgot to finish the Farmer Ted story:

> After learning the ways of the almost-squares, Farmer Ted went back to Builders Square, where the salesman viewed the arrival of his $\mathbb{R}$-rival with trepidation. But Farmer Ted reassured him, "Don't worry—I no longer think it's inane to measure fences in $\mathbb{N}$." From that day onward, the two developed a flourishing business relationship, as Farmer Ted became an integral customer of the store.

And that, according to this paper, is that.

The algebraic entropy of classical mechanics

Robert I. McLachlan and Brett Ryland*

Dedicated to Gerhard Wanner on the occasion of his 60th birthday.
Of trees and the counting of trees, may there be no end!

Abstract

We describe the 'Lie algebra of classical mechanics', modelled on the Lie algebra generated by kinetic and potential energy of a simple mechanical system with respect to the canonical Poisson bracket. It is a polynomially graded Lie algebra, a class we introduce. We describe these Lie algebras, give an algorithm to calculate the dimensions c_n of the homogeneous subspaces of the Lie algebra of classical mechanics, and determine the value of its entropy $\lim_{n\to\infty} c_n^{1/n}$. It is $1.82542377420108\ldots$, a fundamental constant associated to classical mechanics.

*Institute of Fundamental Sciences, Massey University, Palmerston North, New Zealand (R.McLachlan@massey.ac.nz).

1 Introduction. Classes of Lie algebras.

The class of 'simple mechanical systems' are defined by pairs (Q, V), where the configuration space Q is a real Riemannian manifold and the potential energy V is a smooth real function on Q. The phase space T^*Q has a canonical Poisson bracket and a kinetic energy $T : T^*Q \to \mathbb{R}$ associated with the metric on Q. In general, the smooth functions on a Poisson manifold form a Lie algebra under the Poisson bracket. In the case of a simple mechanical system, we are given two distinguished functions, namely the kinetic and potential energies, and one can ask what Lie algebra they generate under the Poisson bracket.

In this paper we study, not the Lie algebra generated by a *particular* V and T, but the Lie algebra defined by the whole *class* of simple mechanical systems. That is, one should think of the dimension of Q as being arbitrarily large, and the metric and potential energies also being arbitrary.

This question arose out of very practical considerations of the calculations required to derive high-order symplectic integrators by splitting and composition, used in applications including molecular, celestial, and accelerator dynamics [17, 10]. The vector field X which is to be integrated is split as $X = A + B$, where A and B have the same properties (e.g. Hamiltonian) as X, but can be integrated exactly. We write $\exp(tX)$ for the time-t flow of X. The most common such integrator is the leap-frog method

$$\varphi(\tau) := \exp(\frac{1}{2}\tau A)\exp(\tau B)\exp(\frac{1}{2}\tau A),$$

where the small parameter τ is the time step.

From the Baker-Campbell-Hausdorff formula [7], the map $\varphi(\tau)$ can be represented (up to any power in τ) as a flow $\exp(\tau\widetilde{X})$, where

$$\widetilde{X} = A + B + \tau^2(\frac{1}{12}[B,[B,A]] - \frac{1}{24}[A,[A,B]])) + \mathcal{O}(\tau^4). \tag{1}$$

Because it is the flow of a vector field $\mathcal{O}(\tau^2)$-close to the original one, the integrator is second order. The function $\widetilde{X}$ is called the *modified vector field* in the numerical integration literature [10].

For simple mechanical systems, we split the Hamiltonian as $H = T + V$. The flow of (the Hamiltonian vector field of) V can of course always be calculated easily, but calculating the flow of the kinetic energy T requires that Q have integrable (and even fairly simple) geodesics. Because the Lie algebras of Hamiltonian vector fields and of Hamiltonian functions are isomorphic under $[X_T, X_V] = X_{\{V,T\}}$, there is a series formally identical to Eq. (1) involving the Hamiltonians T and V with respect to the Poisson bracket.

In the series of Eq. (1) we see the Lie algebra generated by A and B entering. Such series, for example in the proof of the BCH formula, are usually considered in the context of the free Lie algebra $L(A, B)$ with two generators A and B. One can in fact consider the more general composition

$$\prod_{i=1}^{s} \exp(a_i \tau A) \exp(b_i \tau B) = \exp(Z) \tag{2}$$

where $Z \in L(A, B)$. Requiring $Z = \tau(A + B) + O(\tau^{p+1})$ for some integer $p > 1$ gives a system of equations in the a_i and b_i which must be satisfied for the method to have order p. In the case of general A and B, then, at each order $n = 1, \ldots, p$ there are $\dim L_n(A, B)$ such *order conditions*. Here $L_n(A, B)$ is the subspace of $L(A, B)$ consisting of homogeneous elements of order n. Witt's formula [7] states that

$$\dim L_n(A, B) = \frac{1}{n} \sum_{d|n} \mu(d) 2^{n/d} \tag{3}$$

where $\mu(d)$ is the Möbius function defined by $\mu(1) = 1$, $\mu(d) = (-1)^k$ if d is the product of k distinct primes, and $\mu(d) = 0$ otherwise. Notice that in this case

$$\dim L_n(A, B) \sim \frac{2^n}{n};$$

the dimensions grow exponentially with n. The base (2 in this case) of the exponent is called the *entropy* of $L(A, B)$. In general, the entropy of a graded vector space $\bigoplus L_n$ is

$$\limsup_{n \to \infty} (\dim L_n)^{1/n},$$

if this limit exists [21]. (We shall use generalizations of Witt's formula [12, 19] to calculate the dimensions and entropies of other free Lie algebras, see Eqs. (15), (17) below.)

In this approach it is assumed that there are no Lie identities satisfied by the vector fields A and B. This is reasonable if one wants the method to work for all A and B. However, in the case of simple mechanical systems, the Lie algebra is *never* free, regardless of T, V, or the dimension of the system. There are always identities satisfied by kinetic and potential energy. The simplest of these is

$$\{V, \{V, \{V, T\}\}\} \equiv 0. \tag{4}$$

For, working in local coordinates (q, p) with $T = \frac{1}{2} p^T M(q) p$, and recalling the canonical Poisson bracket $\{A, B\} := \sum_i \frac{\partial A}{\partial q_i} \frac{\partial B}{\partial p_i} - \frac{\partial A}{\partial p_i} \frac{\partial B}{\partial q_i}$, we have that

$$\{V, T\} = \sum_{i,j} \frac{\partial V}{\partial q_i} M_{ij}(q) p_j$$

is of degree 1 in p, and that

$$\{V, \{V, T\}\} = \sum_{i,j} \frac{\partial V}{\partial q_i} M_{ij} \frac{\partial V}{\partial q_j} \tag{5}$$

is a function of q only. So V and $\{V, \{V, T\}\}$ commute.

Thus, it was realized early on [16] that in deriving high-order integrators as in Eq. (2) for simple mechanical systems, the order conditions corresponding to $\{V, \{V, \{V, T\}\}\}$ and to all its higher Lie brackets can be dropped. This means that more efficient integrators can be designed for this class of systems. Much work has been done on this special case, both because of its intrinsic theoretical and practical importance, and because it allows such big improvements over the general case. For example, one can design special ('corrector' or 'processor') methods of the form $\varphi\psi\varphi^{-1}$ [3], special methods for nearly-integrable systems such as the solar system [4, 23], special methods involving exact evaluation of the forces associated with the 'modified potential' (Eq. 5) [5], and so on—see [17] for a survey. All of these studies rely on the structure of the Lie algebra generated by kinetic and potential energy. Bases for this Lie algebra have been constructed, more or less by hand, for small orders [5, 6, 20]. In particular, Murua [20] associates a unique tree of a certain type to each independent order condition of symplectic Runge-Kutta-Nyström methods (very closely related to the problem considered here), and enumerates these up to order 6. (Iserles et al. [11] extend this approach to some other classes of polynomial vector fields.) However, a systematic description of the entire Lie algebra is clearly preferred.

Not many classes of Lie algebras have been completely described. Here are two examples from the literature. First, Duchamp and Krob [9] completely describe all partially-commutative Lie algebras

$$L(A_1, \ldots, A_n; [A_i, A_j] = 0, (i, j) \in C)$$

where C specifies the pairs of commuting variables. Second, Kirillov, Kontsevich, and Molev [13] studied the Lie algebra L generated by two vector fields on $\mathbb{R}$ in general position, conjectured that

$$\sum_{\sigma \in S_4} (-1)^{\mathrm{sgn}(\sigma)} [x_{\sigma(1)}, x_{\sigma(2)}, x_{\sigma(3)}, x_{\sigma(4)}, y] = 0 \quad \forall x_1, x_2, x_3, x_4, y \in L \tag{6}$$

generates all identities, and calculated the dimensions of its homogeneous subspaces and the asymptotic growth of their dimension. If their conjecture is true, L is a *PI-algebra* [2, 8], one which the identities which hold in the Lie algebra (such as Eq. (6)) are satisfied by *all* elements of the Lie algebra.

Returning to the case of simple mechanical systems, it is clear that every Lie bracket of T and V is a homogeneous polynomial in p. Furthermore, the degrees of these polynomials combine in a natural way. We therefore introduce the following class $\mathfrak{P}$ of Lie algebras.

We use the notation $[XY] := [X, Y]$, $[XYZ] := [X, [Y, Z]]$, and for sets $\mathfrak{X}$, $\mathcal{Y}$, $[\mathfrak{X}\mathcal{Y}] := [\mathfrak{X}, \mathcal{Y}] := \{[X, Y] \colon X \in \mathfrak{X}, Y \in \mathcal{Y}\}$.

Definition 1 *A Lie algebra L is of class $\mathfrak{P}$ ('polynomially graded') if it is graded, i.e. $L = \bigoplus_{n\geq 0} L_n$, and its homogeneous subspaces L_n satisfy*

$$\begin{aligned} &[L_n, L_m] \subseteq L_{n+m-1} \text{ if } n > 0 \text{ or } m > 0; \text{ and} \\ &[L_0, L_0] = 0 \end{aligned} \tag{7}$$

Note that this implies $[(L_0)^{n+1} L_n] = 0$ for all n. We call the grading of L its grading by degree.

For example, the Lie algebra generated by kinetic and potential energy is of class $\mathfrak{P}$, where the grading is by total degree in p. The Lie algebra of all polynomial vector fields on a linear space is of class $\mathfrak{P}$, where the grading is by total degree. We will give more examples later.

Such a grading is quite different from the natural grading of a free Lie algebra. Two important differences are that (i) It is not abelian. For, $[L_2, [L_0, L_0]] = 0$ while $[L_0, [L_0, L_2]] \subseteq L_0$. (ii) It is not finite, in the sense that elements of L_n are Lie brackets of unboundedly many other elements of L. For example, the bracket of any number of elements of degree 1 is still of degree 1.

We also need the concept of a Lie algebra which is free in a certain class.

Definition 2 *[8] Let F be a Lie algebra of class $\mathfrak{P}$ generated by a set $\mathfrak{X}$. Then F is called a free Lie algebra in the class $\mathfrak{P}$, freely generated by the set $\mathfrak{X}$, if for any Lie algebra R of class $\mathfrak{P}$, every mapping $\mathfrak{X} \to R$ can be extended to a unique homomorphism $F \to R$. We write $F = L_{\mathfrak{P}}(\mathfrak{X})$.*

In addition to the grading by degree, $L_{\mathfrak{P}}(\mathfrak{X})$ also carries the standard grading which we call the grading by *order*, generated by $\operatorname{order}(X) = 1$ for all generators $X \in \mathfrak{X}$ and $\operatorname{order}([Y, Z]) = \operatorname{order}(Y) + \operatorname{order}(Z)$. (The term *order* is chosen here because it corresponds to order in the sense of numerical integrators, as in Eq. (1)).

Because of the importance of the grading by degree for Lie algebras generated by kinetic and potential energy, we make the following definition.

Definition 3 *The Lie algebra $L_{\mathfrak{P}}(A, B)$, free in the class $\mathfrak{P}$, where A has degree 2 and B has degree 0, is called the* Lie algebra of classical mechanics.

Two Lie algebras of class $\mathfrak{P}$ are easy to describe. First, the Lie algebra with k generators of degree ≥ 1 which is free in the class $\mathfrak{P}$ is just the standard free Lie algebra on k generators—the degrees can never decrease if the Lie algebra has no elements of degree

0. Second, the Lie algebra with generators $\mathfrak{X} = \{X_1, \ldots, X_k\}$ of degree 0 and generators $\mathcal{Y} = \{Y_1, \ldots, Y_l\}$ of degree 1, free in the class $\mathfrak{P}$, is $\mathcal{Y} \oplus \bigoplus_{n\geq 0}[\mathcal{Y}^n\mathfrak{X}]$, and only contains elements of degree 0 and 1. (In both of these cases, the grading by degree is in fact abelian.)

However, we want to describe the Lie algebra of classical mechanics, $L_{\mathfrak{P}}(A, B)$. This is the simplest nontrivial case as it includes the essential feature of $\mathfrak{P}$ that degrees can both increase and decrease under Lie brackets.

The paper is organized as follows. In Section 2, we give a construction which describes $L_{\mathfrak{P}}(A, B)$ as the direct sum of an abelian and a free Lie algebra, both with an infinite number of generators. In Section 3, we enumerate the dimensions of the homogeneous (by order) components of $L_{\mathfrak{P}}(A, B)$ and hence in Section 4 numerically compute its entropy. Section 5 considers special cases (e.g., of mechanical systems with Euclidean metric; these turn out not to be free in the class $\mathfrak{P}$) and other examples of polynomially-graded Lie algebras.

2 Structure of the Lie algebra of classical mechanics.

Let $\psi : L(A, B) \to L_{\mathfrak{P}}(A, B)$ be the unique homomorphism from the free Lie algebra to the free Lie algebra of class $\mathfrak{P}$. The kernel $\ker\psi$ can be thought of as the set of identities of $L_{\mathfrak{P}}(A, B)$. For example, we showed above (Eq. (4)) that $[BBBA] \in \ker\psi$. This implies that $[CBBBA] \in \ker\psi$ for all $C \in L(A, B)$. However, we will see below that $[BBBA]$ is not the only generator of the ideal $\ker\psi$.

Our description of $L_{\mathfrak{P}}(A, B)$ is based on the following two observations. First, suppose one wants to describe the Lie algebra with three generators A, B, C which is free in the class of Lie algebras with $C = 0$. Since C generates all identities in this class, this Lie algebra is just $L(A, B)$: one merely has to drop the generator C. To generalize this idea, suppose the free Lie algebra $L(A, B)$ can be factored as $\bigoplus_i L(\mathfrak{X}_i)$ for certain generating sets $\mathfrak{X}_i$ with elements in $L(A, B)$, such that some subset $\mathcal{Y}$ of $\cup_i\mathfrak{X}_i$ generates all the identities in $\mathfrak{P}$. Then, we have

$$L_{\mathfrak{P}}(A, B) \cong \bigoplus_i L(\mathfrak{X}_i \backslash (\mathcal{Y} \cap \mathfrak{X}_i)) \tag{8}$$

—again, we merely drop these generators.

If $\mathcal{Y}$ only generates *some* of the identities of $\mathfrak{P}$, then dropping these generators gives a sum of free Lie algebras which is surjectively homomorphic to $L_{\mathfrak{P}}(A, B)$. This can be used to get upper bounds for the dimensions of the homogeneous subspaces of $L_{\mathfrak{P}}(A, B)$.

Second, given a description of $L_{\mathfrak{P}}(A, B)$ as such a sum (Eq. 8) of free Lie algebras, we can apply standard techniques to describe it in detail, for example to construct bases,

to compute its dimensions with respect to degree and/or order, and to compute the asymptotic growth of these dimensions.

We begin by stating the crucial tool we shall use, the Lazard factorization of free Lie algebras.

Theorem 1 *[14, 7, 15] Let $\mathfrak{X}$ and $\mathcal{Y}$ be sets of generators. Then*

$$L(\mathfrak{X} \cup \mathcal{Y}) \cong L(\mathcal{Y}) \oplus L(\cup_{n\geq 0}[\mathcal{Y}^n\mathfrak{X}]).$$

Applying the Lazard factorization to $L(A, B)$ with $\mathfrak{X} = \{A\}$, $\mathcal{Y} = \{B\}$, gives

$$L(A, B) = B \oplus L(A, [BA], [BBA], [BBBA], \ldots)$$

where the elements $[B^nA]$ for $n \geq 3$ are all identities in $\mathfrak{P}$. Thus, $L_{\mathfrak{P}}(A, B)$ is surjectively homomorphic to $B \oplus L(A, [BA], [BBA])$. The three generators have degrees 2 (A), 1 ($[BA]$), and 0 ($[BBA]$). The idea now is to eliminate this new element of degree 0. (Formally, the generators $[B^nA]$, $n \geq 3$, do remain in the generating set; but they and all succeeding Lie brackets of them will be dropped at the final stage when we pass to $L_{\mathfrak{P}}(A, B)$, so we do not need to keep track of them and just indicate them by $*$.) This gives

$$\begin{aligned} L(A, B) &\cong B \oplus L(A, [BA], [BBA], *) \\ &\cong B \oplus [BBA] \oplus L(A, [BA], [BBA, A], [BBA, BA], [BBA, BBA, A]), *) \end{aligned}$$

where the generators now have degrees 2, 1, 1, 0, and 0 respectively. Continuing in this way we get the following.

Theorem 2 *Let the degree of A be 2 and the degree of B be 0 with respect to the polynomial grading (Eq. 7). Then for all $k \geq 0$ we have the following isomorphism,*

$$L(A, B) \cong \mathcal{Z}_k \oplus L(A, \mathfrak{X}_k, \mathcal{Y}_k, *)$$

where

$$\begin{aligned} \mathfrak{X}_0 = \emptyset, \quad & \mathfrak{X}_{k+1} = \mathfrak{X}_k \cup [\mathcal{Y}_k, A], \\ \mathcal{Y}_0 = \{B\}, \quad & \mathcal{Y}_{k+1} = [\mathcal{Y}_k, \mathfrak{X}_k] \cup [\mathcal{Y}_k, \mathcal{Y}_k, A] = [\mathcal{Y}_k, \mathfrak{X}_{k+1}], \\ \mathcal{Z}_0 = \emptyset, \quad & \mathcal{Z}_{k+1} = \mathcal{Z}_k \cup \mathcal{Y}_k, \end{aligned} \tag{9}$$

and $*$ represents generators which are zero in $\mathfrak{P}$, i.e., elements of the kernel of the homomorphism $L(A, B) \to L_{\mathfrak{P}}(A, B)$. The generating sets have the following properties:

1. *All elements of $\mathcal{Y}_k$ and $\mathcal{Z}_k$ have degree 0, and all elements of $\mathfrak{X}_k$ have degree 1.*
2. *The Lie algebra spanned by $\mathcal{Z}_k$ is abelian.*
3. $\mathfrak{X}_k = [\mathcal{Z}_k, A]$.

4. *All elements of $\mathcal{Y}_k$ and $\mathcal{Z}_k$ have odd order, and all elements of $\mathfrak{X}_k$ have even order.*

5. *The element of smallest order in $\mathcal{Y}_k$ is $(-1)^k[[BA]^k B]$, with order $2k+1$.*

6. *The element of largest order in $\mathcal{Y}_k$ is B_k, defined recursively by $B_0 = B$, $B_{k+1} = [B_k, [B_k, A]]$. It has order $2^{k+1} - 1$.*

7. *The finite sets $\mathfrak{X}_k$ and $\mathcal{Z}_k$ converge to infinite sets $\mathcal{Z}$ and $\mathfrak{X} = [\mathcal{Z}, A]$ in the sense that the sets*

$$\{X : X \in \mathfrak{X}_k, \mathrm{order}(X) \leq n\}$$

are all equal for $k \geq n/2$. We have

$$L(A, B) \cong \mathcal{Z} \oplus L(A, \mathfrak{X}, *)$$

and

$$L_{\mathfrak{P}}(A, B) \cong \mathcal{Z} \oplus L(A, \mathfrak{X}). \tag{10}$$

8. *The sizes of the sets $\mathfrak{X}_k$ and $\mathcal{Y}_k$ obey the iteration*

$$\begin{aligned} |\mathfrak{X}_{k+1}| &= |\mathfrak{X}_k| + |\mathcal{Y}_k| \\ |\mathcal{Y}_{k+1}| &= |\mathcal{Y}_k|\,|\mathfrak{X}_{k+1}| \end{aligned} \tag{11}$$

with initial conditions $|\mathfrak{X}_0| = 0$, $|\mathcal{Y}_0| = 1$. This iteration generates the sequence of $|\mathfrak{X}_k|$ values

$$0, 1, 2, 4, 12, 108, 10476, 108625644, \ldots; \tag{12}$$

there is a constant $\gamma \approx 1.1555$ such that for sufficiently large k, $|\mathfrak{X}_k| = [\gamma^{2^k}]$.

Proof The iteration results from successive elimination of elements of degree 0, each iteration introducing only a finite number of new elements nonzero in $\mathfrak{P}$, which have degrees 0 and 1. The other points then follow easily. The final description of $L_{\mathfrak{P}}(A, B)$, Eq. (10), follows because the generators of $L(A, \mathfrak{X}, *)$ have degree 2 (A), 1 ($\mathfrak{X}$), or are identically zero ($*$). Therefore $L(A, \mathfrak{X}, *)$ contains no elements of degree 0, so $L_{\mathfrak{P}}(A, \mathfrak{X}) = L(A, \mathfrak{X})$. The sequence of Eq. (12) is Sloane's sequence A001696 [22], which comes from the same iteration (Eq. 11); the reference there to [1] shows how to establish its doubly-exponential growth. •

The rapid growth of the sets $\mathfrak{X}_k$ and $\mathcal{Y}_k$ means that it is impossible to carry out the iteration exactly very far. In practice the generating set $\mathcal{Z}$ can be found up to any order n by dropping any terms of order $> n$ as soon they appear in $\mathcal{Y}_k$ (i.e., by quotienting all Lie algebras by the ideal consisting of all elements of order $> n$). We then have $\mathcal{Y}_{[(n+1)/2]} = 0$ and the iteration terminates.

Table 1: Elements of degree 0 and weight ≤ 11 (i.e., functions of q only or 'modified potentials' of simple mechanical systems) appearing at iteration k of Eq. (9). The new elements are numbered consecutively Z_1, $Z_2, \ldots$. The degree 1 elements $X_n := [Z_n, A]$ also appear.

k	$\mathcal{Y}_k$		order
1	$Z_1 = B$		1
2	$Z_2 = [Z_1, X_1]$	$(= [BBA])$	3
3	$Z_3 = [Z_2, X_1]$	$(= [BBA, BA])$	5
	$Z_4 = [Z_2, X_2]$	$(= [BBA, [BBA, A]])$	7
4	$Z_5 = [Z_3, X_1]$	$(= [BBA, BA], BA])$	7
	$Z_6 = [Z_3, X_2]$	$(= [[BBA, BA], [BBA, A]])$	9
	$Z_7 = [Z_3, X_3]$		11
	$Z_8 = [Z_4, X_1]$		9
	$Z_9 = [Z_4, X_2]$		11
5	$Z_{10} = [Z_5, X_1]$		9
	$Z_{11} = [Z_5, X_2]$		11
	$Z_{12} = [Z_6, X_1]$		11
	$Z_{13} = [Z_8, X_1]$		11
6	$Z_{14} = [Z_{10}, X_1]$		11

The results of the six iterations required when $n = 12$ are shown in Table 1. We name the elements of $\mathcal{Z}$ Z_1, $Z_2, \ldots$ as they are successively generated by the algorithm. This gives a short description of the elements of $(L_{\mathfrak{P}})_n(A, B)$ of order ≤ 12 in terms of 14 elements of degree 0, 14 elements of degree 1, and 1 element of degree 2, which generate a total of 283 elements of weight ≤ 12 (see Tables 2 and 3).

3 Dimensions of the homogeneous components.

We now turn to the enumeration of $\mathfrak{X}_k$ and $\mathcal{Y}_k$ by order. We introduce the generating functions

$$x_k(t) = \sum_{n=1}^{\infty} |\{X \in \mathfrak{X}_k : \text{order}(X) = n\}| t^n$$

$$\tilde{y}_k(t) = \sum_{n=1}^{\infty} |\{Y \in \mathcal{Y}_k : \text{order}(Y) = n\}| t^n$$

$$\tilde{z}_k(t) = \sum_{n=1}^{\infty} |\{Z \in \mathcal{Z}_k : \text{order}(Z) = n\}| t^n$$

which from Eq. (9) obey

$$\begin{aligned} x_0 &= 0, \\ \tilde{y}_0 &= 0, \\ \tilde{z}_0 &= t, \\ x_{k+1} &= x_k + t\tilde{y}_k, \\ \tilde{y}_{k+1} &= \tilde{y}_k x_{k+1}, \\ \tilde{z}_{k+1} &= \tilde{z}_k + \tilde{y}_k. \end{aligned}$$

We can eliminate the t-dependence of this map by introducing $y_k = t\tilde{y}_k$ and $z_k = t\tilde{z}_k$. Then $z_k \equiv x_k$ for all k and the rest of the system is

$$\begin{aligned} x_0 &= 0, \\ y_0 &= t^2, \\ x_{k+1} &= x_k + y_k, \\ y_{k+1} &= y_k x_{k+1}. \end{aligned} \tag{13}$$

The polynomials $x_k(t)$ converge to a formal power series $x(t)$. The polynomials $y_k(t)$ converge, again in the sense of formal power series, to 0. The power series $x(t)$ completely determines the dimensions of the homogeneous components of $(L_{\mathfrak{P}})_n(A, B)$ (including its abelian part $\mathcal{Z}$, because $z_k(t) = x_k(t)/t$). We find

$$\begin{aligned} x(t) =& t^2 + t^4 + t^6 + 2t^8 + 3t^{10} + 6t^{12} + 12t^{14} + 24t^{16} + 50t^{18} + 107t^{20} + 232t^{22} + \\ & 508t^{24} + 1124t^{26} + 2513t^{28} + 5665t^{30} + 12858t^{32} + 29356t^{34} + 67371t^{36} + \ldots \end{aligned}. \tag{14}$$

(For example, the $1 + 1 + 1 + 2 + 3 + 6 = 14$ generators of weight ≤ 12 are given in Table 1.) Amazingly, this power series has appeared before (apparently as a curiosity) from the same iteration (Eq. 13), and it appears as Sloane's sequence A045761 [22].

The classical formula of Witt, Eq. (3), can be extended to free Lie algebras with more general generating sets [12, 19]. For any set $\mathcal{A}$ with generating function $a(t) = \sum_{n>0} |\{A \in \mathcal{A} : \text{order}(A) = n\}| t^n$, the dimensions $c_n = \dim L_n(\mathcal{A})$ of the homogeneous components of the graded Lie algebra $L(\mathcal{A}) = \bigoplus_{n>0} L_n(\mathcal{A})$ are given by

$$c_n = \sum_{d|n} \frac{1}{d} \mu(d) b_{n/d}, \tag{15}$$

where

$$-\log(1 - a(t)) = \sum_{n>0} b_n t^n.$$

In Maple, one can compute the dimensions easily by `c=EULERi(INVERT(a))` (these functions are available in [22]), where `a` and `c` are the sequences of coefficients of $a(t)$ and $c(t)$, respectively.

Table 2: Dimensions of Lie algebras graded by order. Column 2: Of the free Lie algebra with two generators. Column 3: Of the Lie algebra of classical mechanics, $L_{\mathfrak{P}}(A, B)$ where A ('kinetic energy') has degree 2 in p and B ('potential energy') has degree 0 in p, i.e. is a function of q only. Column 4: Number of modified potentials of order n in $L_{\mathfrak{P}}(A, B)$. Column 5: Upper bound for maximum number of linearly independent Poisson brackets of order n when $M = \mathbb{R}^n$ with the Euclidean metric, i.e. $A = p^{\mathrm{T}}p$. Column 6: As Column 5, but $V(q)$ is a cubic polynomial.

We apply Eq. (15) to $L_{\mathfrak{P}}(A,B) \cong \mathcal{Z} \oplus L(A,\mathfrak{X})$. The generating function for the grading by order of $\{A\} \cup \mathfrak{X}$ is $t + x(t)$. This gives the dimensions listed in Table 2 for $1 \leq n \leq 40$. A dramatic reduction in the dimensions compared to those of the free Lie algebra of rank 2 is evident.

More generally still, Kang and Kim [12] consider the grading of a free Lie algebra by an abelian semigroup S which satisfies the finiteness condition that any $s \in S$ is a sum of other elements of S in only finitely many ways. Then we have

$$\dim L_s(\mathcal{A}) = \sum_{d|s} \frac{1}{d} \mu(d) b_{s/d} \tag{16}$$

where

$$-\log(1 - a(t)) = \sum_{s \in S} b_s t^s$$

and $d|s$ means that there exists $\tau \in S$ such that $d\tau = s$, in which case we write $s/d = \tau$.

We can use this to calculate the dimensions of $L_{\mathfrak{P}}(A,B)$ with respect to the bigrading by order and degree. We first simplify the grading by degree, Eq. (7), by introducing $\text{degree}'(x) := \text{degree}(x) - 1$. Then (as long as no elements of degree 0 enter, which now holds), the semigroup of the grading by degree$'$ is isomorphic to the nonnegative integers under addition. Including the grading by order gives $S = \mathbb{Z}^{>0} \times \mathbb{Z}^{\geq 0}$. Note that the finiteness condition holds for S since it holds for $\mathbb{Z}^{>0}$. Since $\text{order}(A) = 2$, $\text{degree}'(A) = 1$, and $\text{degree}'(X) = 0$ for all $X \in \mathfrak{X}$, the generating function of $\{A\} \cup \mathfrak{X}$ is $ut + x(t)$ and we apply Eq. (16) with

$$b_{t,u} = -[t^n u^m] \log(1 - ut - x(t)).$$

This gives the dimensions for $n, m \leq 16$ as shown in Table 3.

4 Asymptotics of the dimensions and calculation of the entropy.

From Eq. (15), the asymptotic growth of the dimensions c_n is determined by the analytic structure—the location and type of the singularities—of $-\log(1-a(t))$. These correspond to zeros and singularities of $1 - a(t)$. In particular, if $1 - a(t)$ has a simple zero at $t = \alpha$ and no other zero with $|t| \leq \alpha$, then

$$c_n \sim \frac{1}{n} \left(\frac{1}{\alpha}\right)^n \tag{17}$$

and the Lie algebra has entropy $1/\alpha$.

The generating function of $\{A\} \cup \mathfrak{X}$ is $t + x(t)$. We therefore need to study the analytic structure of the function $1 - (t + x(t))$. We therefore study the map of Eq. (13) considered

Table 3: Dimensions of $L_{\mathfrak{B}}(A, B)$, graded by degree m and by order n.

as a map

$$\varphi : \mathbb{C}^2 \to \mathbb{C}^2, \quad (x, y) \mapsto (x + y, y(x + y))$$

with initial conditions $x = 0$, $y = t^2$. If the iterates of the map converge to $(x^*, 0)$ say, then $x(t) = x^*$. Curiously, the map preserves the area $\frac{1}{y} dx \wedge dy$, although this plays no role in the analysis.

The map φ has a line of degenerate fixed points $(x, 0)$ with eigenvalues x and 1. The fixed points with $|x| > 1$ are unstable and one can show that the fixed points with $|x| < 1$ are stable. The map 'remembers' its initial condition, and the function $x(t)$ is the x-coordinate of the fixed point reached from initial condition $(0, t^2)$.

We can see immediately that (i) for t real and positive, $x(t)$ is strictly increasing; and (ii) if the map converges then $|x(t)| \leq 1$. For t real and positive, the sequence $\{y_k\}$ is increasing, and if there is a k such that $y_k > 1$, then $x_k \to \infty$. Therefore we define

$$\beta = \inf\{t \in \mathbb{R}^+ \colon\ x_k(t) \to \infty\}.$$

Because

$$|x_{k+1}| \leq |x_k| + |z_k|, \quad |z_{k+1}| = |z_k||x_{k+1}|,$$

the map converges in the disk $\{t : |t| < \beta\}$.

We can get a crude bound on β immediately, but more detailed knowledge requires a numerical study of the map φ. Let t be real, let $I(x, y) = y + x - 1 + \sqrt{2y}$, and suppose

$x > 0$, $y > 0$, and $I(x, y) < 0$. Then

$$\begin{aligned} I \circ \varphi - I &= y(x+y) + x + y - 1 + \sqrt{2y(x+y)} - (y + x - 1 + \sqrt{2y}) \\ &= y(x+y) + \sqrt{2y}(\sqrt{x+y} - 1) \\ &\le y(1 - \sqrt{2y}) + \sqrt{2y}\sqrt{1 - \sqrt{2y}} - 1) \\ &\le y(1 - \sqrt{2y}) + \sqrt{2y}(1 - \frac{1}{2}\sqrt{2y}) - 1) \\ &= -\sqrt{2}y^{3/2} \\ &< 0 \end{aligned}$$

Therefore, the orbit must stay in the bounded region $x > 0$, $y > 0$, $I(x, y) < 0$, with x_k increasing and y_k decreasing. Therefore the orbit converges to some fixed point $(x, 0)$. (Here the curve $x = 1-\sqrt{2y}-y$ was chosen because it is a good approximation of the stable manifold of $(1, 0)$.) Since $I(0, t^2) < 0$ for $0 < t^2 < 2 - \sqrt{3}$, we have $\beta > \sqrt{2 - \sqrt{3}} > 0.51$. Better approximations of β can be obtained as the roots of $I \circ \varphi^k(0, \beta^2) = 0$ (i.e., by requiring the kth iterate to land in the trapping region), but these must be calculated numerically. On the other hand, $x_2 = t^2 + t^4 > 1$ if $t > 0.79$, so we have the bounds $0.51 < \beta < 0.79$.

We have that $dx(t)/dt > 0$ on $[0, \beta)$, with $x(0) = 0$ and $x(\beta) = 1$; and $1 - t$ is decreasing. Therefore $1 - t - x(t)$ has exactly one zero in $[0, \beta)$, and it is simple. The zero is α, the reciprocal of the required entropy of $L_{\mathfrak{P}}(A, B)$. The numerical value of α can be determined by solving $1 - t - x(t) = 0$ numerically.[1] This gives the value of the entropy of $L_{\mathfrak{P}}(A, B)$ as

$$1/\alpha = 1.82542377420108\ldots. \tag{18}$$

Are there any other solutions to $1 - t - x(t) = 0$? Because the coefficients of $x(t)$ are all nonnegative, there can be none in the disk $|t| \le \alpha$. To say more we have to proceed numerically. Firstly, if $|x_k|$ and $|y_k|$ get too large then the orbit blows up. Let

$$D = \{(x, y) \in \mathbb{C}^2 \colon |y| > 2|x| > 2\}.$$

Suppose $(x_k, y_k) \in D$. Then

$$|x_{k+1}| \ge ||y_k| - |x_k|| > |x_k| > 1$$

and

$$|y_{k+1}| = |x_{k+1}||y_k| > 2|x_{k+1}|,$$

i.e., we have $(x_{k+1}, y_{k+1}) \in D$. The orbit then stays in D and cannot converge—in fact, it must blow up doubly exponentially. The first iterate $(x_1, y_1) = (t^2, t^4)$ is in D if $|t| > \sqrt{2}$,

[1] In MATLAB, by `function x = f(t); x=0; y=t^2; while y>1e-16, x=x+y; y=y*x; end; x = 1-t-x;` and `alpha = fsolve('f',0.5)`.

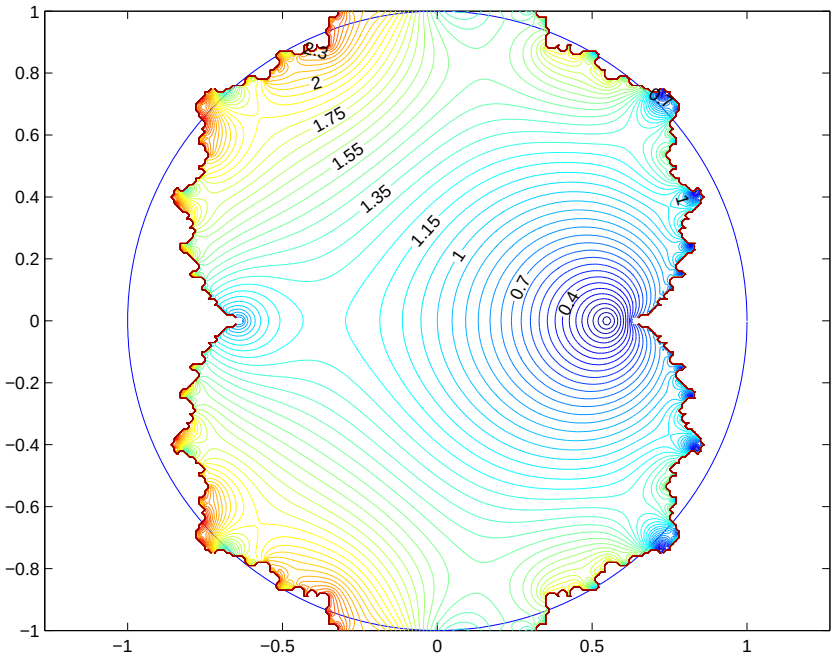

Figure 1: Contour plot of $|1 - t - x(t)|$, showing its main zero at $t = \alpha = 1/1.8254\ldots$ and other zeros (two sequences approaching $t = \beta$. The unit circle is also shown.

and the second iterate $(x_2, y_2) = (t^2 + t^4, t^4(t^2 + t^4))$ is in D if $|t| > 1.27202$. In practice, if an iterate enters this region one can immediately stop the calculation and report that the map diverges.

Using this criterion we computed the function $x(t)$ numerically. See Figures 1 and 2. We have made the following numerical observations:

1. The singularity of $x(t)$ closest to the origin is at

$$t = \beta = 1/1.58207912734\ldots. \tag{19}$$

2. There are no zeros of $1 - t - x(t)$ in the disk $|t| < \beta$.

3. The map converges only in a connected, simply-connected region with a fractal boundary.

4. The function $x(t)$ is analytic everywhere inside this region but has a square root singularity everywhere on its boundary.

5. For each point z on the boundary, $x(t) \sim 1 - a(t - z)^{1/2}$ for some constant a depending on z, as $t \to z$.

6. There is only one zero of $1 - t - x(t)$ in $|t| \leq \beta$.

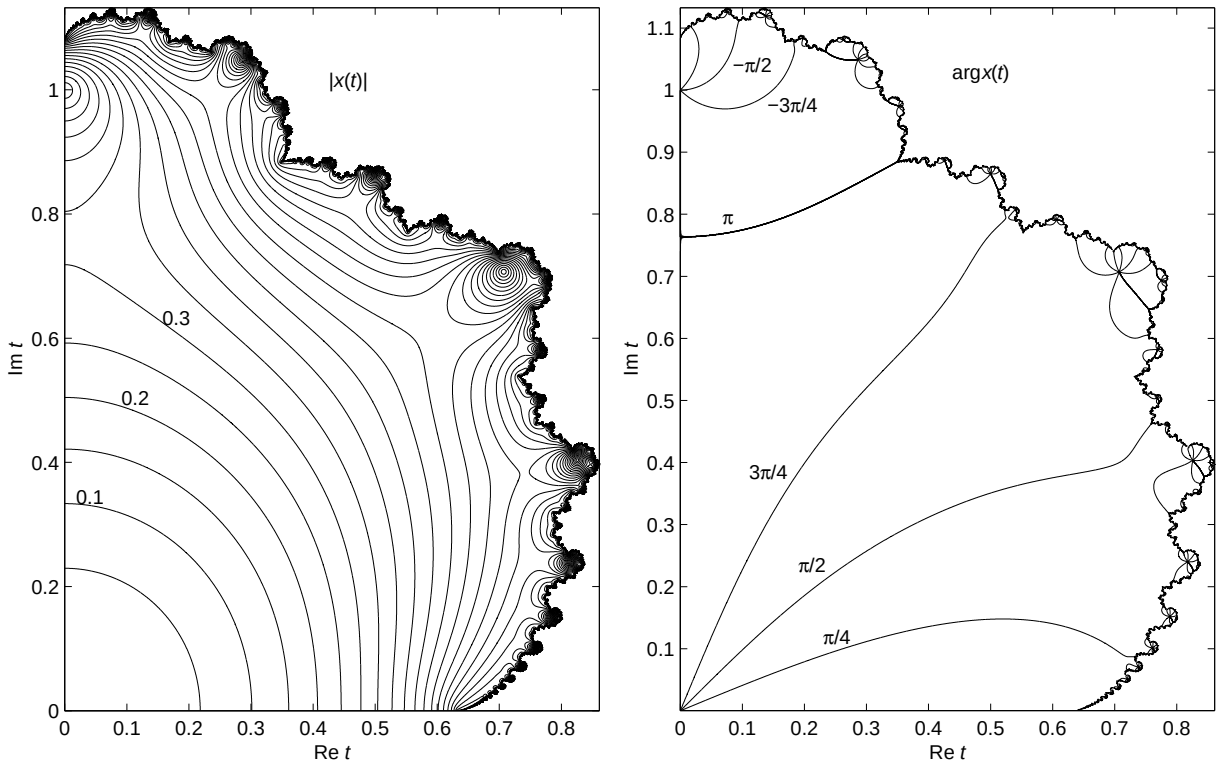

Figure 2: Contour plots of $|x(t)|$ (left, contour interval 0.05) and $\arg x(t)$ (right).

7. The other zeros of $1-t-x(t)$ form two infinite sequences α_n, $\bar{\alpha}_n$, with $Re(\alpha_n) > \beta$ for all n and $\lim_{n\to\infty} \alpha_n = \beta$.

Because of the fractal nature of the boundary, we are unlikely to be able to 'solve' the map φ or find α in closed form. Observation (4) would imply that this boundary forms a natural boundary for the function $x(t)$. Observation (5) would imply that the number of modified potentials of order n, $[t^{n+1}]x(t)$, is $\mathcal{O}(n^{-3/2}\beta^{-n})$. Observation (6) would imply that the next term in the asymptotic growth of $c_n = \dim(L_{\mathfrak{P}})_n(A,B)$ comes from the square root singularity at $t=\beta$. Indeed, by computing c_n numerically for $n < 80$ we find that

$$c_n \sim n^{-1}\alpha^{-n} - \begin{cases} 1.51n^{-1/2}\beta^{-n} & n \text{ odd} \\ 1.61n^{-3/2}\beta^{-n} & n \text{ even} \end{cases}$$

and

$$[t^{n+1}]x(t) \sim 0.9628n^{-3/2}\beta^{-n}$$

for n even. These are all consistent with the observed singularity structure of $1-t-x(t)$.

5 Discussion

5.1 Physical interpretation of the generators

There is a particularly nice interpretation of $L_{\mathfrak{P}}(A,B) \cong \mathcal{Z} \oplus L(A,\mathfrak{X})$ in the specific case of simple mechanical systems. In local coordinates, let $A = T(p) = \frac{1}{2}p^T M(q)p$ be the kinetic energy, where $M(q)$ is the inverse of the metric (or mass matrix), and and $B = V(q)$ be the potential energy. The set $\mathcal{Z}$ consists of functions of q only, and we think of them as 'modified potentials'. Elements of the span of $\mathcal{Z}$,

$$\sum_{Z\in\mathcal{Z}} a_Z \tau^{\mathrm{degree}(Z)} Z = a_1 \tau V + a_2 \tau^3 M(V',V') + \dots,$$

and their flows, can be evaluated explicitly and used to construct high-order integrators of the full system $T+V$ (see Eq. (23) for more terms). Now consider the generator $X = [Z,A] \in \mathfrak{X}$. It is the cotangent lift of the gradient flow of the modified potential Z; we have $X = M(q)(Z(q),p)$ and Hamilton's equations are

$$\begin{aligned}\dot{q} &= M(q)Z'(q) = \mathrm{div}_{M^{-1}(q)} Z =: f(q)\\ \dot{p} &= -f'(q)^{\mathrm{T}} p.\end{aligned}$$

So in a sense the modified potentials and the kinetic energy together contain a complete description of the Lie algebra.

5.2 Euclidean mechanical systems

Recall that on each manifold M, each simple mechanical system (say with kinetic energy T and potential energy V) generates a Lie algebra of class $\mathfrak{P}$. Therefore there is a homomorphism $\psi(M,T,V)$ from $L_{\mathfrak{P}}(A,B)$ onto this Lie algebra. One can ask whether the system (M,T,V) is in general position, i.e. if the two Lie algebras are actually isomorphic and $\ker\psi(M,T,V) = 0$. This is unlikely, because of the existence of identities such as Eq. (6) in Lie algebras of vector fields. One can therefore consider larger *classes* of systems and ask whether they are in general position. That is, does the class satisfy any identities other than those corresponding to the grading by degree, Eq. (7)? We conjecture that for the class of all simple mechanical systems, it does not.

Conjecture 1 *The only identities satisfied by all simple mechanical systems are those due to the grading by degree. That is,*

$$\bigcap_{M,T,V} \ker\psi(M,T,V) = 0.$$

This is best discussed by introducing a smaller class which we shall see is *not* in general position. Namely, let $M = \mathbb{R}^n$ with the Euclidean metric. Then in coordinates the kinetic

energy is $T(p) = \frac{1}{2}\sum_{i=1}^{n} p_i^2$. The first few modified potentials are then

$$\begin{aligned}
Z_1 &= V \\
Z_2 &= [BBA] = V'(V') \\
Z_3 &= [BBA, BA] = 2V''(V', V') \\
Z_4 &= [BBA, [BBA, A]] = 4V''(V''(V'), V') \\
Z_5 &= [[BBA, BA], BA] = 2V'''(V', V', V') + 4V''(V''(V'), V')
\end{aligned}$$

where we regard the kth derivative of V as a real-valued symmetric linear function on k vectors. Each modified potential of order $2n-1$ is a linear combination of the scalar elementary differentials of order n of V. Each such differential can be associated to a free tree with n nodes. (See, for example, [10] for a discussion of elementary differentials and trees.) The number of such trees for $n \geq 1$ is (Sloane's A000055, [22]) 1, 1, 1, 2, 3, 6, 11, 23, 47, 106, 235, ... This should be compared with the number of modified potentials in Eq. (14), namely 1, 1, 1, 2, 3, 6, 12, 24, 50, 107, 232, ... There are three interesting consequences:

(i) For $n \leq 6$, the sequences are the same. In fact, one can check that in the modified potentials of orders $2n-1 \leq 11$, all trees appear, in invertible linear combinations, so these modified potentials are in general independent.

(ii) For $n = 7, 8, 9$, there are more modified potentials than free trees. In particular, only 11 of the 12 modified potentials of order 13 can be linearly independent. This proves that the class of *Euclidean* mechanical systems is not in general position.

(iii) For $n \geq 10$, there are fewer modified potentials than free trees. In fact, the former have entropy $1/\beta = 1.582\ldots$ while the latter (since the free trees have entropy given by Otter's constant, $2.955\ldots$) have entropy $\sqrt{2.955\ldots} = 1.719\ldots$. Thus, for large n, only certain combinations of the trees appear in $\mathcal{Z}$.

So far we have only considered the modified potentials $\mathcal{Z}$ themselves. If these are independent, then $\mathfrak{X} = [\mathcal{Z}, A]$ is independent too. However, there is still a possibility for extra identities to hold in the Lie algebra generated by A and $\mathfrak{X}$. A term of order n and degree m is a sum of elementary differentials of V and p, corresponding to trees with $(n+m+1)/2$ nodes, of which m leaves are labelled p and the remaining nodes are labelled V. In this case we find that for $(n+m+1)/2 \leq 7$ there are always sufficient labelled free trees to prevent forced dependencies among the Lie brackets. For example, of the 11 free trees with 7 nodes, there are 12, 20, 24, 18, 9, 3, and 1 trees in which $m = 0$, 1, 2, 3, 4, 5, and 6 leaves are coloured p, respectively. The dimensions of the corresponding homogeneous subspaces of $L_{\mathfrak{P}}(A, B)$ with $(n+m+1)/2 = 7$ are (from Table 3) 12, 18, 20,

14, 8, 3, and 1, respectively. Thus, only in the case $m = 0$, corresponding to the modified potentials themselves, is a dependency forced in this way.

The algorithm for $L_{\mathfrak{P}}(A, B)$, Eqs. (9) and (13), can be modified to take into account the dependencies amongst the Lie brackets in the Euclidean case. To get an upper bound on the dimensions and entropy of the Lie algebra in this case, we assume that the dependency appears only when forced. Let c_n be the number of free trees with n nodes. At iteration k, we already have $z_{k,2n} := [t^{2n}]\tilde{z}_k$ elements of order $2n-1$ in $\mathcal{Z}_k$, and $y_{k,2n} := [t^{2n}]\tilde{y}_k$ elements of order $2n-1$ have just been created in $\mathcal{Y}_k$. If $z_{k,2n} + y_{k,2n} > c_n$, we replace $\mathcal{Y}_k$ by a smaller set, of $c_n - z_{k,2n} - y_{k,2n}$ elements, which together with the order $2n-1$ elements of $\mathcal{Z}_k$, forms a basis of the c_n elementary differentials. In terms of the generating functions, we add the final step to the iteration of Eq. (13):

$$y_{k+1} \leftarrow \sum_{n \geq 1} \min(y_{k+1,2n}, c_n - z_{k+1,2n}) t^{2n} \tag{20}$$

Let the resulting limiting formal series be $x_E(t)$, $y_E(t)$, and $z_E(t)$. The generating function for $x_E(t)$ is then computed to be

$$\begin{aligned} x_E(t) =& t^2 + t^4 + t^6 + 2t^8 + 3t^{10} + 6t^{12} + 11t^{14} + 23t^{16} + 47t^{18} + 102t^{20} + 221t^{22} + \\ & 484t^{24} + 1069t^{26} + 2386t^{28} + 5364t^{30} + 12143^{32} + 27645t^{34} + 63259t^{36} + \ldots \end{aligned} \tag{21}$$

which should be compared with Eq. (14). At order 14, 16, and 18 the dimensions are limited by the number of elementary differentials, but for $n > 9$, $[t^{2n}]x_E(t) < [t^{2n}]x(t) < c_n$. Because the new map on generating functions, Eq. (20), is not analytic, it is harder to determine the location of its smallest singularity. We found the smallest root of successive polynomial truncations of $1 - t - x_E(t)$ and extrapolated these results to obtain

$$1/\alpha_E = 1.8250339\ldots, \quad 1/\beta_E = 1.574\ldots. \tag{22}$$

These are upper bounds for the entropy of the class of Euclidean mechanical systems and their modified potentials, respectively.

(Murua [20] has also considered this case, in the context of order conditions for Hamiltonians of the form $\frac{1}{2}\sum p_i^2 + V(q)$. He finds a unique independent tree of a certain type for each order condition, and enumerates these up to order 6. It would be interesting to compare the two approaches at higher order.)

The situation is quite different for non-Euclidean, i.e. general, mechanical systems. Repeating the above calculation for a general kinetic energy $T(p) = \frac{1}{2}p^T M(q)p$, we get

the following modified potentials. The associated trees will be explained below.

$$
\begin{aligned}
Z_1 &= V = \bullet \\
Z_2 &= [BBA] = M(V', V') = \\
Z_3 &= [BBA, BA] = 2M(V', V''(M(V'))) + M'(V', V', M(V')) = 2 + \\
Z_4 &= [BBA, [BBA, A]] \\
&= 4V'(M(V''(M(V''(M(V')))))) + 3V'(M(V''(M(M'(V', V')))))+ \\
&\qquad M(M'(V', V'), M'(V', V')) \\
&= 4 + 3 + \\
Z_5 &= [[BBA, BA], BA] \\
&= 4V'(M(V''(M(V''(M(V'))))))) + 2V'''(M(V'), M(V'), M(V'))+ \\
&\qquad 6M'(V', M(V'), V''(M(V'))) + M'(V', V', M(V''(M(V'))))+ \\
&\qquad M'(V', M(V'), M'(V', V')) + M''(M(V'), M(V'), V', V') \\
&= 4 + 2 + 6 + + + +
\end{aligned}
\tag{23}
$$

In this case each modified potential of order $2n-1$ is a scalar elementary differential of V *and* M. These correspond to bicoloured free trees with $2n-1$ nodes, of which n nodes are labelled V (shown as solid circles above) and $n-1$ nodes are labelled M (shown as open circles above); the latter must have at least 2 branches since a derivative of M has at least 2 indices. Of the 1, 1, 3, 11, 47, and 235 free trees of order 1, 3, 5, 7, 9, and 11 respectively, exactly 1, 1, 2, 8, 34, and 175 of them can be coloured (labelled) in this way. The calculation above shows that of these colourable trees, precisely one colouring of 1, 1, 2, and 7 of these colourable trees occur in the modified potentials of orders ≤ 7. (The other colourings of these trees do not occur, because of the way in which the trees at each order are built from the trees of lower order. The colourable 7-node tree also does not occur.) It is clear that there is enormously much more freedom in this case than in the ('Euclidean', $T(p) = \frac{1}{2}\sum p_i^2$) case considered previously. Therefore, we believe that all the modified potentials are independent in this case. This supports Conjecture 1.

5.3 Other polynomially graded Lie algebra

We close with a list of some other Lie algebras of class $\mathfrak{P}$. In each case one can consider the case of two generators A and B of degrees 2 and 0 and the induced homomorphism from $L_{\mathfrak{P}}(A, B)$.

1. The case of classical mechanics. The objects are real functions on a cotangent bundle, homogeneous polynomial in p. This can be specialized to the following cases.

(a) Q any Riemannian manifold, any potential energy, degree(X) is the total degree of X in p. Entropy is $\leq 1.8254\ldots$, Eq. (18), with Conjecture 1 implying equality.

(b) $Q = \mathbb{R}^n$ with the Euclidean metric. Entropy is $\leq 1.8250\ldots$, Eq. (22). It is remarkable that these two Lie algebras, not previously distinguished from each other in the literature, differ starting at order 13, and have slightly different entropy.

(c) $Q = \mathbb{R}^n$, functions polynomial in p *and* q. We can then introduce a bigrading by degree in p and by degree in q. To get a new Lie algebra, one of the generators has to be degree 0 in each grading, which forces Q Euclidean, $A = \frac{1}{2}\sum p_i^2$, $B = V(q)$ polynomial. For example, we have computed the dimensions of the Lie algebra generated by cubic potentials for small n in Table 2—they are remarkably small. See [11] for an analysis of this case in terms of special types of trees.

2. Homogeneous polynomial vector fields on $\mathbb{R}^m$ graded by total degree in $x_1, \ldots, x_k$ for some $1 \leq k \leq m$. In the case $k = m$, the vector fields in $\mathfrak{X}$ associated with $L(A, B)$ (degree(A) = 2, degree(B) = 0) are associated with free trees in which each node has degree at most 2 (since only the first two derivatives of A are nonzero). Their numbers are 1, 1, 1, 2, 3, 6, 11, 23 (so far the same as for the free trees), then 46, 98, 207, 451, ... (Sloane's A001190 [22]), which gives an upper bound for the number of independent elements of $\mathcal{Z}$ of each odd order. These grow more slowly than the free trees, and even more slowly than $\mathcal{Z}$, with entropy 1.5758, compared to 1.5821 (Eq. (19)) for $\mathcal{Z}$. Perhaps in this case the trees $\mathfrak{T}$ generate the Lie algebra as $\mathfrak{T} \oplus L(A, [\mathfrak{T}, A])$?

3. As the previous item, but multigrading by total degree in different subsets of the variables.

4. Homogeneous polynomial vector fields with the variables partitioned (x, y) with $x \in \mathbb{R}^k$, $y \in \mathbb{R}^m$, and the vector fields of the form $p\frac{\partial}{\partial x} + q\frac{\partial}{\partial y}$ with either $\text{degree}_y(q) \leq \text{degree}_y(p) + 1$, or $p \equiv 0$ and $\text{degree}_y(q) = 0$. Simple mechanical systems form examples of this class. So do high-order ODEs of the form $y^{(n)} = f(y, \ldots, y^{(n-2)})$ when re-written as first-order systems

$$\begin{aligned} \dot{x}_i &= x_{i+1}, \qquad i = 0, \ldots, n-2, \\ \dot{x}_{n-1} &= f(x_1, \ldots, x_{n-2}), \end{aligned}$$

with $x_i = y^{(i)}$, $k = n - 1$, and $m = 1$.

5. Consider the Schrödinger equation

$$i\dot{\psi} = \nabla^2\psi + V(x)\psi,$$

where ∇^2 is the Euclidean Laplacian. The two operators ∇^2 and $V(x)$ generate a Lie algebra of class $\mathfrak{P}$, where the grading is by degree of the differential operators. For example,

$$[\nabla^2, V]\psi = \nabla \cdot (V\psi) + V\nabla \cdot \psi$$

is of degree 1,

$$[V, V, \nabla^2]\psi = (\nabla \cdot (V^2))\psi$$

is of degree 0, and

$$[V, V, V, \nabla^2]\psi \equiv 0.$$

Acknowledgements. We would like to thank Mark Sofroniou and Reinout Quispel for pointing out the connection to free trees. RM would like to thank Ernst Hairer and Gerhard Wanner for their hospitality at the University of Geneva where this paper was written.

Sommaire

Ce mémoire considère le problème où deux interlocuteurs distants possèdent chacun une chaîne de bits, le but étant qu'un des interlocuteurs apprenne la chaîne de son vis-à-vis en minimisant la communication. Contrairement au modèle original de la complexité de la communication, la difficulté est due au fait que les chaînes sont corrélées. Ce modèle est inhérent à plusieurs applications pratiques incluant la synchronisation de données mobiles, la réconciliation de séquences de symboles comme les séquences de nucléotides dans les molécules d'ADN, le calcul distribué, la sauvegarde de fichiers et la distribution quantique de clés secrètes.

Nous analysons les modèles déterministe, déterministe amorti, probabiliste avec générateurs aléatoires privés et probabiliste avec générateur aléatoire public. Nous montrons entre autres que pour les applications mentionnées précédemment, tous ces modèles sont équivalents. Nous considérons également le nombre de messages que les interlocuteurs doivent échanger pour réconcilier leurs chaînes, car la non-interactivité est nécessaire pour certaines applications.

Mots-clés : réconciliation, complexité de la communication, données corrélées, théorie de l'information, codes correcteurs d'erreurs.

Abstract

This thesis considers the problem where two distant parties each possess a chain of bits, the goal being for one party to learn his encounter's input while minimizing the communication. Unlike the original communication complexity model, the difficulty arises because the inputs are correlated. This model is inherent to several practical applications including synchronisation of mobile data, reconciliation of sequences of symbols such as nucleotides sequences in DNA molecules, distributed computations, remote file storage and quantum key distribution.

We analyse the deterministic, amortized deterministic, private coin randomized and public coin randomized models. Among other things, we show that all these models are equivalent for the applications previously mentioned. We also consider the number of messages the parties need to exchange to reconcile their inputs, since non-interactivity is required for some applications.

Keywords : reconciliation, communication complexity, correlated data, information theory, error-correcting codes.

Remerciements

Mes premiers remerciements s'adressent à mes directeurs de recherche, Pierre McKenzie et Stefan Wolf, pour leur professionnalisme, leur dynamisme et leurs compétences académiques. Je remercie Pierre de m'avoir fait confiance dès les premiers moments de ce qui était pour moi un retour aux études, et Stefan pour ses idées originales et sa porte toujours ouverte.

Ce mémoire a été entrepris suite à une série de discussions avec Hervé Caussinus. Je le remercie d'avoir suggéré un sujet de recherche si intéressant.

Je remercie Alain Tapp pour les discussions que nous avons partagées, ainsi que Martin Sauerhoff et Pascal Tesson de m'avoir finalement arrêté de travailler sur des problèmes résolus il y a une décennie.

Je remercie le Fonds québécois de la recherche sur la nature et les technologies (NATEQ) de m'avoir accordé une bourse, et le Conseil de recherches en sciences naturelles et en génie du Canada (CRSNG) du soutien financier complémentaire par l'entremise des subventions de recherche de Pierre McKenzie.

Je remercie mes parents de m'avoir transmis leur soif de savoir et d'avoir patiemment répondu aux innombrables questions que je leur ai posées durant ma jeunesse. Finalement, je remercie Isabelle de sa spontanéité, sa joie de vivre, son authenticité, en somme de faire partie de ma vie ...

Avant-propos

Lorsque des humains, des ordinateurs ou des parties d'un système veulent résoudre un problème conjointement, ils doivent communiquer. Cela peut être nécessaire lorsque la tâche à effectuer est trop lourde pour être réalisée par une seule partie, ou encore parce que les données du problème sont décentralisées. La communication peut être explicite comme dans le cas de deux internautes s'échangeant des fichiers sur Internet, ou implicite dans le cas d'un processeur qui accède à des données sur un disque dur.

La complexité de la communication est la théorie mathématique des processus requérant de la communication. Elle mesure la quantité d'information qui doit être échangée pour calculer une fonction ou résoudre un problème. La complexité d'un problème est inhérente à celui-ci et ne dépend donc pas d'un protocole particulier le résolvant. Contrairement à la complexité du calcul, la complexité de la communication ne tient pas compte de la puissance de calcul des participants. Il existe d'ailleurs des problèmes distribués pouvant être résolus à l'aide de protocoles requérant peu de communication, mais nécessitant un temps de calcul exponentiel. Évidemment, un compromis entre la communication et le temps de calcul est nécessaire pour quiconque désire obtenir des protocoles pouvant être utilisés en pratique.

La théorie de l'information définit un modèle dans lequel un émetteur envoie un message à un récepteur, celui-ci recevant une version bruitée du message original. L'entropie quantifie l'incertitude du receveur par rapport au message envoyé par l'émetteur, et l'information est la réduction de l'entropie. La théorie de l'information s'intéresse au taux de transmission de données qui peut être atteint et à la façon d'encoder les données efficacement afin que le récepteur puisse décoder le message original malgré la présence de bruit.

Ce mémoire traite de la complexité de la communication de données corrélées, située à mi-chemin entre la complexité de la communication et la théorie de l'information. Dans notre modèle, deux interlocuteurs distants possèdent chacun une chaîne de bits, les deux chaînes étant corrélées, et le but est qu'un des interlocuteurs apprenne la chaîne de son vis-à-vis en minimisant la communication. Nous supposons que la communication est effectuée sur un canal de transmission sans erreur et qu'elle alterne d'un interlocuteur à l'autre selon un protocole sur lequel ils se sont entendus initialement.

Le premier chapitre présente le modèle déterministe de communication de données corrélées. Le deuxième chapitre analyse la complexité déterministe amortie, c'est-à-dire la résolution simultanée de plusieurs exemplaires d'un problème ou de plusieurs problèmes différents. Le troisième chapitre étudie la complexité de la communication probabiliste, ce qui à notre connaissance n'a jamais été fait auparavant. Finalement, le quatrième chapitre traite de la complexité de la communication de problèmes équilibrés, modèle qui englobe toutes les applications pratiques mentionnées au sommaire. Mentionnons que nous avons obtenu plusieurs nouveaux résultats, parmi lesquels la classification presque complète du modèle probabiliste ainsi que la démonstration que les modèles déterministe et

probabiliste sont équivalents pour les problèmes équilibrés sont certainement les plus intéressants.

Bien que le modèle de communication de données corrélées ait été originalement étudié dans le but de résoudre plusieurs problèmes pratiques de communication, il n'en demeure pas moins qu'il peut être abstrait mathématiquement de façon élégante. Toutefois, comme les préalables mathématiques nécessaires à la compréhension de ce mémoire sont assez variés, nous avons choisi de les regrouper en annexe afin de ne pas alourdir inutilement le texte. Mentionnons finalement que tous les logarithmes sont en base 2.

Chapitre 1

Complexité déterministe

Dans ce chapitre, nous introduisons un modèle déterministe pour les problèmes de communication dont les données sont corrélées, ainsi que les mesures de complexité que nous utilisons pour en faire l'analyse. À l'exception du théorème 1.25, du lemme 1.28 et de la preuve du lemme 1.22, ce chapitre ne contient pas de nouveau matériel et permet surtout d'introduire les notions dont nous aurons besoin pour les chapitres subséquents.

1.1 Modèle original de la complexité de la communication

Le modèle original de la complexité de la communication classique à deux participants a été introduit par Yao [54] en 1979 et est traité en détails dans l'excellent ouvrage de Kushilevitz et Nisan [27]. Il a été initialement étudié afin d'obtenir des bornes inférieures pour la communication dans les puces VLSI [50] ainsi que pour la communication lors de calculs distribués [1].

Soient X, Y, Z des ensembles finis et $f : X \times Y \to Z$ une fonction. Deux interlocuteurs distants, Alice et Bob[1], possèdent respectivement des éléments $x \in X$ et $y \in Y$. Alice n'a aucune information sur y, Bob n'a aucune information sur x, et tous deux veulent calculer $f(x, y)$ en minimisant la communication.

Pour calculer f, Alice et Bob exécutent un protocole $\mathcal{P}$ sur lequel ils se sont entendus initialement. $\mathcal{P}$ est en fait un arbre binaire où chaque noeud interne i est étiqueté par une fonction $a_i : X \to \{0, 1\}$ ou $b_i : Y \to \{0, 1\}$, et où chaque feuille est étiquetée par un élément $z \in Z$. Lors de l'exécution de $\mathcal{P}$ sur l'entrée (x, y), les interlocuteurs parcourent l'arbre de la racine vers les feuilles en fonction des valeurs de a_i et de b_i. Lorsqu'un noeud est étiqueté par une fonction a_i, Alice calcule $a_i(x)$; si $a_i(x) = 0$, le noeud suivant du protocole est l'enfant gauche du noeud i, tandis que si $a_i(x) = 1$, le protocole se poursuit avec l'enfant droit. Comme Bob ne connaît pas x, Alice doit transmettre un bit à Bob afin qu'il sache quel est le noeud suivant. Lorsqu'un noeud est étiqueté par une fonction b_i, c'est Bob qui calcule $b_i(y)$ et qui envoie le résultat à Alice. La valeur de $f(x, y)$ est la valeur de la feuille atteinte par le protocole à partir de la racine sur l'entrée (x, y), et le nombre de bits de communication en pire cas entre Alice et Bob correspond exactement à la hauteur de l'arbre.

Définition 1.1. Le *coût* d'un protocole $\mathcal{P}$ est la hauteur de l'arbre défini par ce protocole.

Définition 1.2. Soit $f : X \times Y \to Z$ une fonction. La complexité de la communication déterministe de f, notée $D(f)$, est le coût minimal de $\mathcal{P}$, parmi tous les protocoles $\mathcal{P}$ calculant f.

[1]Les prénoms Alice et Bob sont utilisés partout dans la littérature ; il en est de même dans ce mémoire.

La définition 1.3, équivalente à la précédente, exprime mieux la communication intrinsèque au modèle.

Définition 1.3. La *complexité de la communication déterministe* de f, $D(f)$, est le nombre minimal de bits[2] qu'Alice et Bob doivent échanger pour calculer f à coup sûr pour toute paire (x, y).

Le lemme suivant illustre une façon triviale qui permet aux interlocuteurs de calculer f. Un des objectifs de l'étude de la complexité de la communication est évidemment de trouver des protocoles plus performants ou de démontrer qu'il n'est pas possible de faire mieux.

Lemme 1.4. *Pour toute fonction* $f : X \times Y \to Z$,

$$D(f) \leq \lceil \log |X| \rceil + \lceil \log |Z| \rceil.$$

Démonstration. Alice envoie x à Bob, ce qui nécessite $\lceil \log |X| \rceil$ bits de communication. De son côté, Bob calcule $z = f(x, y)$ et envoie la réponse à Alice, ce qui peut être fait avec $\lceil \log |Z| \rceil$ bits. □

Le lemme précédent implique que la valeur de f après l'exécution du protocole $\mathcal{P}$ est connue d'Alice et de Bob. Cette contrainte peut augmenter $D(f)$ d'au plus $\lceil \log |Z| \rceil$ bits, mais nous ne l'imposons pas pour ce mémoire pour une raison évidente que sera expliquée à la section 1.2.

Une autre variante du modèle original de Yao est la notion de rondes. Il peut être intéressant de considérer non pas le nombre de bits de communication entre les interlocuteurs, mais plutôt l'interaction véritable entre ceux-ci. En effet, pour

[2] Nous supposons que toutes les communications entre les interlocuteurs sont binaires.

certaines fonctions, il existe des protocoles efficaces pour lesquels Alice envoie une seule série de bits à Bob, tandis que pour d'autres fonctions, de nombreux échanges sont nécessaires afin de réduire la communication. En pratique, il est avantageux d'avoir des protocoles ayant le moins de rondes possibles, et il existe même plusieurs problèmes qui requièrent des protocoles non interactifs.

Définition 1.5. Un protocole à k rondes est un protocole tel que pour toute entrée, il y a au plus $k-1$ alternances entre les bits envoyés par Alice et les bits envoyés par Bob. La *complexité de la communication déterministe d'un protocole à k rondes*, notée $D^k(f)$, est le coût du meilleur protocole à k rondes pour f.

Définition 1.6. Un protocole à plus d'une ronde est dit *interactif*, tandis qu'un protocole à une ronde est dit *non interactif*.

1.2 Complexité de la communication de données corrélées

Le sujet de ce mémoire est la complexité de la communication de données corrélées. Ce modèle a été introduit par Orlitsky [35, 36, 37, 38], même si des articles antérieurs, entre autres par Witsenhausen [53], se sont attaqués à certains problèmes sans considérer le modèle de façon globale. Les appellations «communication interactive» et «communication avec information partielle» sont utilisées dans la littérature mais, selon nous, l'expression «communication de données corrélées» est plus appropriée.

Le modèle original de Yao requiert qu'Alice et Bob puissent calculer $f(x, y)$ pour toutes les paires (x, y) possibles. Dans le modèle avec données corrélées, chaque interlocuteur possède de l'information sur la chaîne de son vis-à-vis en fonction de sa propre chaîne, et cela permet d'éliminer certaines paires.

Définition 1.7. Le *support* de (X, Y), noté $S_{X,Y} \subseteq X \times Y$, est l'ensemble des paires possibles entre Alice et Bob. La notation S est utilisée lorsqu'il n'y a pas de confusion possible.

Définition 1.8. L'*ambiguité* de x, notée $a_A(x)$, est l'ensemble des $y \in Y$ possibles pour un $x \in X$. Formellement, $a_A(x) \stackrel{\text{déf}}{=} \{y \in Y \mid (x, y) \in S\}$. L'ambiguité de y, notée $a_B(y)$, est définie de manière analogue.

Autrement dit, l'ambiguité d'Alice, $a_A(x)$, est l'ensemble de toutes les chaînes possibles chez Bob lorsqu'elle possède la chaîne x.

Définition 1.9. L'*ambiguité maximale* de X, $\widehat{a_A}(S) \stackrel{\text{déf}}{=} \max_{x \in X}\{|a_A(x)|\}$, est le nombre maximal de valeurs possibles de Y pour toute valeur de X. L'ambiguité maximale de Y, notée $\widehat{a_B}(S)$, est définie de manière analogue. Nous écrivons $\widehat{a_A}$ et $\widehat{a_B}$ lorsqu'il n'y a pas de confusion possible.

Les paramètres du modèle sont les suivants : Alice possède une chaîne $x \in X$ et Bob possède une chaîne $y \in Y$ avec la restriction que $(x, y) \in S$, et le but est que Bob apprenne la valeur de x. Il n'est pas nécessaire qu'Alice apprenne la valeur de y. Le modèle analyse la communication entre les interlocuteurs et suppose que ceux-ci ont une puissance de calcul illimitée.

Définition 1.10. La *complexité de la communication déterministe* d'un problème ayant un ensemble de support $S \subseteq X \times Y$, notée $D(S)$, est le nombre minimal

de bits qu'Alice et Bob doivent échanger afin que Bob apprenne la chaîne d'Alice à coup sûr pour toute paire $(x, y) \in S$. Nous écrivons $D^k(S)$ lorsque le nombre de rondes est borné par k. Comme le modèle de communication est asymétrique, nous supposons que la dernière ronde est effectuée d'Alice vers Bob (le but étant que Bob apprenne x, il est en effet inutile qu'il envoie le dernier message).

Définition 1.11. Notons $D_{x|y}$ la *complexité de la communication déterministe de S lorsqu'Alice connaît la chaîne de Bob.*

1.3 Le problème de la ligue sportive

Le problème de la ligue sportive a été introduit pas Orlitsky [35] et vaut la peine d'être présenté en guise d'introduction. Une ligue sportive a 2^n équipes, chacune ayant comme nom une chaîne de n bits. Bob est un maniaque de sport et connaît les deux équipes qui participent à la grande finale de la ligue, mais une panne d'électricité l'a empêché de regarder le match et d'apprendre l'identité de l'équipe gagnante. Alice, de son côté, a entendu à la radio le nom de l'équipe gagnante, mais n'a aucune idée de l'équipe qu'elle a vaincue en finale. Bob veut apprendre d'Alice le nom de l'équipe gagnante en minimisant la communication avec elle. Formellement, $S = \{(e_1, \{e_1, e_2\}) \mid e_1 \neq e_2\}$, où $e_1, e_2 \in \{0,1\}^n$.

Si la communication entre les deux interlocuteurs est non interactive, Alice ne peut rien faire de mieux que de communiquer à Bob les n bits de l'équipe gagnante. En effet, si Alice communique moins de n bits à Bob, il existe deux équipes e_1 et e_2 pour lesquelles elle envoie le même message. Si e_1 et e_2 sont les deux équipes participant à la finale, alors Bob ne peut pas déduire l'équipe gagnante avec certitude à partir du message qu'il reçoit.

Par contre, une économie substantielle est possible lorsque deux rondes de communication sont permises. Bob envoie à Alice la position d'un des bits où les chaînes diffèrent, ce qui nécessite $\lceil \log n \rceil$ bits de communication. Alice n'a qu'à communiquer à Bob la valeur du bit de l'équipe gagnante pour la position demandée. Ce protocole requiert $\lceil \log n \rceil + 1$ bits de communication, un gain exponentiel par rapport au protocole non interactif.

1.4 Résultats préliminaires

Pour analyser mathématiquement les problèmes de communication avec données corrélées, il est fort utile d'utiliser leur représentation sous forme de graphes. Voici trois approches équivalentes.

- La première approche a été définie par Witsenhausen [53]. Soit $x \in X$ la chaîne d'Alice et $y \in Y$ la chaîne de Bob, toujours avec la condition que $(x, y) \in S$. Appelons G_{XY} le graphe bipartie formé des deux ensembles de sommets X et Y et dont les arêtes entre les sommets des ensembles X et Y correspondent aux paires $(x, y) \in S$. Définissons le graphe G_X pour lequel les sommets sont les éléments de l'ensemble X et où deux sommets x_1 et x_2 sont reliés par une arête si et seulement si il y a un sommet y de G_{XY} adjacent à la fois à x_1 et à x_2 .
- La deuxième approche est celle que nous utilisons dans ce mémoire et a été introduite par Orlitsky [35]. Étant donné le support $S \subseteq X \times Y$, introduisons l'hypergraphe G_S (voir l'annexe A.2). Les sommets de G_S sont les éléments de X, et pour tout $y \in Y$, il y a une hyperarête $E(y) = \{x \mid (x, y) \in S\}$.

- Une troisième approche, que nous ne définissons pas ici, a été présentée par Karpovsky, Levitin et Trachtenberg [26]. Même si elle peut être utilisée pour faire l'analyse de problèmes de communication avec données corrélées lorsque $X = Y$, cette approche est surtout utile pour des modèles de détection et de correction d'erreurs.

Définition 1.12. G_S est appelé l'*hypergraphe caractéristique* de S.

Il est important de remarquer que le graphe G_S est défini en sachant que Bob veut apprendre la chaîne d'Alice. Le graphe serait différent si Alice voulait apprendre la chaîne de Bob, à moins que le support S soit symétrique[3].

Remarque 1.13. L'ambiguité de Bob correspond au degré maximal des hyperarêtes de G_S (voir l'annexe A.2).

Définition 1.14. Un ensemble de support S est *trivial* si $D(S) = 0$, autrement dit si $\widehat{a_B} = 1$.

Nous présentons maintenant les premiers résultats sur la complexité de la communication de problèmes avec données corrélées. Ils ont tous été démontrés par Orlitsky [35, 38].

Lemme 1.15. *Pour tout problème de communication avec données corrélées,*

$$D^1(S) \geq D^2(S) \geq \cdots \geq D(S).$$

Démonstration. Trivial. □

[3] Un support symétrique est un support S tel que $(x, y) \in S \Leftrightarrow (y, x) \in S$.

Lemme 1.16. *Si $S_1 \subseteq S_2$, alors pour tout $k \in \mathbb{N}$,*

$$D^k(S_1) \leq D^k(S_2).$$

Démonstration. Il s'agit de remarquer que tout protocole pour S_2 est également un protocole pour S_1. □

Lemme 1.17. *Pour tout problème de communication avec données corrélées S,*

$$D(S) \geq \lceil \log \widehat{a_B} \rceil.$$

Démonstration. Supposons qu'il existe un protocole $\mathcal{P}$ requérant $\alpha < \lceil \log \widehat{a_B} \rceil$ bits de communication. Cela implique qu'il existe $y_i \in Y$ pour lequel $|\{x \mid (x, y) \in S\}| > 2^\alpha$. Si la chaîne de Bob est y_i, il existe donc au moins deux éléments distincts de X pour lesquels les bits transmis entre Alice et Bob sont les mêmes, ce qui est une contradiction. □

Lemme 1.18. *Pour tout problème de communication avec données corrélées S,*

$$D^1_{x|y}(S) = D_{x|y}(S) = \lceil \log \widehat{a_B} \rceil.$$

Démonstration. Par le lemme 1.17, $D(S) \geq \lceil \log \widehat{a_B} \rceil$. Montrons que $D(S) \leq \lceil \log \widehat{a_B} \rceil$. Soit G_S l'hypergraphe caractéristique de S. Initialement, Alice et Bob s'entendent sur un encodage des sommets des hyperarêtes de G_S, ce qui peut être fait avec $\lceil \log \widehat{a_B} \rceil$ bits. Lors de l'exécution du protocole, Alice, qui connaît y et par le fait même l'hyperarête a_y correspondant à l'ambiguité de Bob, n'a qu'à envoyer l'encodage de x. Nous obtenons donc que $D(S) \leq D^1(S) \leq \lceil \log \widehat{a_B} \rceil$. □

Lemme 1.19. *Pour tout problème de communication S,*

$$D^1(S) = \lceil \log \chi(G_S) \rceil,$$

où $\chi(G_S)$ est le nombre chromatique de G_S.

Démonstration.

- $D^1(S) \leq \lceil \log \chi(G_S) \rceil$

  Alice et Bob s'entendent sur un coloriage de G_S utilisant $\chi(G_S)$ couleurs. Alice envoie la couleur du sommet x à Bob. Par construction de G_S, tous les sommets x tels que $(x, y) \in S$ sont de couleur différente, ce qui permet à Bob de déduire x à partir de sa couleur et de y.

- $D^1(S) \geq \lceil \log \chi(G_S) \rceil$

  Supposons qu'il existe un protocole $\mathcal{P}$ requérant $\alpha < \lceil \log \chi(G_S) \rceil$ bits de communication. Cela veut dire qu'il existe un y pour lequel Alice envoie le même message pour au moins deux éléments de X, ce qui ne permet pas à Bob de les distinguer avec certitude.

□

Pour la majorité des problèmes, le lemme 1.19 est inutilisable en pratique, car le calcul exact du nombre chromatique d'un graphe est un problème $\mathcal{NP}$-difficile (consulter [42] pour plus de détails sur les classes de complexité du calcul). En fait, Feige et Kilian [17] ont montré que si $\mathcal{NP} \not\subseteq \mathcal{ZPP}$, il est impossible d'approximer en temps polynomial le nombre chromatique d'un graphe de n sommets à un facteur $n^{1-\epsilon}$ près, pour toute constante $\epsilon > 0$. Malgré ce résultat peu encourageant, il existe des méthodes heuristiques, par exemple des algorithmes évolutifs hybrides [20], qui permettent d'obtenir des bornes supérieures

intéressantes pour le nombre chromatique de graphes de taille raisonnable (moins de 1000 sommets). Par le fait même, de telles méthodes permettent d'obtenir des bornes supérieures intéressantes pour $D^1(S)$.

Le lemme 1.22 illustre qu'un protocole interactif peut permettre jusqu'à un gain exponentiel sur le nombre de bits communiqués par rapport à un protocole non interactif. Pour le démontrer, nous aurons besoin du fait que tout problème de communication avec données corrélées respecte la propriété d'absence de préfixe[4].

Définition 1.20. Notons $\sigma_{\mathcal{P}}(x, y)$ la concaténation de tous les messages transmis lors de l'exécution d'un protocole $\mathcal{P}$ sur l'entrée (x, y).

Lemme 1.21 (Propriété d'absence de préfixe). *Soit $S = X \times Y$ un problème de communication avec données corrélées, et soient $(x', y), (x, y), (x, y') \in S$ avec $x \neq x'$. Alors $\sigma_{\mathcal{P}}(x', y)$ n'est pas un préfixe de $\sigma_{\mathcal{P}}(x, y')$, et $\sigma_{\mathcal{P}}(x, y')$ n'est pas un préfixe de $\sigma_{\mathcal{P}}(x', y)$ (en particulier ils ne peuvent pas être égaux).*

Démonstration. Voir [35]. □

La propriété d'absence de préfixe est importante, car les modèles qui ne la respectent pas peuvent comprimer les messages et ainsi réduire la communication, tel qu'illustré par Papadimitriou et Sipser [43]. De plus, elle élimine la nécessité d'avoir un symbole spécial pour indiquer la fin de l'exécution du protocole.

Lemme 1.22 (Mercier 2002, démonstration seulement). *Pour tout problème de communication avec données corrélées S,*

$$D(S) \geq \lceil \log D^1(S) \rceil.$$

[4] «Prefix-freeness property» en anglais.

Démonstration. Soit $\mathcal{P}$ un protocole avec support S dont la complexité de la communication est $D(S)$. Construisons un protocole non interactif $\mathcal{P}$' de complexité $2^{D(S)}$. Alice considère toutes les $2^{D(S)}$ séquences possibles de $D(S)$ bits. Pour chacune de ces séquences α, elle transmet $f(\alpha)$ à Bob, où

$$f(\alpha) = \begin{cases} 1 \text{ si } \exists y' \in a_A(x) \mid \sigma_{\mathcal{P}}(x, y') \text{ est un préfixe de } \alpha \\ 0 \text{ sinon} \end{cases}$$

Bob trouve l'unique $x' \in a_B(y)$ tel que $\sigma_{\mathcal{P}}(x', y)$ est un préfixe d'un α pour lequel $f(\alpha) = 1$, et il conclut que c'est la chaîne d'Alice.

Pour justifier que l'algorithme fonctionne, il faut montrer qu'il existe un et un seul $x' \in a_B(y)$ tel que $\sigma_{\mathcal{P}}(x', y)$ est un préfixe d'un α pour lequel $f(\alpha) = 1$. Il est clair qu'il en existe au moins un, car $f(\sigma_{\mathcal{P}}(x, y)) = 1$. Supposons qu'il existe un $x' \in X, x' \neq x$, tel que $\sigma_{\mathcal{P}}(x', y)$ est un préfixe de α' pour lequel $f(\alpha') = 1$. Le fait que $f(\alpha') = 1$ implique qu'il existe un $y' \in a_A(x)$ tel que $\sigma_{\mathcal{P}}(x, y')$ est un préfixe de α'. Comme $\sigma_{\mathcal{P}}(x, y')$ et $\sigma_{\mathcal{P}}(x', y)$ sont des préfixes de α', il suit que $\sigma_{\mathcal{P}}(x, y')$ est un préfixe de $\sigma_{\mathcal{P}}(x', y)$ ou que $\sigma_{\mathcal{P}}(x', y)$ est un préfixe de $\sigma_{\mathcal{P}}(x, y')$. Ceci est une contradiction, car S respecte la propriété d'absence de préfixe. □

Le lemme 1.23 améliore d'un bit la borne du lemme précédent, mais la preuve de ce résultat un peu plus fort, bien que conceptuellement simple, prend plusieurs pages.

Lemme 1.23. *Pour tout problème de communication avec données corrélées S,*

$$D(S) \geq \lceil \log D^1(S) \rceil + 1.$$

Démonstration. Voir [35]. □

Terminons cette section par un retour sur le problème de la ligue sportive de la section 1.3. Nous avons montré que $D^1(S) = n$ et que $D^2(S) \leq \lceil \log n \rceil + 1$. Le lemme 1.23 nous permet de conclure que le protocole à deux rondes est optimal, c'est-à-dire que $D^2(S) = D^3(S) = \cdots = D(S) = \lceil \log n \rceil + 1$. Dans un autre ordre d'idées, si Alice connaît y, alors un seul bit de communication suffit d'après le lemme 1.18.

1.5 Deux rondes sont presque optimales

Le dernier exemple de la section précédente semble assez étonnant : pour le problème de la ligue sportive, il est inutile d'utiliser un protocole à plus de deux rondes, car cela ne permet pas de diminuer le nombre de bits communiqués. Dans cette section, nous présentons un des résultats les plus intéressants de la complexité de la communication de données corrélées, à savoir que pour tout problème, deux messages sont presque optimaux. Ce résultat contraste avec le modèle original de Yao : Duris, Galil et Schnitger [15] ont en effet démontré que pour tout $k \in \mathbb{N}$, il existe des suites de fonctions $(f_i)_{i \in \mathbb{N}}$ avec $f_i : \{0,1\}^i \times \{0,1\}^i \to \{0,1\}$ pour lesquelles $D^k(f_n)$ est exponentiellement plus grand que $D^{k+1}(f_n)$. Avant de démontrer le résultat principal de cette section, nous avons besoin de quelques notions préliminaires.

Lemme 1.24. $1 \cdot \frac{p-1}{p} \cdot \frac{p-2}{p} \cdots \frac{p-t+1}{p} \geq \left(1 - \frac{t}{p}\right)^t$, *où* $p \in \mathbb{N}$.

Démonstration.

$$\begin{aligned} 1 \cdot \frac{p-1}{p} \cdot \frac{p-2}{p} \cdots \frac{p-t+1}{p} &\geq 1 \cdot \left(1-\frac{1}{p}\right) \cdot \left(1-\frac{2}{p}\right) \cdots \left(1-\frac{t-1}{p}\right) \\ &\geq \left(1-\frac{t}{p}\right) \cdot \left(1-\frac{t}{p}\right) \cdots \left(1-\frac{t}{p}\right) \geq \left(1-\frac{t}{p}\right)^t. \end{aligned}$$

□

Le prochain théorème garantit l'existence d'une famille de fonctions de «hachage» qui permettront par la suite de démontrer plusieurs résultats intéressants. Une famille $H_{m,t}$ avec des paramètres légèrement différents que ceux présentés a été explicitement construite par Fredman, Komlòs et Szemerèdi [19].

Théorème 1.25 (Mercier 2002). *Soient m et t deux entiers supérieurs à 1. Il existe une famille de $k = 4t\lceil \log m \rceil$ fonctions, $H_{m,t}$, telles que :*

1. *Toute fonction $h \in H_{m,t}$ va de $\{1, \ldots, m\}$ à $\{1, \ldots, p\}$, où $p = 4t^2$;*
2. *Pour tout sous-ensemble $A \subseteq \{1, \ldots, m\}$ de taille au plus t, au moins la moitié des fonctions dans $H_{m,t}$ sont injectives sur A.*

Démonstration. Choisissons au hasard une fonction $h : \{1, \ldots, m\} \to \{1, \ldots, p\}$. La probabilité que h soit injective sur un ensemble $A \subseteq \{1, \ldots, m\}$ de taille au plus t est bornée par $1 \cdot \frac{p-1}{p} \ldots \frac{p-t+1}{p} \geq \left(1-\frac{t}{p}\right)^t = \left(1-\frac{1}{4t}\right)^t \geq \frac{3}{4}$ (voir le lemme 1.24). Choisissons maintenant au hasard k fonctions $h_1, h_2 \ldots, h_k$: $\{1, \ldots, m\} \to \{1, \ldots, p\}$ et définissons les variables aléatoires Z_i prenant la valeur 0 si h_i est injective sur A et 1 sinon. Il est clair que $E[Z_i] \leq 3/4$. La probabilité qu'au moins la moitié des fonctions h_i ne soient pas injectives sur A est :

$$\begin{aligned}
\Pr\left(\sum_{i=1}^{k} Z_i \geq \frac{k}{2}\right) &= \Pr\left(\frac{\sum_{i=1}^{k} Z_i}{k} \geq \frac{1}{2}\right) \\
&= \Pr\left(\frac{\sum_{i=1}^{k} Z_i}{k} - \frac{1}{4} \geq \frac{1}{4}\right) \\
&\leq \Pr\left(\left|\frac{\sum_{i=1}^{k} Z_i}{k} - \frac{1}{4}\right| \geq \frac{1}{4}\right) \\
&\leq \Pr\left(\left|\frac{\sum_{i=1}^{k} Z_i}{k} - \frac{1}{4}\right| \geq \frac{3}{16}\right) \\
&\leq 2e^{-\frac{k(3/16)^2}{2\cdot 3/16}} \text{ par l'inégalité de Chernoff (voir l'annexe A.4)} \\
&= 2e^{-\frac{3k}{32}} \\
&< 1 \text{ pour } k > 7,39.
\end{aligned}$$

La dernière inégalité est toujours vraie, car $k = 4t\lceil \log m \rceil$ et $m, t \geq 2$. Il existe donc une famille de k fonctions pour lesquelles au moins la moitié sont injectives sur A. □

Utilisons maintenant une famille de fonctions de hachage pour démontrer que pour tout problème de communication avec données corrélées, il existe un protocole à deux rondes qui nécessite au plus quatre fois le nombre de bits de communication requis par le protocole optimal.

Lemme 1.26. *Pour tout problème de communication avec données corrélées S,*

$$D^2(S) \leq \lceil \log\lceil \log \chi(G_S)\rceil\rceil + 3\lceil \log \widehat{a_B}\rceil + 4.$$

Démonstration. Soit S un problème de communication non trivial (il est clair que le lemme est vrai si S est trivial) et G_S son hypergraphe caractéristique. Alice et Bob s'entendent sur un coloriage ψ de G_S avec $\chi(G_S)$ couleurs ainsi que sur une famille de fonctions $H = H_{\chi(G_S),\widehat{a_B}}$ possédant les propriétés énoncées au théorème 1.25.

Bob considère l'hyperarête a_y qui détermine $a_B(y)$, les valeurs de x possibles chez Alice. Il choisit une fonction $h \in H$ qui est injective sur les couleurs de a_y et envoie sa description à Alice, ce qui requiert $\lceil \log(4\lceil \log \chi(G_S)\rceil \cdot \widehat{a_B})\rceil$ bits de communication. Une telle fonction existe grâce aux propriétés de H et parce que le nombre de sommets de l'hyperarête a_y est au plus $\widehat{a_B}$. Alice envoie ensuite $h(\psi(x))$ à Bob, ce qui nécessite $\lceil \log(4(\widehat{a_B})^2)\rceil$ bits de communication. Bob utilise alors $h(\psi(x))$ pour calculer $\psi(x)$, et comme tous les noeuds de a_y sont de couleur différente, il peut obtenir la valeur de x. La communication totale est donc $\lceil \log(4\lceil \log \chi(G_S)\rceil \cdot \widehat{a_B})\rceil + \lceil \log(4(\widehat{a_B})^2)\rceil \leq \lceil \log\lceil \log \chi(G_S)\rceil\rceil + 3\lceil \log \widehat{a_B}\rceil + 4$. □

Corollaire 1.27. *Pour tout problème avec données corrélées S,*

$$D^2(S) \leq 4D(S) + 3.$$

Démonstration.

$$\begin{aligned} D^2(S) &\leq \lceil \log \lceil \log \chi(G_S) \rceil \rceil + 3 \lceil \log \widehat{a_B} \rceil + 4 && \text{(lemme 1.26)} \\ &= \lceil \log D^1(S) \rceil + 3 \lceil \log \widehat{a_B} \rceil + 4 && \text{(lemme 1.19)} \\ &\leq D(S) - 1 + 3 \lceil \log \widehat{a_B} \rceil + 4 && \text{(lemme 1.23)} \\ &\leq D(S) - 1 + 3D(S) + 4 && \text{(lemme 1.17)} \\ &= 4D(S) + 3. \end{aligned}$$

□

Le corollaire 1.27 a été démontré par Orlitsky [35], qui par la suite a réussi à obtenir $D^2(S) \leq 4D(S) + 2$ [38]. Le lemme 1.28 nous permet d'améliorer ce résultat pour les problèmes de communication dont la complexité est assez grande.

Lemme 1.28 (Mercier 2002). *Soit S un problème avec données corrélées dont la complexité de la communication dépend de n, la taille de la chaîne d'Alice. Pour tout $c \in \mathbb{N}$, il existe un $n_0 \in \mathbb{N}$ tel que pour tout $n \geq n_0$,*

$$D^2(S) \leq 4D(S) - c.$$

Démonstration. Soit G_S l'hypergraphe caractéristique de S. Pour démontrer le lemme 1.26, nous avons utilisé une famille de $k = 4\widehat{a_B} \lceil \log \chi(G_S) \rceil$ fonctions de hachage. Il est possible de diminuer le nombre de fonctions, et par le fait même le nombre de bits de communication, en augmentant la base du logarithme précédent. Posons $k' = \lceil 4\widehat{a_B} \log_b \chi(G_S) \rceil$. Si nous appliquons un protocole similaire à la preuve du lemme 1.26 avec une famille de k' fonctions de hachage, cela entraîne que $D^2(S) \leq \lceil \log \lceil \log \chi(G_S) \rceil \rceil + 3 \lceil \log \widehat{a_B} \rceil + 6 - \log \log b$, et en appliquant la démarche utilisée pour démontrer le corollaire 1.27, il suit

que $D^2(S) \leq 4D(S) + 5 - \log\log b$. En posant $b = 2^{\left(2^{5+c}\right)}$, nous obtenons $D^2(S) \leq 4D(S) - c$.

Le prix à payer est que pour montrer l'existence d'une famille de k' fonctions de hachage possédant les propriétés énoncées au théorème 1.25, il faut que $k' = \lceil 4\widehat{a_B} \log_b \chi(G_S) \rceil > 7,39$, ce qui entraîne qu'il est nécessaire que $\widehat{a_B} \cdot \log \chi(G_S) > 1,585 \cdot 2^{5+c}$. Si S est un problème dont la complexité de la communication dépend de n, alors il existe un n_0 assez grand pour lequel $\widehat{a_B} \cdot \chi(G_S) > 1,585 \cdot 2^{5+c}$ pour tout $n \geq n_0$. □

1.6 En augmentant le nombre de rondes

Nous venons de démontrer que pour tout problème de communication avec données corrélées, il existe un protocole à deux rondes qui est presque optimal. Cette section résume les principaux résultats connus lorsque le nombre de rondes augmente, ainsi que les principaux problèmes ouverts reliés à cette question. Nous n'avons pas jugé bon d'inclure les preuves, car elles sont assez longues, plutôt techniques et ne sont pas utiles pour les chapitres subséquents de ce mémoire.

Une variante du problème de la ligue sportive a été formulée par Orlitsky [36]. Une ligue sportive possède $d \cdot e$ équipes réparties également en d divisions. Les deux meilleures équipes de chaque division participent aux séries éliminatoires, et toutes ces équipes sont connues de Bob. Alice, de son côté, connaît l'identité de l'équipe championne de la ligue. Le but est que Bob apprenne l'identité de l'équipe gagnante. Soit S l'ensemble de support de ce problème avec données corrélées. Considérons le protocole à trois rondes suivant : Alice envoie la division dans laquelle évolue l'équipe gagnante, ce qui nécessite $\lceil \log d \rceil$ bits de communication.

Bob considère ensuite les deux équipes de la division reçue par Alice participant aux séries éliminatoires. Il envoie à Alice une position pour laquelle les deux chaînes diffèrent, ce qui requiert $\lceil \log e \rceil$ bits de communication. Finalement, Alice envoie la valeur du bit de l'équipe gagnante à la position demandée. La complexité du protocole est donc $D^3(S) \leq \lceil \log d \rceil + \lceil \log e \rceil + 1$.

Orlitsky [36] a démontré que lorsque e et d sont choisis judicieusement, tout protocole à deux rondes nécessite plus de communication que le protocole à trois rondes[5]. En fait, il a démontré le résultat suivant :

Théorème 1.29. *Pour tout $\epsilon > 0$ et pour tout $c \geq 0$, il existe un problème avec données corrélées S tel que*

$$D^2(S) \geq (2 - \epsilon) D^3(S) \geq c.$$

Ce résultat et le corollaire 1.27 permettent de poser la question suivante :

Problème ouvert 1.30. Quel est le rapport maximal entre $D^2(S)$ et $D(S)$?

Zhang et Xia [56] et Ahlswede, Cai et Zhang [3] ont ensuite démontré que trois messages n'étaient pas optimaux :

Théorème 1.31. *Pour tout $\epsilon > 0$ et pour tout $c \geq 0$, il existe un problème de communication avec données corrélées S tel que*

$$D^3(S) \geq (2 - \epsilon) D^4(S) \geq c.$$

Zhang et Xia ont également émis la conjecture que $D^4(S) \leq D(S) + o(D(S))$, mais sans parvenir à la démontrer.

[5] Le problème considéré par Orlitsky est légèrement différent de celui présenté ici.

Problème ouvert 1.32. Existe-t-il un k tel que $D^k(S) \leq D(S) + o(D(S))$?

Nous avons essayé de résoudre cette conjecture en généralisant le problème de la ligue sportive, mais nous n'avons pas réussi à obtenir des résultats qui valent la peine d'être mentionnés ici.

Chapitre 2

Complexité déterministe amortie

La résolution simultanée de plusieurs exemplaires[1] d'un problème est parfois plus efficace du point de vue de la communication que la résolution séquentielle des exemplaires de façon optimale. En fait, cela peut même être vrai pour des problèmes différents. Ce phénomène contraire à l'intuition s'applique autant à la communication interactive que non interactive et est appelé le problème de la somme directe[2].

Le problème de la somme directe en complexité de la communication a été introduit par Karchmer, Raz et Wigderson [25] comme une approche prometteuse pour séparer $\mathcal{NC}^1$ de $\mathcal{NC}^2$. Il a été abondamment étudié (consulter entre autres [16, 24, 23]) et pourrait certainement faire l'objet d'un mémoire à lui seul. Dans ce chapitre, nous nous contentons de présenter les principales notions reliées au problème de la somme directe pour les protocoles de communication avec données corrélées (consulter également [4, 5]). Les nouveaux résultats que nous avons obtenus sont les théorèmes 2.8, 2.11, 2.13 et 2.18, les corollaires 2.9, 2.14 et 2.15,

[1] Nous supposons toujours que tous les exemplaires sont indépendants.
[2] «Direct-sum problem» en anglais

la conjecture 2.24 ainsi que toute la section 2.4.

2.1 Définitions

Définition 2.1. Notons $D(S,T)$ la *complexité de la communication déterministe simultanée* des problèmes avec données corrélées S et T, et $D(f,g)$ la complexité de la communication déterministe simultanée des fonctions f et g.

Définition 2.2. Notons $D(S^l)$ la complexité de la communication déterministe simultanée de l exemplaires d'un problème avec données corrélées S, et $D(f^l)$ la complexité de la communication déterministe simultanée de l exemplaires d'une fonction f.

Lorsque plusieurs exemplaires d'un même problème sont résolus simultanément, il peut être utile d'utiliser une mesure de complexité qui représente la complexité de la communication moyenne par exemplaire.

Définition 2.3. La *complexité de la communication déterministe amortie* de S, notée $\overline{D}(S)$, est donnée par l'expression

$$\overline{D}(S) \stackrel{\text{déf}}{=} \lim_{l\to\infty} \frac{1}{l} D(S^l).$$

Il n'est pas difficile de voir que la limite existe par sous-additivité, et que $\overline{D}(S) \leq D(S)$, $D(S,T) \leq D(S) + D(T)$ et $D(S^l) \leq l \cdot D(S)$.

Définition 2.4. Soient $S \subseteq X_S \times Y_S$ et $T \subseteq X_T \times Y_T$ des problèmes de communication avec données corrélées dont les hypergraphes caractéristiques sont $G_S = (V_S, A_S)$ et $G_T = (V_T, A_T)$. Notons $G_S \times G_T = (V_S \times V_T, A)$ le produit

des hypergraphes G_S et G_T. Les hyperarêtes de $G_S \times G_T$ sont définies de la façon suivante : pour tout $(y_s, y_t) \in Y_S \times Y_T$, il y a une hyperarête $A(y_s, y_t) = \{(x_s, x_t) \mid (x_s, y_s) \in S \wedge (x_t, y_t) \in T\}$.

Définition 2.5. Appelons G_S^l le produit, au sens de la définition 2.4, de l copies de l'hypergraphe G_S.

2.2 Communication non interactive

Lorsque plusieurs problèmes doivent être résolus de façon non interactive, il peut être avantageux de les résoudre simultanément plutôt que de les résoudre de façon séquentielle.

Lemme 2.6. *Soient $S_1, S_2, \ldots, S_l$ des problèmes de communication avec données corrélées. Alors*

$$D^1(S_1, S_2, \ldots, S_l) = \lceil \log \chi(G_{S_1} \times G_{S_2} \times \cdots \times G_{S_l}) \rceil.$$

Démonstration. Il s'agit d'appliquer la preuve du lemme 1.19 à l'entrée $((x_{s_1}, x_{s_2}, \ldots, x_{s_l}), (y_{s_1}, y_{s_2}, \ldots, y_{s_l}))$. □

Corollaire 2.7. *Pour tout problème de comunication avec données corrélées S,*

$$D^1(S^l) = \lceil \log \chi(G_S^l) \rceil.$$

Démonstration. Découle directement du lemme précédent. □

L'intérêt du corollaire 2.7 est dû au fait qu'il existe des graphes G tels que $\chi(G^l) < (\chi(G))^l$. En fait, ce corollaire a été démontré par Witsenhausen [53]

dans le but d'analyser un graphe célèbre présenté par Shannon [47] en relation avec la capacité sans erreur de canaux de communication. Nous présentons ce graphe comme exemple d'introduction. Alice et Bob possèdent respectivement des chaînes $x \in \mathbb{Z}_5$ et $y \in \mathbb{Z}_5$ avec $y \equiv x \pmod 5$ ou $y \equiv x+1 \pmod 5$, et Bob veut apprendre la valeur de x. L'ensemble de support de ce problème avec données corrélées est donc $S = \{(x,y) \mid y \equiv x+1 \pmod 5 \vee y \equiv x \pmod 5\}$. Il n'est pas difficile de voir que G_S est un pentagone et que $\chi(G_S) = 3$. Or, avec un peu de travail et beaucoup de patience, on peut montrer que $\chi(G_S^2) = 5 < 9$. Par conséquent, nous pouvons appliquer le corollaire 2.7 et obtenir que $D^1(S) = 2$ et que $D^1(S^2) = 3$. La résolution simultanée des deux exemplaires permet de sauver un bit de communication.

Il est important de remarquer que les économies possibles dépendent de la structure des graphes. Par exemple, si G_S est un graphe complet de k sommets, alors G_S^l est un graphe complet de k^l sommets. Autrement dit, lorsque $S = X \times Y$, il n'y a rien à gagner à résoudre simultanément les exemplaires d'un problème.

Nous pouvons également utiliser le lemme 2.6 pour résoudre simultanément des problèmes différents. Soit $T = \{(x,y) \mid y \equiv x+1 \pmod 3 \vee y \equiv x \pmod 3\}$, où $x, y \in \mathbb{Z}_3$. G_T est un triangle, et donc $\chi(G_T) = 3$ et $\chi(G_S) \cdot \chi(G_T) = 9$. Or, nous pouvons montrer que $\chi(G_S \times G_T) = 8$, ce qui entraîne que $D^1(G_S \times G_T) = 3 < D^1(G_S) + D^1(G_T) = 4$. La résolution simultanée des deux problèmes différents permet de sauver un bit de communication.

Le prochain théorème limite la communication qui peut être sauvée en résolvant simultanément deux problèmes avec données corrélées. Nous l'avons démontré indépendamment à partir des résultats obtenus par Witsenhausen [53] et Linial et Vazirani [28], mais le résultat a déjà été publié par Feder, Kushilevitz,

Naor et Nisan [16].

Théorème 2.8 (Feder, Kushilevitz, Naor, Nisan 1995 [16] ; Mercier 2002). *Soient S et T deux problèmes avec données corrélées dont les hypergraphes caractéristiques sont respectivement G_S et G_T, $|G_S| \leq |G_T|$. Alors*

$$D^1(S,T) \geq D^1(S) + D^1(T) - \log\log|G_S| - 4.$$

Démonstration. Linial et Vazirani [28] ont montré que pour deux graphes[3] quelconques G et H avec $|G| \leq |H|$, $\chi(G \times H) \geq \frac{(\chi(G)-1)\chi(H)}{\ln|G|}$. En appliquant ce résultat à G_S et G_T et en utilisant le lemme 2.6, nous obtenons :

$$\begin{aligned} D^1(S,T) &\geq \left\lceil \log\left(\frac{(\chi(G_S)-1)\chi(G_T)}{\ln|G_S|}\right)\right\rceil \\ &\geq \log(\chi(G_S)-1) + \log\chi(G_T) - \log\ln|G_S| \\ &\geq \lceil\log(\chi(G_S))\rceil + \lceil\log\chi(G_T)\rceil - \log\ln|G_S| - 3 \\ &\geq D^1(S) + D^1(T) - \log\log|G_S| - 4. \end{aligned}$$

□

Corollaire 2.9 (Feder, Kushilevitz, Naor, Nisan 1995 [16] ; Mercier 2002). *Pour tout problème de communication avec données corrélées S dont l'hypergraphe caractéristique est G_S,*

$$D^1(S^2) \geq 2D^1(S) - \log\log|G_S| - 4.$$

[3] Le résultat est également valide pour les hypergraphes.

Pour tout problème avec données corrélées dont les entrées sont de longueur n, le gain maximal possible pour la résolution de deux exemplaires simultanément est donc un terme additif de $\log n$ bits par rapport à la résolution séquentielle des exemplaires. Linial et Vazirani [28] ont montré qu'il existe des graphes de n sommets pour lesquels cette borne pouvait être atteinte.

Corollaire 2.10. *Pour tout problème de communication avec données corrélées S dont l'hypergraphe caractéristique est G_S,*

$$D^1(S) \geq \overline{D^1}(S) \geq D^1(S) - \log\log|G_S| - 4.$$

Démonstration. Le première inégalité est triviale. Pour la deuxième inégalité, un résultat similaire a été démontré par récurrence sur l par Feder, Kushilevitz, Naor et Nisan [16]. □

Ce dernier résultat signifie que pour un problème de communication avec données corrélées S dont les entrées sont de longueur n, le gain maximal possible pour la résolution simultanée de plusieurs exemplaires est un terme additif de $\log n + 4$ bits par exemplaire.

2.3 Communication interactive

Dans cette section, nous analysons le problème de la somme directe pour les protocoles interactifs. Encore une fois, il est parfois possible de réduire la communication en résolvant simultanément plusieurs exemplaires d'un même problème ou même plusieurs problèmes différents. La communication maximale qui peut être économisée n'est toutefois pas connue ; c'est d'ailleurs une des principales

questions ouvertes en complexité de la communication.

Théorème 2.11 (Mercier 2002). *Soient $S_1, S_2, \ldots, S_l$ des problèmes de communication avec données corrélées. Alors*

$$D^2(S_1, S_2, \ldots, S_l) \in O\left(l \cdot \log \max_{1\leq i\leq l}(\widehat{a_B}(S_i)) + \log l \cdot \log\log \max_{1\leq i\leq l}(\chi(G_{S_i}))\right).$$

Démonstration. Alice possède des chaînes $x_1 \in X_1, \ldots, x_l \in X_l$ et Bob des chaînes $y_1 \in Y_1, \ldots, y_l \in Y_l$ avec la restriction que $(x_i, y_i) \in S_i$ pour $1 \leq i \leq l$. Soient $G_{S_1}, G_{S_2}, \ldots, G_{S_l}$ les hypergraphes associés respectivement aux problèmes avec données corrélées $S_1, S_2, \ldots, S_l$. Pour chaque G_{S_i}, Alice et Bob s'entendent sur un coloriage ψ_i avec $\chi(G_{S_i})$ couleurs. Ils s'entendent également sur une famille de fonctions $H = H_{\max_{1\leq i\leq l}(\chi(G_{S_i})), \max_{1\leq i\leq l}(\widehat{a_B}(S_i))}$ possédant les propriétés énoncées au théorème 1.25.

Bob considère les couleurs des sommets des hyperarêtes $a_{y_1}, a_{y_2}, \ldots, a_{y_l}$. Pour chaque a_{y_i}, le nombre de sommets est au plus $\max_{1\leq i\leq l}(\widehat{a_B}(S_i))$. Par le théorème 1.25, il suit que pour chaque a_{y_i}, au moins la moitié des fonctions de H sont injectives sur les couleurs des sommets. Par le lemme A.15, il existe donc une fonction $h_1 \in H$ qui est injective pour au moins la moitié des hyperarêtes $a_{y_1}, a_{y_2}, \ldots, a_{y_l}$. Bob considère ensuite la moitié restante des hyperarêtes pour lesquelles h_1 n'est pas injective. Il trouve une fonction $h_2 \in H$ qui est injective pour au moins la moitié de ces hyperarêtes, et ainsi de suite. De cette façon, Bob trouve $\lceil \log(l+1) \rceil$ fonctions telles que pour toute hyperarête a_{y_i}, au moins une des fonctions est injective sur les couleurs de ses sommets. Bob envoie le nom de ces fonctions à Alice, ce qui nécessite $\lceil \log(l+1) \rceil \lceil \log(4\lceil \log \max_{1\leq i\leq l}(\chi(G_{S_i})) \rceil \cdot \max_{1\leq i\leq l}(\widehat{a_B}(S_i))) \rceil$ bits de communication.

Bob doit également communiquer à Alice quelle fonction h_j doit être utilisée avec chaque a_{y_i}. Comme chaque h_j est injective pour $\frac{1}{2^j}$ des hyperarêtes, il est avantageux de coder les fonctions en unaire, c'est-à-dire d'utiliser la chaîne 1^j pour h_j. Cette étape requiert donc $\sum_{i=1}^{\lceil \log (l+1) \rceil} \frac{l}{2^i} \cdot i \leq 2l-1$ bits de communication pour les fonctions et l zéros servant de séparateurs.

Finalement, lors de la deuxième ronde, Alice envoie $h_j(\psi_i(x_i))$ pour chacun des x_i, ce qui nécessite $l\lceil \log(4(\max_{1\leq i\leq l}(\widehat{a_B}(S_i)))^2) \rceil$ bits de communication. Comme les fonctions h_j sont injectives, Bob peut calculer les valeurs $\psi_i(x_i)$, et puisque tous les noeuds des hyperarêtes a_{y_i} sont de couleurs différentes, il peut en déduire la valeur des x_i. La communication totale est donc :

$$\begin{aligned}
D^2(S_1 + \cdots + S_l) &\leq \lceil \log (l+1) \rceil \cdot \left\lceil \log \left(4 \left\lceil \log \max_{1\leq i\leq l}(\chi(G_{S_i})) \right\rceil \cdot \max_{1\leq i\leq l}(\widehat{a_B}(S_i)) \right) \right\rceil \\
&\quad + 2l - 1 + l + l \left\lceil \log \left(4 \left(\max_{1\leq i\leq l}(\widehat{a_B}(S_i)) \right)^2 \right) \right\rceil \\
&= \lceil \log (l+1) \rceil \left\lceil \log \left\lceil \log \max_{1\leq i\leq l}(\chi(G_{S_i})) \right\rceil \right\rceil \\
&\quad + \lceil \log (l+1) \rceil \left\lceil \log \max_{1\leq i\leq l}(\widehat{a_B}(S_i)) \right\rceil + 2\lceil \log (l+1) \rceil \\
&\quad + 2l \left\lceil \log \max_{1\leq i\leq l}(\widehat{a_B}(S_i)) \right\rceil + 5l - 1 \\
&\in O\left(l \cdot \log \max_{1\leq i\leq l}(\widehat{a_B}(S_i)) + \log l \cdot \log \log \max_{1\leq i\leq l}(\chi(G_{S_i})) \right)
\end{aligned}$$

□

Le corollaire suivant a été initialement démontré par Feder, Kushilevitz, Naor et Nisan [16] et découle directement du théorème 2.11.

Corollaire 2.12. *Pour tout problème de communication avec données corrélées S,*

$$\begin{aligned} D^2(S^l) &\leq \lceil \log(l+1) \rceil \lceil \log \lceil \log \chi(G_S) \rceil \rceil + \lceil \log(l+1) \rceil \lceil \log \widehat{a_B} \rceil \\ &\quad + 2\lceil \log(l+1) \rceil + 2l \lceil \log \widehat{a_B} \rceil + 5l - 1 \\ &\in O(l \cdot \log \widehat{a_B} + \log l \cdot \log \log \chi(G_S)). \end{aligned}$$

Démonstration. Il s'agit de remarquer que $\max_{1 \leq i \leq l}(\widehat{a_B}(S_i)) = \widehat{a_B}$ et que $\max_{1 \leq i \leq l}(\chi(G_{S_i})) = \chi(G_S)$. □

Pour certains cas que nous analysons sous peu, le théorème 2.13 permet de sauver plus de bits de communication que le théorème 2.11.

Théorème 2.13 (Mercier 2002). *Soient $S_1, S_2, \ldots, S_l$ des problèmes de communication avec données corrélées. Alors*

$$D^2(S_1, S_2, \ldots, S_l) \in O\left(l \log \sum_{i=1}^{l} \widehat{a_B}(S_i) + \log \log \max_{1 \leq i \leq l}(\chi(G_{S_i})) \right).$$

Démonstration. Alice possède des chaînes $x_1 \in X_1, \ldots, x_l \in X_l$ et Bob des chaînes $y_1 \in Y_1, \ldots, y_l \in Y_l$ avec la restriction que $(x_i, y_i) \in S_i$ pour $1 \leq i \leq l$. Soient $G_{S_1}, G_{S_2}, \ldots, G_{S_l}$ les hypergraphes associés aux problèmes avec données corrélées $S_1, S_2, \ldots, S_l$. Pour chaque G_{S_i}, Alice et Bob s'entendent sur un coloriage ψ_i avec $\chi(G_{S_i})$ couleurs. Alice et Bob s'entendent également sur une famille de fonctions $H = H_{\max_{1 \leq i \leq l}(\chi(G_{S_i})), \sum_{i=1}^{l} \widehat{a_B}(S_i)}$ possédant les propriétés énoncées au théorème 1.25.

Bob considère les couleurs des hyperarêtes $a_{y_1}, a_{y_2}, \ldots, a_{y_l}$. Il choisit une fonction $h \in H$ qui est injective sur ces couleurs et envoie sa description à Alice, ce qui requiert $\lceil \log(4 \lceil \log \max_{1 \leq i \leq l}(\chi(G_{S_i})) \rceil \cdot \sum_{i=1}^{l} \widehat{a_B}(S_i)) \rceil$ bits de communication.

Une telle fonction existe à cause des propriétés de H et parce que le nombre total de sommets des hyperarêtes $a_{y_1}, \ldots, a_{y_l}$ est au plus $\sum_{i=1}^{l} \widehat{a_B}(S_i)$.

Alice envoie ensuite les l valeurs $h(\psi_i(x_i))$ à Bob, ce qui nécessite $l \cdot \lceil \log(4(\sum_{i=1}^{l} \widehat{a_B}(S_i))^2) \rceil$ bits de communication. Comme la fonction h est injective, Bob peut calculer les valeurs $\psi_i(x_i)$, et puisque tous les noeuds des hyperarêtes a_{y_i} sont de couleurs différentes, il peut en déduire la valeur des x_i. La communication totale est donc :

$$\begin{aligned} D^2\left(S_1 + \cdots + S_l\right) &\leq \left\lceil \log\left(4\left\lceil \log \max_{1\leq i\leq l}\left(\chi(G_{S_i})\right)\right\rceil \cdot \sum_{i=1}^{l} \widehat{a_B}(S_i)\right)\right\rceil \\ &\quad + l \cdot \left\lceil \log\left(4\left(\sum_{i=1}^{l} \widehat{a_B}(S_i)\right)^2\right)\right\rceil \\ &= \left\lceil \log\left\lceil \log \max_{1\leq i\leq l}(\chi(G_{S_i}))\right\rceil\right\rceil + \left\lceil \log \sum_{i=1}^{l} \widehat{a_B}(S_i)\right\rceil \\ &\quad + 2l\left\lceil \log \sum_{i=1}^{l} \widehat{a_B}(S_i)\right\rceil + 2l + 2 \\ &\in O\left(\log\log \max_{1\leq i\leq l}(\chi(G_{S_i})) + l \log \sum_{i=1}^{l} \widehat{a_B}(S_i)\right) \end{aligned}$$

□

Corollaire 2.14 (Mercier 2002). *Pour tout problème de communication avec données corrélées S,*

$$\begin{aligned} D^2(S^l) &\leq \lceil \log\lceil \log \chi(G_S)\rceil\rceil + \lceil \log(l \cdot \widehat{a_B})\rceil + 2l\lceil \log(l \cdot \widehat{a_B})\rceil + 2l + 2 \\ &\in O(\log\log \chi(G_S) + l \log l + l \log \widehat{a_B}). \end{aligned}$$

Démonstration. Il s'agit de remarquer que $\sum_{i=1}^{l} \widehat{a_B}(S_i) = l \cdot \widehat{a_B}$ et que $\max_{1 \leq i \leq l}(\chi(G_{S_i})) = \chi(G_S)$. □

Voici un autre corollaire surprenant découlant du théorème 2.13.

Corollaire 2.15 (Mercier 2002). *Soit S un problème de communication avec données corrélées dont l'hypergraphe caractéristique est G_S et pour lequel $\widehat{a_B} \in O(1)$. Si $l \in O(1)$, alors*

$$D(S^l) \leq D(S) + O(1).$$

Démonstration. En utilisant dans l'ordre le corollaire 2.14 ainsi que les lemmes 1.19 et 1.23, nous obtenons :

$$\begin{aligned} D(S^l) &\leq \lceil \log \lceil \log \chi(G_S) \rceil \rceil + \lceil \log(l \cdot \widehat{a_B}) \rceil + 2l \lceil \log(l \cdot \widehat{a_B}) \rceil + 2l + 2 \\ &= \lceil \log D^1(S) \rceil + O(1) \\ &\leq D(S) + O(1) \end{aligned}$$

□

Le tableau 2.1 résume la communication requise pour résoudre l exemplaires d'un problème avec données corrélées S en utilisant les protocoles du lemme 1.26 et des corollaires 2.12 et 2.14. Si $l \in o(\log \log \chi(G_S))$, le protocole du corollaire 2.14 est le plus efficace, tandis que si $l \in \omega(\log \log \chi(G_S))$, le meilleur protocole est celui du corollaire 2.12. Notons que le protocole du corollaire 2.14 est le pire des trois si $l \in \omega(\log \chi(G_S))$, en fait pire encore que la résolution séquentielle des exemplaires. Il est donc essentiel de connaître le nombre d'exemplaires à résoudre avant de choisir un protocole.

TAB. 2.1 – Résolution de l exemplaires d'un problème avec données corrélées S

Protocole	**Communication requise**
Lemme 1.26	$O(l \cdot \log\log \chi(G_S) + l \cdot \log \widehat{a_B})$
Corollaire 2.12	$O(\log l \cdot \log\log \chi(G_S) + l \cdot \log \widehat{a_B})$
Corollaire 2.14	$O(\log\log \chi(G_S) + l \log \widehat{a_B} + l \log l)$

TAB. 2.2 – Résolution de plusieurs exemplaires du problème de la ligue sportive

Nombre d'exemplaires	**Résolution séquentielle**	**Corollaire 2.12**	**Corollaire 2.14**
16	$16\lceil \log n \rceil + 16$	$5\lceil \log n \rceil + 126$	$\lceil \log n \rceil + 199$
$\boldsymbol{\Theta(\log\log n)}$	$\Theta(\log n \log\log n)$	$O(\log n \log\log\log n)$	$O(\log n)$
$\boldsymbol{\Theta(\log n)}$	$\Theta(\log^2 n)$	$O(\log n \log\log n)$	$O(\log n \log\log n)$
$\boldsymbol{\Theta(n)}$	$\Theta(n \log n)$	$O(n)$	$O(n \log n)$

Quant au tableau 2.2, il analyse la performance des trois protocoles pour résoudre plusieurs exemplaires du problème de la ligue sportive. Rappelons que pour ce problème, $\widehat{a_B} = 2$ et $\chi(G_S) = 2^n$. Deux résultats méritent d'être soulignés. Premièrement, le corollaire 2.15 implique que $D(S^l) \leq D(S) + O(1)$ lorsque $l \in O(1)$. Deuxièmement, le corollaire 2.12 nous permet de déduire que la complexité de la communication amortie est constante. En fait, nous verrons à la section 2.5 que $\overline{D}(S) = 1$ pour le problème de la ligue sportive.

2.4 Le problème de la ligue sportive, prise 2

Les théorèmes 2.11 et 2.13 peuvent être utilisés pour résoudre simultanément plusieurs problèmes avec données corrélées différents plus efficacement que s'ils étaient résolus séparément de façon optimale. Dans cette section, nous construisons une famille de problèmes différents pour lesquels la communication peut

être réduite lorsqu'ils sont résolus simultanément. À notre connaissance, une telle famille n'avait jamais été contruite.

Le problème de la ligue sportive défini à la section 1.3 est modifié de la façon suivante : Bob connaît les k équipes participant aux séries éliminatoires de la ligue et veut apprendre d'Alice le nom de l'équipe gagnante. Appelons L_k le problème de la ligue sportive ayant $k+1$ équipes participant aux séries éliminatoires, L_1 étant le problème initial.

Lemme 2.16. *$D(L_k) \in \Theta(\log n)$ lorsque $k \in O(\log n)$.*

Démonstration. Soit G_{L_k} l'hypergraphe caractéristique de L_k. Il est clair que $\chi(G_{L_k}) = 2^n$ et que $\widehat{a_B}(L_k) = k+1$. Le lemme 1.19 implique que $D^1(L_k) = n$, et il suit par le lemme 1.23 que $D(L_k) \geq \lceil \log n \rceil + 1$. Comme $D(L_k) \leq D^2(L_k) \leq \lceil \log n \rceil + 3\lceil \log(k+1) \rceil + 4$ par le lemme 1.26, il suit que $D(L_k) \in \Theta(\log n)$ lorsque $k \in O(\log n)$. □

Les deux exemples suivants montrent qu'il est possible d'avoir $D(L_1, L_2, \ldots, L_l) < D(L_1) + D(L_2) + \ldots D(L_l)$.

- Si $l \in O(1)$, alors $D(L_1) + D(L_2) + \cdots + D(L_k) \geq l\lceil \log n \rceil$ par les lemmes 1.19 et 1.23, alors que par le théorème 2.13, nous obtenons que $D(L_1, L_2, \ldots, L_k) \leq \lceil \log n \rceil + O(1)$.
- Si $l \in \Theta(\log n)$, alors $D(L_1) + D(L_2) + \cdots + D(L_k) \in \Theta(\log^2 n)$ bits de communication par le lemme 2.16, alors que les théorèmes 2.11 et 2.13 impliquent que $D(L_1, L_2, \ldots, L_k) \in O(\log n \log\log n)$.

2.5 Quatre rondes sont optimales

Dans cette section, nous montrons que quatre rondes de communication sont optimales pour la complexité de la communication déterministe amortie.

Le théorème 2.17 a été démontré par Naor, Orlitsky et Shor [33]. La démonstration, qui n'est pas présentée ici, n'est pas très complexe et utilise encore une fois une famille de fonctions de hachage.

Théorème 2.17. *Soit S un problème de communication dont l'hypergraphe caractéristique G_S possède $a(G_S)$ hyperarêtes. Alors*

$$D^4(S) \leq \log\log a(G_S) + \log \widehat{a_B} + 3\log\log \widehat{a_B} + 7.$$

Le théorème 2.17 peut être utilisé pour calculer plusieurs exemplaires d'un même problème, ou encore plusieurs problèmes différents, comme en font foi le théorème et le corollaire suivants :

Théorème 2.18 (Mercier 2002). *Soient $S_1, S_2, \ldots, S_l$ des problèmes de communication avec données corrélées. Alors*

$$D^4(S_1, S_2, \ldots, S_L) \leq \log\log \prod_{i=1}^{l} a(G_{S_i}) + \log \prod_{i=1}^{l} \widehat{a_B}(S_i) + 3\log\log \prod_{i=1}^{l} \widehat{a_B}(S_i) + 7.$$

Démonstration. Soit $G_S = G_{S_1} \times G_{S_2} \times \cdots \times G_{S_l}$ l'hypergraphe caractéristique des problèmes $(S_1, S_2, \ldots, S_l)$ tel qu'introduit à la définition 2.4. Il n'est pas difficile de voir que $a(G_S) = a(G_{S_1}) \times a(G_{S_2}) \times \cdots \times a(G_{S_l})$ et que $\widehat{a_B}(S) = \widehat{a_B}(S_1) \times \widehat{a_B}(S_2) \times \cdots \times \widehat{a_B}(S_l)$. En appliquant le théorème précédent à l'hypergraphe G_S, nous obtenons le résultat souhaité. □

Corollaire 2.19. *Pour tout problème de communication non trivial avec données corrélées S,*

$$D^4(S^l) \leq l \log \widehat{a_B} + 4 \log l + \log \log a(G_S) + 3 \log \log \widehat{a_B} + 7.$$

Démonstration. Il s'agit d'appliquer directement le théorème 2.18 en remarquant que $\prod_{i=1}^{l} \widehat{a_B}(S_i) = (\widehat{a_B})^l$ et que $\prod_{i=1}^{l} a(G_{S_i}) = (a(G_S))^l$. □

Ce corollaire nous permet de démontrer que quatre rondes de communication sont optimales pour la complexité de la communication amortie déterministe, résultat qui a été démontré par Naor, Orlitsky et Shor [33].

Corollaire 2.20. *Pour tout problème de communication non trivial S avec données corrélées,*

$$\overline{D^4}(S) = \overline{D^5}(S) = \cdots = \overline{D}(S) = \log \widehat{a_B}.$$

Démonstration. Pour la borne supérieure, le corollaire 2.19 entraîne que

$$\overline{D^4}(S) = \lim_{l \to \infty} \frac{D^4(S^l)}{l} \leq \log \widehat{a_B}.$$

Pour la borne inférieure, nous pouvons utiliser le lemme 1.17 et obtenir que $D(S) \geq \lceil \log \widehat{a_B}(S^l) \rceil \geq l \log \widehat{a_B}$. Par conséquent,

$$\overline{D^4}(S) \geq \overline{D}(S) = \lim_{l \to \infty} \frac{D(S^l}{l} \geq \log \widehat{a_B}.$$

□

En comparant le corollaire 2.20 et le lemme 1.18, nous obtenons directement le corollaire 2.21.

Corollaire 2.21. *La complexité de la communication amortie déterministe d'un problème avec données corrélées correspond exactement à la complexité de la communication déterministe lorsqu'Alice connaît la chaîne de Bob.*

Une remarque à propos du corollaire 2.21 est que c'est uniquement lorsqu'il y a une différence appréciable entre la complexité de la communication lorsqu'Alice ne connaît pas la chaîne de Bob et la complexité de la communication lorsqu'elle la connaît qu'il peut être avantageux de résoudre simultanément plusieurs exemplaires d'un problème avec données corrélées. Nous verrons au chapitre 4 que pour les applications comme la réconciliation de fichiers, la comparaison de séquences de nucléotides ou la distribution de clés secrètes, ce n'est malheureusement pas le cas.

2.6 Discussion

Plusieurs nouveaux résultats ont été présentés dans les sections précédentes, mais malheureusement, ils ne permettent pas d'améliorer beaucoup la compréhension des principales questions ouvertes reliées au problème de la somme directe en complexité de la communication. La présente section traite de deux de ces questions ouvertes en lien avec les résultats de ce chapitre. Nous énonçons également une nouvelle conjecture.

Problème ouvert 2.22. Existe-t-il des fonctions f et g telles que $D(f,g) < D(f) + D(g)$?

Il ne semble pas possible d'adapter les résultats obtenus pour les problèmes avec données corrélées afin de résoudre le problème de la somme directe pour le

modèle original de Yao. En effet, passer d'un protocole pour un problème avec données corrélées S à un protocole pour une fonction n'est pas aussi simple qu'il n'y paraît. Soit $\mathcal{P}$ un protocole pour S nécessitant $D(S)$ bits de communication. Si on simule $\mathcal{P}$ sur des données non corrélées jusqu'à ce que $D(S)$ bits aient été communiqués, la fonction calculée est la suivante :

$$f(x,y) = \begin{cases} x \text{ si } (x,y) \in S \\ \text{n'importe quoi sinon} \end{cases}$$

Si on n'exige pas qu'Alice apprenne la valeur de f, tous les résultats obtenus en résolvant simultanément plusieurs exemplaires de S (ou plusieurs problèmes différents) sont également valides pour f. Le problème est que f, malgré le fait que son domaine soit $X \times Y$, n'est pas une «fonction» mais plutôt une relation. Une autre particularité de f est que si $D(S) < n$ [4], alors Bob est condamné à ne pas savoir avec certitude si la sortie qu'il a obtenue est x. S'il pouvait différencier x de la sortie «n'importe quoi», il pourrait vérifier l'égalité de deux chaînes avec certitude avec moins de n bits de communication, ce qui est impossible (démontré par Yao [54]).

Lorsqu'un seul exemplaire d'un problème est résolu, il est possible de remplacer la partie «n'importe quoi sinon» par quelque chose de plus tangible et d'obtenir une vraie fonction. Par exemple, pour le problème original de la ligue sportive, «n'importe quoi sinon» pourrait être remplacé par «y tel que $y \in \{y_1, y_2\}$ et le i-ième bit de y est égal au i-ième bit de x, i étant la première position pour laquelle y_1 et y_2 diffèrent». Malheureusement, cette astuce ne fonctionne pas si nous voulons résoudre simultanément plusieurs exemplaires d'un problème

[4] Nous supposons que $X \subseteq \{0,1\}^n$.

à l'aide des fonctions de hachage utilisées précédemment.

Conjecture 2.23. $\overline{D}(S) \geq D(S) - O(\log n)$.

Il n'est pas difficile de voir que les lemmes 2.12 et 2.14 ne permettent pas de sauver plus de $\log n$ bits de communication par exemplaire, économie qui peut être atteinte pour le problème de la ligue sportive (voir la fin de la section 1.4). De plus, comme ces lemmes sont assez astucieux, ils laissent présager qu'il n'est pas possible de faire mieux. Il semble donc qu'il faille travailler sur une borne supérieure pour le nombre de bits qui peuvent être sauvés lorsque plusieurs exemplaires d'un problème avec données corrélées sont résolus simultanément. Dans le cas des fonctions, Feder, Kushilevitz, Naor et Nisan [16] ont montré que $D(f) \geq \overline{D}(f) \geq \sqrt{D(f)/2} - \log n - O(1)$. Malheureusement, leur preuve utilise la complexité de la communication non déterministe et ne peut pas être généralisée aux relations ou aux problèmes avec données corrélées.

Conjecture 2.24 (Mercier 2002). La différence entre la complexité de la communication lorsqu'Alice ne connaît pas la chaîne de Bob et la complexité de la communication lorsqu'elle la connaît est dans $O(\log n)$ bits.

Cette nouvelle conjecture est équivalente à la conjecture 2.23 par le corollaire 2.21, mais elle est toutefois plus naturelle et est selon nous une autre façon d'attaquer la problème de la somme directe qui mérite d'être étudiée.

Chapitre 3

Complexité probabiliste

Dans ce chapitre, nous analysons la complexité de la communication probabiliste de données corrélées. Dans ce modèle, Alice et Bob sont autorisés à «tirer à pile ou face» et à considérer le résultat des tirages pour décider des messages à envoyer. Cela implique que les bits de communication ainsi que la réponse de Bob ne sont plus fixés par l'entrée (x, y), mais deviennent plutôt des variables aléatoires.

Le complexité de la communication probabiliste de problèmes avec données corrélées n'a jamais été systématiquement étudiée auparavant, et c'est ce que nous faisons dans ce chapitre. Nous avons obtenu plusieurs nouveaux résultats, dont certains contrastent avec le modèle original de Yao. En plus de classifier presque entièrement le modèle probabiliste, notre contribution la plus intéressante est la démonstration que pour plusieurs classes de problèmes, les modèles probabiliste et déterministe sont équivalents du point de vue de la communication. Nous émettons la conjecture que cette propriété est également valide pour tous les problèmes avec données corrélées et montrons qu'elle permet de résoudre le

problème de la somme directe.

3.1 Générateurs aléatoires privés - définitions

Dans le modèle probabiliste de communication de données corrélées, Alice possède une chaîne $x \in X$ et Bob possède une chaîne $y \in Y$ avec la restriction que $(x, y) \in S$, et encore une fois le but est que Bob apprenne la valeur de x. La différence avec le modèle déterministe est qu'Alice et Bob possèdent respectivement des chaînes aléatoires indépendantes finies c_A et c_B de longueur arbitraire. Toute combinaison de $(x, y) \in R$, c_A et c_B détermine une feuille de l'arbre du protocole. Il est donc possible que pour une entrée (x, y), le protocole retourne des valeurs différentes pour différentes valeurs de c_A et c_B. La notation que nous utilisons est similaire à celle utilisée par Kushilevitz et Nisan [27].

Définition 3.1. Soient $f : X \times Y \to \{0, 1\}$ une fonction et $\mathcal{P}$ un protocole probabiliste pour lequel Alice possède une chaîne aléatoire c_A et Bob une chaîne aléatoire c_B.

- $\mathcal{P}$ calcule une fonction f *sans erreur* si, pour toute paire (x, y),

$$\Pr[\mathcal{P}(x, y) = f(x, y)] = 1.$$

- $\mathcal{P}$ calcule une fonction f avec *erreur* ϵ si, pour toute paire (x, y),

$$\Pr[\mathcal{P}(x, y) = f(x, y)] \geq 1 - \epsilon.$$

- $\mathcal{P}$ calcule une fonction f avec *erreur unilatérale*[1] ϵ si, pour toute paire

[1] «One-sided error» en anglais.

(x, y) telle que $f(x, y) = 0$,

$$\Pr[\mathcal{P}(x, y) = 0] = 1,$$

et pour toute paire (x, y) telle que $f(x, y) = 1$,

$$\Pr[\mathcal{P}(x, y) = 1] \geq 1 - \epsilon.$$

Il est important de remarquer que toutes les probabilités de la définition 3.1 sont distribuées sur les choix aléatoires de c_A et c_B et non sur les entrées x et y. Nous analysons cette dernière variante à la section 3.6.

Définition 3.2. La *communication en pire cas* d'un protocole probabiliste $\mathcal{P}$ sur l'entrée (x, y) est le nombre maximal de bits communiqués pour n'importe quel choix des chaînes aléatoires c_A et c_B. Le *coût en pire cas* de $\mathcal{P}$ est le maximum, pour toutes les entrées (x, y), de la communication en pire cas de $\mathcal{P}$ sur (x, y).

Définition 3.3. La *communication moyenne* d'un protocole probabiliste $\mathcal{P}$ sur l'entrée (x, y) est le nombre espéré de bits communiqués pour tous les choix des chaînes aléatoires c_A et c_B. Le *coût moyen* de $\mathcal{P}$ est le maximum, pour toutes les entrées (x, y), de la communication moyenne de $\mathcal{P}$ sur (x, y).

Définition 3.4. Soit $f : X \times Y \to \{0, 1\}$ une fonction.

- La *complexité de la communication probabiliste sans erreur* de f, notée $R_0(f)$, est le coût moyen minimal d'un protocole probabiliste qui calcule f sans erreur[2].
- La *complexité de la communication probabiliste avec erreur* ϵ de f, notée

[2]La lettre R est utilisée pour «randomized communication complexity».

$R_\epsilon(f)$, est le coût en pire cas minimal d'un protocole probabiliste qui calcule f avec erreur ϵ, pour $0 < \epsilon < 1/2$.

- La *complexité de la communication probabiliste avec erreur unilatérale* ϵ de f, notée $R_{\epsilon,uni}(f)$, est le coût en pire cas minimal d'un protocole probabiliste qui calcule f avec erreur unilatérale ϵ, pour $0 < \epsilon < 1$.
- Nous écrivons $R_0^k(f)$, $R_\epsilon^k(f)$ et $R_{\epsilon,uni}^k(f)$ lorsque le nombre de rondes est limité à k.

Définition 3.5. Soit S un problème avec données corrélées.

- La *complexité de la communication probabiliste sans erreur* de S, notée $R_0(S)$, est le coût moyen minimal d'un protocole probabiliste qui calcule S sans erreur.
- La *complexité de la communication probabiliste avec erreur* ϵ de S, notée $R_\epsilon(S)$, est le coût en pire cas minimal d'un protocole probabiliste qui calcule S avec erreur ϵ, pour $0 < \epsilon < 1/2$.
- Nous écrivons $R_0^k(S)$ et $R_\epsilon^k(S)$ lorsque le nombre de rondes est limité à k.

$R_\epsilon(S)$ est donc le nombre de bits transmis en pire cas par le meilleur protocole qui, pour toute paire $(x, y) \in R$, permet à Bob d'apprendre la chaîne d'Alice avec probabilité au moins $1 - \epsilon$.

Nous utilisons le coût en pire cas pour les protocoles avec erreur, car cette mesure est généralement plus intéressante à utiliser. De plus, pour ces protocoles, la complexité de la communication en pire cas est à un facteur multiplicatif près de la complexité de la communication moyenne. Par contre, pour les protocoles probabilistes sans erreur, la complexité de la communication en pire cas est égale à la complexité de la communication déterministe, car un protocole déterministe est simplement un protocole pour lequel les chaînes c_A et c_B ont été fixées initia-

lement. Pour les protocoles probabilistes sans erreur, le seul cas intéressant est donc la complexité de la communication moyenne.

3.2 Générateurs aléatoires privés - résultats

Dans cette section, nous présentons plusieurs résultats pour la complexité probabiliste de problèmes de communication avec données corrélées. Commençons par une borne supérieure triviale.

Lemme 3.6 (Mercier 2002).

$$R_\epsilon(S) \leq D(S).$$

Démonstration. Soit $\mathcal{P}$ un protocole déterministe pour S nécessitant $D(S)$ bits de communication. $\mathcal{P}$ peut être considéré comme un protocole probabiliste pour lequel Alice et Bob ne tiennent pas compte des chaînes aléatoires c_A et c_B. □

Essayons maintenant d'obtenir des bornes inférieures intéressantes pour la complexité de la communication probabiliste. Le lemme 3.7 démontre que pour tout problème avec données corrélées, la différence entre la complexité de la communication probabiliste et la complexité de la communication déterministe non interactive est au plus exponentielle.

Lemme 3.7 (Mercier 2002). *Pour tout problème avec données corrélées S,*

$$R_\epsilon(S) \in \Omega(\log D^1(S) - c(\epsilon)),$$

où $c(\epsilon)$ dépend uniquement de ϵ.

Démonstration. Le lemme 3.8 de Kushilevitz et Nisan [27] affirme que pour toute fonction booléenne $f : X \times Y \to \{0, 1\}$,

$$D(f) \leq 2^{R_\epsilon(f)} \left(\log \left(\frac{1}{2} - \epsilon \right)^{-1} + R_\epsilon(f) \right).$$

Sans démontrer ce résultat formellement, mentionnons que l'idée est, étant donné un protocole probabiliste nécessitant $R_\epsilon(f)$ bits de communication, de construire un protocole déterministe dont la complexité est $2^{R_\epsilon(f)} \left(\log \left(\frac{1}{2} - \epsilon \right)^{-1} + R_\epsilon(f) \right)$. Une analyse détaillée de la preuve nous permet de voir qu'elle s'applique aux problèmes avec données corrélées et que le protocole déterministe obtenu est non interactif. Nous obtenons donc :

$$\begin{aligned}
D^1(S) &\leq 2^{R_\epsilon(S)} \left(\log \left(\frac{1}{2} - \epsilon \right)^{-1} + R_\epsilon(S) \right) \\
R_\epsilon(S) &\geq \log D^1(S) - \log \left(\log \left(\frac{1}{2} - \epsilon \right)^{-1} + R_\epsilon(S) \right) \\
R_\epsilon(S) &\geq \log D^1(S) - \log R_\epsilon(S) - c_1(\epsilon) \\
2R_\epsilon(S) &\geq \log D^1(S) - c_1(\epsilon) \\
R_\epsilon(S) &\geq \frac{1}{2} \log D^1(S) - c(\epsilon).
\end{aligned}$$

□

Revenons au problème de la ligue sportive défini à la section 1.3, pour lequel $D(S) = \lceil \log n \rceil + 1$ et $D^1(S) = n$. D'après les lemmes 3.6 et 3.7, nous pouvons conclure que $R_\epsilon(S) \in \Theta(\log n)$ pour toute constante ϵ telle que $0 < \epsilon < \frac{1}{2}$, et donc que les modèles déterministe et probabiliste sont équivalents du point de vue de la communication.

Corollaire 3.8. *Lorsque la différence entre $D^1(S)$ et $D(S)$ est exponentielle, les modèles déterministe et probabiliste sont équivalents du point de vue de la communication, autrement dit $\Theta(D(S)) = \Theta(R_\epsilon(S))$.*

Il est intéressant de noter que les lemmes 3.6 et 3.7 entraînent que $\frac{1}{2} \log D^1(S) - c(\epsilon) \leq R_\epsilon(S) \leq D(S)$, ce qui démontre, comme nous l'avons déjà vu au lemme 1.23, que la différence entre $D^1(S)$ et $D(S)$ est au plus exponentielle.

Pour les problèmes dont la différence entre la complexité déterministe interactive et non interactive est petite, le lemme 3.7 n'exclut pas la possibilité qu'un algorithme permettant de réduire sensiblement la communication puisse exister. Afin d'obtenir une meilleure borne inférieure pour ces problèmes, nous utilisons le fait que Bob doit apprendre la chaîne d'Alice et non pas uniquement calculer une fonction.

Lemme 3.9 (Mercier 2002). *Pour tout problème de communication avec données corrélées S,*

$$R_\epsilon(S) \geq \lceil \log \widehat{a_B} \rceil.$$

Démonstration. Supposons que $R_\epsilon(S) \leq \lceil \log \widehat{a_B} \rceil - 1$. Par définition, il existe un protocole $\mathcal{P}$ pour S nécessitant au plus $\lceil \log \widehat{a_B} \rceil - 1$ bits de communication et tel que pour toute paire $(x, y) \in S$, la probabilité que Bob n'obtienne pas la valeur de x est au plus ϵ.

Soit y une chaîne telle que $|a_B(y)| = \widehat{a_B}$. Comme $\mathcal{P}$ requiert au plus $\lceil \log \widehat{a_B} \rceil - 1$ bits de communication, cela veut dire qu'il existe deux chaînes $x_1, x_2 \in a_B(y)$, $x_1 \neq x_2$, pour lesquelles la communication entre Alice et Bob est la même. Il suit que peu importe la stratégie de Bob, il existe une chaîne $x_i \in \{x_1, x_2\}$ pour laquelle la probabilité d'erreur de $\mathcal{P}$ sur l'entrée (x_i, y) est au moins $\frac{1}{2}$, ce qui est une contradiction. □

Nous pouvons remarquer que la borne inférieure du lemme 3.9 correspond à la complexité déterministe amortie (voir le corollaire 2.20), ou encore à la complexité lorsqu'Alice connaît la chaîne de Bob (voir le lemme 1.18). Une autre constatation est que cette borne est très mauvaise pour les problèmes pour lesquels la différence entre la complexité de la communication déterministe interactive et non interactive est grande. Prenons par exemple le problème de la ligue sportive, pour lequel $\widehat{a_B} = 2$. La borne du lemme 3.9 ne donne pas mieux que $R_\epsilon(S) \geq 1$, ce qui est loin de la borne obtenue par le lemme 3.7. Par contre, pour une classe de problèmes avec une petite différence entre $D^1(S)$ et $D(S)$, nous verrons à la section 4.3 que la borne donnée par le lemme 3.9 peut être atteinte, et qu'encore une fois les modèles déterministe et probabiliste sont équivalents.

Le prochain théorème résume les résultats démontrés depuis le début de cette section.

Théorème 3.10 (Mercier 2002). *Pour tout problème de communication avec données corrélées S,*

$$\max\left(\lceil \log \widehat{a_B} \rceil, \frac{1}{2} \log D^1(S) - c(\epsilon)\right) \leq R_\epsilon(S) \leq D(S).$$

Démonstration. Découle directement des lemmes 3.6, 3.7 et 3.9. □

Bien que le modèle probabiliste ne semble pas permettre de diminuer le nombre de bits de communication (du moins c'est ce que nous pensons), il permet par contre d'obtenir des protocoles non interactifs efficaces. Le théorème 3.11 permet d'obtenir une borne supérieure pour la complexité de la communication probabiliste non interactive.

Théorème 3.11. *Pour tout problème de communication avec données corrélées S,*

$$R^1_\epsilon(S) \leq 4D(S) + \left\lceil 2 \log \frac{1}{\epsilon} \right\rceil .$$

Démonstration. Nous pensons avoir une preuve très élégante du résultat, mais comme elle contient une petite faille que nous n'avons pas encore réussi à corriger, nous ne pouvons malheureusement pas l'inclure ici. Voir [35] pour la démonstration originale.

□

3.3 Générateur aléatoire public - définitions

Pour le modèle probabiliste que nous avons considéré jusqu'à maintenant, Alice et Bob ont chacun leur pièce de monnaie. Bob ne peut pas voir les résultats des tirages d'Alice, et vice-versa. Dans cette section, nous supposons qu'Alice et Bob ont accès à une pièce de monnaie «publique». Ce modèle est appelé modèle probabiliste avec générateur aléatoire public, ou plus simplement *modèle probabiliste public*. Formellement, Alice et Bob possèdent une chaîne aléatoire commune c obéissant à une distribution de probabilité Π. Les bits de communication envoyés par Alice dépendent de x et de c, tandis que ceux de Bob dépendent de y et de c.

Un protocole probabiliste avec générateur aléatoire public peut également être vu comme une distribution $\{\mathcal{P}_c\}_{c\in\Pi}$ de protocoles déterministes. Alice et Bob choisissent conjointement une chaîne c indépendamment de l'entrée (x, y) et exécutent ensuite le protocole déterministe $\mathcal{P}_c$. La probabilité de succès d'un tel protocole sur l'entrée $(x, y) \in S$ est la probabilité de choisir un protocole déterministe, selon la distribution de probabilité Π, qui calcule S correctement.

Définition 3.12. Soit $f : X \times Y \to \{0, 1\}$ une fonction. La *complexité de la communication probabiliste publique avec erreur* ϵ de f, notée $R_{\epsilon,pub}(f)$, est le coût minimal d'un protocole avec générateur aléatoire public qui calcule f avec une probabilité d'erreur bornée par ϵ pour toute paire (x, y). Nous écrivons $R^k_{\epsilon,pub}(f)$ lorsque le nombre de rondes est borné par k.

Définition 3.13. Soit S un problème avec données corrélées. La *complexité de la communication probabiliste publique avec erreur* ϵ de S, notée $R_{\epsilon,pub}(S)$, est le coût minimal d'un protocole avec générateur aléatoire public qui permet à Bob d'apprendre la chaîne d'Alice avec une probabilité d'erreur bornée par ϵ pour toute paire $(x, y) \in S$. Nous écrivons $R^k_{\epsilon,pub}(S)$ lorsque le nombre de rondes est borné par k.

3.4 Générateur aléatoire public - résultats

Regardons tout d'abord comment un générateur aléatoire public peut nous aider à résoudre le problème de la ligue sportive. Alice choisit un sous-ensemble aléatoire des bits de l'équipe gagnante et envoie le $\oplus$ de ces bits à Bob, ce qui nécessite un bit de communication. Bob calcule ensuite le $\oplus$ équivalent pour chacune des deux équipes finalistes. Il n'est pas difficile de voir que la probabilité de

distinguer deux chaînes différentes à l'aide de cette méthode est $\frac{1}{2}$. Donc, si Alice et Bob exécutent ce processus k fois, la probabilité de ne pas pouvoir éliminer l'équipe perdante devient $\frac{1}{2^k}$. Appelons Z la variable aléatoire représentant le nombre d'équipes qui ne sont pas éliminées après k itérations. Comme l'équipe gagnante n'est jamais éliminée, nous obtenons que $E[Z] = 1 + \frac{1}{2^k}$. En supposant que Bob choisisse au hasard si l'équipe perdante n'est pas éliminée après k itérations, la probabilité qu'il apprenne correctement l'identité de l'équipe gagnante est

$$\begin{aligned}
\Pr[\text{succès}] &= E\left[\frac{1}{\text{nombre d'équipes qui ne sont pas éliminées}}\right] \\
&= E\left[\frac{1}{Z}\right] \\
&\geq \frac{1}{E[Z]} \text{ par l'inégalité de Jensen (voir l'annexe A.4)} \\
&\geq \frac{1}{1+\frac{1}{2^k}}.
\end{aligned}$$

En posant $k = \lceil \log(\frac{1}{\epsilon} - 1) \rceil$, nous obtenons

$$\begin{aligned}
\Pr[\text{succès}] &\geq \frac{1}{1+\frac{1}{2^{\left\lceil \log(\frac{1-\epsilon}{\epsilon}) \right\rceil}}} \\
&\geq \frac{1}{1+\frac{1}{\frac{1-\epsilon}{\epsilon}}} \\
&= \frac{1}{1+\frac{\epsilon}{1-\epsilon}} \\
&= 1-\epsilon,
\end{aligned}$$

ce qui nous permet de conclure que

$$\begin{aligned} R^1_{\epsilon,pub}(S) &\leq k \\ &= \left\lceil \log\left(\frac{1}{\epsilon} - 1\right)\right\rceil. \end{aligned}$$

Nous avons vu à la section précédente que le problème de la ligue sportive requiert $\Theta(\log n)$ bits de communication dans le modèle avec générateurs privés pour toute constante ϵ telle que $0 < \epsilon < \frac{1}{2}$. Comme $R^1_{\epsilon,pub}(S) \in \Theta(1)$, nous pouvons affirmer que le modèle probabiliste public peut être meilleur que le modèle probabiliste privé.

Remarque 3.14. Il est possible d'obtenir $R^1_{\epsilon,pub}(S) \leq \left\lceil \log \frac{1}{\epsilon} \right\rceil - 1$ pour le problème de la ligue sportive en calculant la probabilité de succès de façon exacte plutôt que de la minorer à l'aide de l'inégalité de Jensen. Malheureusement, cela ne permet pas d'économiser plus d'un bit de communication.

Le théorème 3.15 montre que tout protocole probabiliste public peut être transformé en protocole probabiliste privé dont la probabilité d'erreur est un peu plus grande et qui communique un peu plus de bits. Notre résultat s'inspire d'un théorème similaire pour les fonctions booléennes qui a été démontré par Newman [34].

Théorème 3.15 (Mercier 2002). *Soit $S \subseteq X \times Y$ un problème avec données corrélées pour lequel $X = \{0,1\}^n$. Pour tout $\delta > 0$ et pour tout $\epsilon > 0$,*

$$R_{\epsilon+\delta}(S) \leq R_{\epsilon,pub}(S) + O\left(\log \frac{1}{\delta} + \log(n + \log \widehat{a_A})\right).$$

Démonstration. Soit $\mathcal{P}$ un protocole probabiliste public pour S dont l'erreur est bornée par ϵ et nécessitant $R_\epsilon^{pub}(S)$ bits de communication. Nous supposons que le générateur aléatoire obéit à une distribution de probabilité μ. Considérons $Z(x, y, c)$, une variable aléatoire égale à 1 si la réponse donnée par Bob suite à l'exécution de $\mathcal{P}$ sur l'entrée (x, y) avec la chaîne aléatoire c est mauvaise (différente de x) et égale à 0 sinon. Comme $\mathcal{P}$ résout S avec erreur au plus ϵ, il suit que $\underset{c\in\mu}{E}[Z(x, y, c)] \leq \epsilon$ pour toute paire $(x, y) \in S$.

Construisons un nouveau protocole qui utilise moins de bits aléatoires. Soient t un paramètre à être fixé plus tard et $c_1, c_2, \ldots, c_t$ des chaînes binaires. Définissons le protocole $\mathcal{P}_{c_1,c_2,\ldots,c_t}$ suivant : Alice et Bob choisissent un i au hasard entre 1 et t et exécutent le protocole $\mathcal{P}$ avec la chaîne c_i comme chaîne aléatoire commune. Montrons qu'il existe des chaînes $c_1, c_2, \ldots, c_t$ telles que $\underset{i}{E}[Z(x, y, c_i)] \leq \epsilon + \delta$ pour toute paire $(x, y) \in S$. Choisissons les t chaînes $c_1, c_2, \ldots, c_t$ au hasard selon la distribution de probabilité μ. Considérons une paire $(x, y) \in S$ arbitraire, et calculons la probabilité que $\underset{i}{E}[Z(x, y, c_i)] > \epsilon + \delta$ (où i est uniformément distribué). Ceci est exactement la probabilité que $\frac{1}{t}\sum_{i=1}^{t} Z(x, y, c_i) > \epsilon + \delta$. Comme $\underset{c\in\mu}{E}[Z(x, y, c)] \leq \epsilon$, nous obtenons par l'inégalité de Chernoff (voir l'annexe A.4) que

$$\Pr_{c_1,\ldots,c_t}\left[\frac{1}{t}\sum_{i=1}^{t} Z(x, y, c_i) - \epsilon > \delta\right] \leq 2e^{-2\delta^2 t}.$$

En choisissant $t = \frac{1}{\delta^2}\left((n + 1)\ln 2 + \ln \widehat{a_A}\right)$, nous obtenons :

$$\begin{aligned} 2e^{-2\delta^2 t} &\leq 2e^{-2(n+1)\ln 2 - 2\ln \widehat{a_A}} \\ &\leq 2 \cdot 2^{-2(n+1)} \cdot \widehat{a_A}^{-2} \\ &< \frac{2^{-n}}{\widehat{a_A}}. \end{aligned}$$

Donc, pour un choix aléatoire de $c_1, \ldots, c_t$, la probabilité qu'il existe au moins une paire $(x, y) \in S$ (il y a au plus $2^n \cdot \widehat{a_A}$ telles paires) telle que $\underset{i}{E}[Z(x, y, c_i)] > \epsilon + \delta$ est plus petite que $2^n \cdot \widehat{a_A} \cdot \frac{2^{-n}}{\widehat{a_A}} = 1$. Par conséquent, il existe un choix de $c_1, \ldots, c_t$ tel que pour toute paire $(x, y) \in S$, l'erreur du protocole $\mathcal{P}_{c_1,c_2,\ldots,c_t}$ est au plus $\epsilon + \delta$.

Le nombre de bits aléatoires utilisés par $\mathcal{P}_{c_1,c_2,\ldots,c_t}$ est $\lceil \log t \rceil$. Autrement dit, pour transformer le protocole public $\mathcal{P}_{c_1,c_2,\ldots,c_t}$ en protocole privé, Alice n'a qu'à choisir un i au hasard entre 1 et t et à l'envoyer à Bob, ce qui nécessite $\lceil \log t \rceil$ bits de communication. Nous obtenons donc :

$$\begin{aligned} R_{\epsilon+\delta}(S) &\leq R_{\epsilon,pub}(S) + \lceil \log t \rceil \\ &= R_{\epsilon,pub}(S) + \left\lceil \log \left(\frac{1}{\delta^2} \left((n+1) \ln 2 + \ln \widehat{a_A} \right) \right) \right\rceil \\ &\leq R_{pub,\epsilon}(S) + O\left(\log \frac{1}{\delta} + \log(n + \log \widehat{a_A}) \right). \end{aligned}$$

□

Corollaire 3.16 (Mercier 2002). *Soit $S \subseteq \{0,1\}^n \times \{0,1\}^n$ un problème de communication avec données corrélées. Pour tout $\delta > 0$ et pour tout $\epsilon > 0$,*

$$R_{\epsilon+\delta}(S) \leq R_{\epsilon,pub}(S) + O\left(\log \frac{1}{\delta} + \log n \right).$$

Démonstration. Comme $Y = \{0,1\}^n$, il suit $\widehat{a_A} \leq 2^n$. En appliquant le théorème 3.15, nous obtenons

$$\begin{aligned} R_{\epsilon+\delta}(S) &\leq R_{\epsilon,pub}(S) + O\left(\log\frac{1}{\delta} + \log(n + \log 2^n)\right) \\ &\leq R_{\epsilon,pub}(S) + O\left(\log\frac{1}{\delta} + \log n\right). \end{aligned}$$

□

Le corollaire 3.16 signifie que lorsque $S \subseteq \{0,1\}^n \times \{0,1\}^n$ (ou lorsque $\widehat{a_A} \in O(2^n)$), la différence entre la complexité probabiliste privée et la complexité probabiliste publique est au plus un terme additif dans $O(\log n)$ bits.

Essayons maintenant de borner la complexité probabiliste publique comme nous l'avons fait à la section précédente pour la complexité probabiliste privée. Le lemme 3.17 nous donne une borne supérieure triviale que nous améliorons ensuite avec le lemme 3.18.

Lemme 3.17 (Mercier 2002).

$$R_{\epsilon,pub}(S) \leq R_\epsilon(S).$$

Démonstration. Un protocole avec générateurs aléatoires privés peut être simulé par un protocole public dont la chaîne aléatoire commune c est la concaténation de c_A et c_B. □

Lemme 3.18 (Mercier 2002). *Pour tout problème de communication non trivial avec données corrélées S,*

$$R^1_{\epsilon,pub}(S) \leq \lceil \log(\widehat{a_B} - 1) \rceil + \left\lceil \log\frac{1-\epsilon}{\epsilon} \right\rceil.$$

Démonstration. Nous utilisons un argument similaire à celui utilisé pour résoudre le problème de la ligue sportive. Rappelons qu'Alice possède une chaîne x et que Bob possède une chaîne y définissant $a_B(y) = \{x_1, \ldots, x_l\} = \{x \mid (x, y) \in S\}$. Alice choisit k sous-ensembles aléatoires de bits de sa chaîne x et, pour chacun de ces sous-ensembles, envoie le $\oplus$ des bits à Bob. Celui-ci calcule les k $\oplus$ équivalents pour chacune des chaînes x_i de $a_B(y)$. Chaque fois que le $\oplus$ d'un sous-ensemble des bits d'un x_i diffère du résultat correspondant envoyé par Alice, Bob déduit que $x_i \neq x$ et élimine ce sommet. Lorsque Bob a terminé les comparaisons, il tire au hasard une chaîne parmi celles qui n'ont pas été éliminées et conclut que c'est la chaîne d'Alice.

La probabilité de ne pas éliminer un sommet x_i est 1 si $x_1 = x$ et $\frac{1}{2^k}$ sinon. Appelons Z la variable aléatoire représentant le nombre de chaînes qui ne sont pas éliminées après k itérations. Comme il y a $|a_B(y)| - 1$ chaînes à éliminer, il suit que $E(Z) = 1 + \frac{1}{2^k}(|a_B(y)| - 1) \leq 1 + \frac{1}{2^k}(\widehat{a_B} - 1)$. La probabilité que Bob apprenne correctement la chaîne d'Alice est donc

$$\begin{aligned}
\Pr[\text{succès}] &= E\left[\frac{1}{\text{nombre de chaînes qui ne sont pas éliminées}}\right] \\
&= E\left[\frac{1}{Z}\right] \\
&\geq \frac{1}{E[Z]} \text{ par l'inégalité de Jensen (voir l'annexe A.4)} \\
&\geq \frac{1}{1 + \frac{1}{2^k}(\widehat{a_B} - 1)}.
\end{aligned}$$

En posant $k = \lceil \log(\widehat{a_B} - 1) \rceil + \left\lceil \log \frac{1-\epsilon}{\epsilon} \right\rceil$, nous obtenons

$$\begin{aligned}
\Pr[\text{succès}] &\geq \frac{1}{1 + \frac{1}{2^{\lceil \log(\widehat{a_B}-1)\rceil + \left\lceil \log \frac{1-\epsilon}{\epsilon} \right\rceil}} \cdot (\widehat{a_B} - 1)} \\
&\geq \frac{1}{1 + \frac{1}{\frac{1-\epsilon}{\epsilon}}} \\
&= \frac{1}{1 + \frac{\epsilon}{1-\epsilon}} \\
&= 1 - \epsilon,
\end{aligned}$$

ce qui nous permet de conclure que

$$\begin{aligned}
R^1_{\epsilon,pub}(S) &\leq k \\
&= \lceil \log(\widehat{a_B} - 1) \rceil + \left\lceil \log \frac{1-\epsilon}{\epsilon} \right\rceil .
\end{aligned}$$

□

Le prochain théorème résume les résultats démontrés depuis le début de cette section.

Théorème 3.19 (Mercier 2002). *Pour tout problème de communication non trivial avec données corrélées S,*

$$\lceil \log \widehat{a_B} \rceil \leq R^1_{\epsilon,pub}(S) \leq \lceil \log(\widehat{a_B} - 1) \rceil + \left\lceil \log \frac{1-\epsilon}{\epsilon} \right\rceil .$$

Démonstration. La borne inférieure provient du fait que le lemme 3.9 s'applique également au modèle probabiliste public, et la borne supérieure a été démontrée au lemme 3.18. □

TAB. 3.1 – Modèles équivalents pour les problèmes avec données corrélées

Complexité de la communication déterministe lorsqu'Alice connaît la chaîne de Bob
Complexité de la communication déterministe amortie
Complexité de la communication probabiliste avec générateur aléatoire public

À la lumière des résultats précédents, le théorème 3.20 et le tableau 3.1 résument les modèles équivalents pour les problèmes de communication avec données corrélées.

Théorème 3.20. *Pour tout problème de communication avec données corrélées S,*

$$\Theta(\overline{D}(S)) = \Theta(D_{x|y}(S)) = \Theta(R_{\epsilon,pub}(S)).$$

Plus précisément,

$$\begin{aligned} D_{x|y}(S) &\leq R_{\epsilon,pub}(S) \leq D_{x|y}(S) + \left\lceil \log \frac{1-\epsilon}{\epsilon} \right\rceil ; \\ \overline{D}(S) &\leq R_{\epsilon,pub}(S) \leq \overline{D}(S) + \left\lceil \log \frac{1-\epsilon}{\epsilon} \right\rceil + 1. \end{aligned}$$

Démonstration. Il s'agit de combiner le théorème 3.19, le lemme 1.18 et le corollaire 2.20. □

La différence entre les trois modèles est que les protocoles permettant de minimiser la communication amortie nécessitent au moins deux rondes de communication et un nombre d'exemplaires à résoudre qui tend vers l'infini, tandis que pour la communication probabiliste publique et la communication lorsqu'Alice connaît la chaîne de Bob, il existe des protocoles optimaux qui peuvent être

exécutés sur un seul exemplaire et ne nécessitent qu'une ronde de communication.

3.5 L'équivalence des modèles déterministe et probabiliste permet de résoudre le problème de la somme directe

Nous n'avons pas réussi à trouver de problème avec données corrélées pour lequel il existe un algorithme probabiliste avec générateurs aléatoires privés qui est plus efficace que le meilleur des protocoles déterministes. Récapitulons : d'une part, à la section 3.2, nous avons démontré que les modèles probabiliste et déterministe sont équivalents pour les problèmes dont la différence entre la complexité déterministe interactive et non interactive est maximale. D'autre part, à la section 4.3, nous montrons que les modèles probabiliste et déterministe sont équivalents pour une classe de problèmes dont la différence entre la complexité déterministe interactive et non interactive est petite. Ces résultats nous incitent à formuler la conjecture suivante :

Conjecture 3.21 (Mercier 2002). Pour tout problème avec données corrélées, le modèle probabiliste avec générateurs aléatoires privés et le modèle déterministe sont équivalents du point de vue de la communication.

Il y a de bonnes raisons de croire que cette conjecture est difficile à démontrer. En particulier, elle permet de résoudre le problème de la somme directe pour les problèmes de communication avec données corrélées tels que $\widehat{a_A} \in O(2^n)$, ce qui inclut les problèmes ayant un support de la forme $S \subseteq \{0,1\}^n \times \{0,1\}^n$.

Théorème 3.22 (Mercier 2002). *Si les modèles déterministe et probabiliste sont équivalents du point de vue de la communication, alors la communication qui peut être économisée en résolvant simultanément plusieurs exemplaires d'un problème avec données corrélées est un terme additif dans $O(\log n)$ bits par exemplaire.*

Démonstration. Démontrons plutôt la contraposée du théorème. Supposons que $D(S) - \overline{D}(S) \in \omega(\log n)$ (sans perte de généralité, nous ne considérons pas les fonctions dans $\overline{\omega(\log n) \cup O(\log n)}$).

Par le corollaire 2.20, il suit que $D(S) - \log \widehat{a_B} \in \omega(\log n)$, ce qui est équivalent à $D(S) \in \omega(\widehat{a_B} + \log n)$. Comme $\log \widehat{a_B} \in \Theta(R_{\epsilon,pub}(S))$ par le théorème 3.19, nous obtenons que

$$D(S) \in \omega(R_{\epsilon,pub}(S) + \log n). \tag{3.1}$$

Le corollaire 3.16 entraîne que

$$R_\epsilon(S) \in O(R_{\epsilon,pub}(S) + \log n), \tag{3.2}$$

et en combinant (3.1) et (3.2), nous obtenons que $D(S) \in \omega(R_\epsilon(S))$. □

Notons que la réciproque du théorème n'est pas nécessairement vraie : il est possible que les modèles probabiliste et déterministe ne soient pas équivalents et que la communication qui puisse être économisée en résolvant simultanément plusieurs exemplaires d'un problème avec données corrélées soit quand même un terme additif dans $O(\log n)$ bits par exemplaire.

3.6 Complexité distributionnelle

Le modèle de la complexité de la communication distributionnelle, introduit par Yao [55] et traité en détails par Kushilevitz et Nisan [27], considère la distribution de probabilité de $S \subseteq X \times Y$. Cela contraste avec le modèle probabiliste, pour lequel nous avons considéré l'espace des probabilités sur les choix aléatoires effectués par Alice et Bob et considéré les entrées en pire cas. Cette section présente brièvement les résultats qu'Orlitsky [37] a obtenus sur la complexité de la communication distributionnelle de problèmes avec données corrélées.

Définition 3.23. Le support de S, noté $S_{X,Y}$, est défini de la façon suivante :

$$S_{X,Y} \stackrel{\text{déf}}{=} \{(x, y) \mid p(x, y) > 0\}.$$

La notation S est utilisée lorsqu'il n'y a pas de confusion possible.

La définition 3.23 ressemble à la définition 1.7 ; en fait, nous aurions pu définir S de cette façon dès le départ. Si nous ne l'avons pas fait, c'est que comme nous considérons la communication en pire cas pour la complexité déterministe et la complexité probabiliste, la distribution de probabilité de S n'a pas d'importance.

Définition 3.24. Soit $S \subseteq X \times Y$ un ensemble de support qui obéit à une distribution de probabilité μ. $D^k_{\epsilon,\mu}(S)$ est le coût du meilleur protocole déterministe à k rondes qui calcule S pour au moins une fraction $1 - \epsilon$ de toutes les entrées de S, pondérées par μ.

Définition 3.25. $D^k_{0,\mu}(S)$ est la communication espérée (pondérée par μ) du meilleur protocole déterministe à k rondes pour S.

Lemme 3.26.

$$H(X|Y) \leq D_{0,\mu}(S) \leq \cdots \leq D^2_{0,\mu}(S) \leq D^1_{0,\mu}(S) \leq H(X) + 1.$$

Même si $H(X|Y)$ peut être beaucoup plus petit que $H(X)$, ces bornes sont les meilleures qui puissent être exprimées en terme d'entropie de Shannon (voir l'annexe A.5). La borne supérieure est atteinte si S est un produit cartésien, et la borne inférieure est atteinte si S est uniformément distribué.

Lemme 3.27. *Si S est uniformément distribué, alors quatre rondes sont asymptotiquement optimales :*

$$D^4_{0,\mu}(S) \leq D_{0,\mu}(S) + o(D_{0,\mu}(S)).$$

Chapitre 4

Problèmes équilibrés

Depuis le début de ce mémoire, nous ne nous sommes pas préoccupés des liens entre l'ambiguité maximale d'Alice $\widehat{a_A}$ et l'ambiguité maximale de Bob $\widehat{a_B}$. Pour certains problèmes, comme par exemple le problème de la ligue sportive, la différence entre $\widehat{a_A}$ et $\widehat{a_B}$ est grande. Dans ce chapitre, nous analysons la complexité de la communication des problèmes avec données corrélées pour lesquels l'ambiguité maximale d'Alice est égale à l'ambiguité maximale de Bob. Le principal résultat est que les modèles déterministe, déterministe amorti, probabiliste avec générateurs aléatoires privés et probabiliste avec générateur aléatoire public sont équivalents.

4.1 Définitions

Définition 4.1. Un ensemble de support S est *équilibré* si et seulement si $\widehat{a_B} = \widehat{a_A}$.

Définition 4.2. Un ensemble de support *symétrique* S est un support tel que $(x, y) \in S$ si et seulement si $(y, x) \in S$.

Tous les résultats de ce chapitre s'appliquent aux ensembles de support équilibrés, et donc aux supports symétriques (car tout support symétrique est équilibré). Si nous mentionnons les problèmes de communication symétriques avec données corrélées, c'est qu'ils apparaissent de façon naturelle dans toutes les applications mentionnées au sommaire, c'est-à-dire les problèmes pour lesquels les données d'Alice et de Bob sont séparées par une certaine «distance».

- x et y sont deux chaînes binaires dont la distance de Hamming est bornée (par exemple si x a été transmis sur un canal imparfait) ;
- x et y sont des mesures de la même quantité, des entiers dont la valeur absolue de la différence est bornée ;
- x et y sont deux versions d'un fichier original à partir duquel certaines modifications ont été effectuées ;
- etc.

4.2 Résultats

Dans cette section, nous présentons les bornes pour la complexité de la communication déterministe de problèmes équilibrés avec données corrélées. Tous ces résultats ont été démontrés dans un excellent article d'Orlitsky [38]. Nous n'avons pas jugé bon d'inclure toutes les preuves, car certaines sont assez longues et apportent peu à la compréhension de ce mémoire.

Lemme 4.3. *Pour tout problème de communication avec données corrélées S,*

$$D^1(S) \leq \log \widehat{a_A} + \log \widehat{a_B} + 1.$$

Démonstration. Chaque sommet de G_S appartient à au plus $\widehat{a_A}$ hyperarêtes, et chaque hyperarête de G_S contient au plus $\widehat{a_B}$ sommets. Par conséquent, $\chi(G_S) \leq \widehat{a_A} \cdot (\widehat{a_B} - 1) + 1 \leq \widehat{a_A} \cdot \widehat{a_B}$, et

$$\begin{aligned} D^1(S) &= \lceil \log \chi(G_S) \rceil \text{ (lemme 1.19)} \\ &\leq \lceil \log \widehat{a_A} \cdot \widehat{a_B} \rceil \\ &\leq \log \widehat{a_A} + \log \widehat{a_B} + 1. \end{aligned}$$

□

Le lemme précédent nous permet de démontrer que lorsqu'un problème avec données corrélées est équilibré, la complexité de la communication déterministe non interactive est au plus deux fois plus grande que la complexité de la communication déterministe interactive. Ce résultat est encore plus impressionnant que le corollaire 1.27 et n'a évidemment aucun équivalent dans le modèle de Yao.

Corollaire 4.4. *Pour tout problème équilibré de communication avec données corrélées S,*

$$D^1(S) \leq 2D(S) + 1.$$

Démonstration.

$$\begin{aligned} D^1(S) &\leq \log \widehat{a_A} + \log \widehat{a_B} + 1 \\ &= 2 \log \widehat{a_B} + 1 \\ &\leq 2D(S) + 1. \text{ (lemme 1.17)} \end{aligned}$$

□

Orlitsky a démontré que la borne donnée par le corollaire 4.4 était pratiquement optimale.

Lemme 4.5. *Pour tout $\alpha \geq 0$, il existe un problème équilibré avec données corrélées S tel que*

$$D^1(S) \geq 2D(S) - 6 \geq \alpha.$$

Démonstration. Consulter [38]. □

Il a également démontré, en utilisant une famille de fonctions de hachage similaire à celles utilisées dans les chapitres précédents, que trois rondes de communication étaient optimales pour tout problème équilibré.

Théorème 4.6. *Pour tout problème équilibré de communication avec données corélées S,*

$$D(S) \leq D^3(S) \leq \log \widehat{a_B} + 3 \log \log \widehat{a_B} + 11.$$

Démonstration. Consulter [38]. □

Corollaire 4.7. *Pour tout ensemble de support équilibré S,*

$$D^3(S) \leq D(S) + o(D(S)).$$

Démonstration. Il s'agit d'utiliser le fait que $D(S) \geq \log \widehat{a_B}$ (lemme 1.17). □

4.3 Les modèles de communication sont équivalents

Les résultats de la section 4.2 et des trois premiers chapitres nous permettent de démontrer que pour les problèmes équilibrés avec données corrélées, tous les modèles que nous avons considérés sont équivalents du point de vue de la communication. Le tableau 4.1 et le théorème 4.8 résument ce résultat.

Théorème 4.8 (Mercier 2002). *Soit une constante $0 < \epsilon < \frac{1}{2}$. Pour tout problème équilibré de communication avec données corrélées S,*

$$\Theta(D(S)) = \Theta(\overline{D}(S)) = \Theta(D_{x|y}(S)) = \Theta(R_\epsilon(S)) = \Theta(R_{\epsilon,pub}(S)).$$

Démonstration. Nous savons que $\Theta(\overline{D}(S)) = \Theta(D_{x|y}(S)) = \Theta(R_{\epsilon,pub}(S))$ par le théorème 3.20. De plus, le lemme 4.6 et le corollaire 2.20 entraînent que $\Theta(D(S)) = \Theta(\overline{D}(S))$. Finalement, remarquons que $R_{\epsilon,pub}(S) \leq R_\epsilon(S) \leq D(S)$ par les lemmes 3.6 et 3.17. □

Le théorème 4.8 ne tient pas compte des constantes multiplicatives, qui sont en fait toutes égales à 1. Nous présentons donc un théorème plus précis.

TAB. 4.1 – Modèles équivalents pour les problèmes équilibrés avec données corrélées

Complexité de la communication déterministe
Complexité de la communication déterministe lorsqu'Alice connaît la chaîne de Bob
Complexité de la communication déterministe amortie
Complexité de la communication probabiliste avec générateurs aléatoires privés
Complexité de la communication probabiliste avec générateur aléatoire public

Théorème 4.9 (Mercier 2002). *Pour tout problème équilibré de communication avec données corrélées S,*

$$\begin{aligned} D_{x|y}(S) \leq \quad & D(S) \quad && \leq D_{x|y}(S) + o(D_{x|y}(S)), \\ D_{x|y}(S) \leq \quad & R_{\epsilon}(S) \quad && \leq D_{x|y}(S) + o(D_{x|y}(S)), \\ D_{x|y}(S) \leq \quad & R_{\epsilon,pub}(S) \quad && \leq D_{x|y}(S) + o(D_{x|y}(S)). \\ D_{x|y}(S) - 1 \leq \quad & \overline{D}(S) \quad && \leq D_{x|y}(S) + 1. \end{aligned}$$

Démonstration. La première équation peut être déduite à partir du lemme 1.17, du lemme 1.18 et du théorème 4.6 ; la deuxième équation à partir des lemmes 1.18, 3.6 et 3.9 ; la troisième équation à partir du théoreme 3.20 et du lemme 3.17 ; la quatrième équation à partir du corollaire 2.20 et du lemme 1.18. □

Remarquons que contrairement au modèle probabiliste public et au modèle lorsqu'Alice connaît la chaîne de Bob, le lemme 4.5 implique qu'il faut parfois plus d'une ronde de communication pour obtenir un protocole déterministe optimal. Cela dit, le corollaire 4.4 nous assure qu'il existe un protocole déterministe non

interactif requérant au plus deux fois le nombre de bits de communication du protocole optimal.

Pour terminer ce mémoire, il est important de mentionner que les théorèmes 4.8 et 4.9 n'affirment absolument rien sur le temps de calcul des protocoles. Il est possible qu'un problème n'admette pas d'algorithme déterministe efficace du point de vue de la communication et fonctionnant en temps polynomial, mais qu'il en possède un probabiliste.

Annexe A

Préalables mathématiques

A.1 Notation asymptotique

Lorsqu'il est nécessaire d'analyser l'efficacité d'un algorithme, il est souhaitable de déterminer mathématiquement la quantité de ressources nécessaires en fonction de la taille des exemplaires considérés. La notation asymptotique, introduite à cette fin, évalue le comportement des fonctions à la limite, c'est-à-dire pour des exemplaires assez grands. Cela permet entre autres de comparer entre elles plusieurs fonctions difficilement comparables autrement (par exemple lorsque $f(n_1) < g(n_1)$ et $f(n_2) > g(n_2)$). Bien sûr, il peut arriver que l'analyse asymptotique d'une fonction ne soit d'aucune utilité pratique sur des exemplaires de la vie de tous les jours, néanmoins dans la grande majorité des cas, un algorithme asymptotiquement supérieur à un autre le sera également en pratique. Un autre avantage indéniable de l'analyse asymptotique est qu'elle permet de simplifier grandement l'écriture de la complexité des algorithmes.

Voici les principales définitions utilisées dans ce mémoire pour faire l'analyse asymptotique d'algorithmes. Pour un traitement détaillé du sujet, consulter un ouvrage d'algorithmique, par exemple le livre de Brassard et Bratley [9].

Définition A.1. Soient $f, g : \mathbb{N} \to \mathbb{R}^+$ deux fonctions.

$$
\begin{aligned}
f(n) \in O(g(n)) &\Leftrightarrow (\exists c > 0)(\exists n_0 > 0) \mid (\forall n \geq n_0)[f(n) \leq c \cdot g(n)] \\
f(n) \in \Omega(g(n)) &\Leftrightarrow (\exists c > 0)(\exists n_0 > 0) \mid (\forall n \geq n_0)[f(n) \geq c \cdot g(n)] \\
f(n) \in \Theta(g(n)) &\Leftrightarrow f(n) \in O(g(n)) \wedge f(n) \in \Omega(g(n)) \\
f(n) \in o(g(n)) &\Leftrightarrow (\forall c > 0)(\exists n_0 > 0) \mid (\forall n \geq n_0)[f(n) \leq c \cdot g(n)] \\
f(n) \in \omega(g(n)) &\Leftrightarrow (\forall c > 0)(\exists n_0 > 0) \mid (\forall n \geq n_0)[f(n) \geq c \cdot g(n)]
\end{aligned}
$$

Remarque A.2. Tel que suggéré par Brassard [8], la notation asymptotique est définie en termes d'ensembles dans ce mémoire, ce qui est selon nous plus facile à manipuler, mais surtout beaucoup moins choquant que des égalités dont les deux membres ne peuvent pas être permutés.

A.2 Graphes et hypergraphes

Voici quelques définitions élémentaires reliées aux graphes et aux hypergraphes. Pour plus de détails, consulter un ouvrage sur la théorie des graphes, par exemple «Extremal Graph Theory» de Bollobás [7].

Définition A.3. Un *graphe* $G = (S, A)$ est une paire ordonnée formée d'un ensemble de sommets $S \neq \emptyset$ et d'un ensemble d'arêtes A. Les arêtes sont de la forme $\{s_1, s_2\}$, où $s_1 \neq s_2$ et $s_1, s_2 \in S$.

Définition A.4. Deux sommets s_1 et s_2 sont *adjacents* s'il existe une arête $a = \{s_1, s_2\} \in A$. Deux arêtes sont adjacentes si elles ont un sommet commun. Deux graphes sont *isomorphes* s'il existe une bijection entre leurs ensembles de sommets qui préserve l'adjacence.

Définition A.5. L'*ordre* d'un graphe G, noté $|G|$, est le nombre de sommets de G. La *taille* d'un graphe G, notée $a(G)$, est le nombre d'arêtes de G.

Définition A.6. $\Gamma(s)$ est l'ensemble des sommets adjacents à un sommet s et $d(s) = |\Gamma(s)|$ est le *degré* de s.

Définition A.7. Le *degré minimal* des sommets de G est noté $\delta(G)$, alors que le *degré maximal* des sommets de G est noté $\Delta(G)$. Si $\delta(G) = \Delta(G) = k$, alors G est dit *k-régulier*.

Définition A.8. Un *k-coloriage* de $G = (S, A)$ est une fonction $f : S \to \{1, 2, \ldots, k\}$ telle que $f(s_1) \neq f(s_2)$ pour toute arête $\{s_1, s_2\}$. Le *nombre chromatique* de G est $\chi(G) \stackrel{\text{déf}}{=} \min\{k \mid G \text{ est } k\text{-coloriable}\}$.

Définition A.9. Un *coloriage de deuxième ordre* de G est un coloriage propre de G avec la propriété additionnelle que les voisins de tout sommet du graphe ont des couleurs différentes. Le *nombre chromatique de deuxième ordre* de G est $\chi_2(G) \stackrel{\text{déf}}{=} \min\{k \mid G^2 \text{ est } k\text{-coloriable}\}$.

Définition A.10. Un *ensemble indépendant* d'un graphe $G = (S, A)$ est un ensemble de sommets $S' \subseteq S$ tel qu'aucune paire de sommets de S' n'est reliée par une arête de A. Notons $\alpha(G)$ le nombre maximal de sommets d'un ensemble indépendant de G.

Définition A.11. Un *hypergraphe* H est un ensemble S avec une famille Σ de sous-ensembles non vides de S. Évidemment, $s \in S$ est un sommet de H et $A \in \Sigma$ est une hyperarête de H. Autrement dit, une hyperarête de l'hypergraphe peut contenir plus de deux sommets distincts.

Définition A.12. L'*ordre* d'un hypergraphe, noté $|H|$, est le nombre de sommets de H. La *taille* d'un hypergraphe, notée $a(H)$ est le nombre d'hyperarêtes de H.

Définition A.13. Le *degré minimal* des sommets de l'hypergraphe H est noté $\delta_S(H)$, alors que le *degré maximal* des sommets de H est noté $\Delta_S(H)$. De manière analogue, $\delta_A(H)$ et $\Delta_A(H)$ sont respectivement utilisés pour les degrés minimal et maximal des hyperarêtes de H, où le degré d'une hyperarête est le nombre de sommets qu'elle contient.

Définition A.14. Un *k-coloriage* d'un hypergraphe H ayant un ensemble de sommets S est une fonction $f : S \to \{1, 2, \ldots, k\}$ telle que pour toute hyperarête $\{a_1, \ldots, a_l\}$ de l'hypergraphe, $f(a_i) \neq f(a_j)$ pour tout $1 \leq i < j \leq l$. Autrement dit pour chaque hyperarête, tous les sommets qu'elle contient sont de couleur différente. Le *nombre chromatique* de H est $\chi(H) \stackrel{\text{déf}}{=} \min\{k \mid H \text{ est } k\text{-coloriable}\}$.

A.3 Principe de Dirichlet

Voici une version améliorée du principe de Dirichlet, souvent appelé principe du pigeonnier.

Lemme A.15. *Soient des pigeons de k couleurs ainsi que s trous. Nous supposons qu'un pigeon est d'une seule couleur et que chaque trou ne peut pas contenir plus d'un pigeon de la même couleur. Si chaque trou contient au moins* $\lceil \frac{k}{2} \rceil$ *pigeons,*

alors il existe une couleur telle qu'au moins $\lceil \frac{s}{2} \rceil$ *trous contiennent des pigeons de cette couleur.*

Démonstration. Remarquons d'abord qu'il y a au moins $s\lceil \frac{k}{2} \rceil$ pigeons dans les trous. Supposons que chaque couleur est présente dans au plus $\lfloor \frac{s-1}{2} \rfloor$ trous. Cela entraîne que le nombre de pigeons dans les trous est au plus $k\lfloor \frac{s-1}{2} \rfloor < (\frac{s}{2})k \leq s\lceil \frac{k}{2} \rceil$. Contradiction. □

A.4 Probabilités

Cette section contient quelques inégalités provenant de la théorie des probabilités qui sont utiles pour ce mémoire. Consulter [32, 45] pour les preuves ainsi que pour des informations additionnelles sur le sujet.

Théorème A.16 (Inégalité de Markov). *Pour toute variable aléatoire* X *supérieure ou égale à 0 et pour tout* $\alpha > 0$,

$$\Pr[X \geq \alpha] \leq \frac{E[X]}{\alpha}.$$

L'inégalité de Markov peut également être exprimée comme

$$\Pr[X \geq \alpha \cdot E[X]] \leq \frac{1}{\alpha}.$$

Lorsque des algorithmes probabilistes sont analysés, il est essentiel de pouvoir borner la probabilité qu'une variable aléatoire X s'éloigne de son espérance $E(X)$. En fait, lorsqu'une variable aléatoire est générée plusieurs fois, cela revient à borner le vitesse de convergence de la valeur moyenne des tirages obtenus.

Théorème A.17 (Inégalité de Chernoff). *Soient $X_1, X_2, \ldots, X_n$ des variables aléatoires booléennes indépendantes pour lesquelles $\Pr[X_i = 1] = p \leq 1/2$. Pour tout δ tel que $0 < \delta \leq p(1-p)$,*

$$\Pr\left[\left|\frac{\sum_{i=1}^{n} X_i}{n} - p\right| \geq \delta\right] \leq 2e^{-\frac{\delta^2 n}{2p(1-p)}}.$$

L'inégalité de Chernoff peut être généralisée pour des variables aléatoires continues.

Théorème A.18 (Inégalité de Hoeffding). *Soient $X_1, X_2, \ldots, X_n$ des variables aléatoires indépendantes ayant la même distribution de probabilité sur l'intervalle réel $[a, b]$. Si $E[X] = p$, alors*

$$\Pr\left[\left|\frac{\sum_{i=1}^{n} X_i}{n} - p\right| \geq \delta\right] \leq 2e^{-\frac{2\delta^2 n}{b-a}}.$$

La dernière inégalité dont nous aurons besoin porte sur des espérances plutôt que des probabilités.

Théorème A.19 (Inégalité de Jensen). *Soit f une fonction convexe. Alors*

$$E[f(X)] \geq f(E[X])$$

pour autant que ces espérances existent et soient finies.

A.5 Entropie

L'entropie est une mesure de l'incertitude d'une variable aléatoire qui possède plusieurs propriétés cohérentes avec la notion intuitive d'information. Consulter

l'ouvrage de Cover et Thomas [12] pour une introduction à la théorie de l'information.

Soit X une variable aléatoire discrète avec alphabet Σ telle que $p(x) = \Pr(X = x)$, $x \in \Sigma$.

Définition A.20. L'*entropie* d'une variable aléatoire discrète X, notée $H(X)$, est définie par :

$$H(X) \stackrel{\text{déf}}{=} -\sum_{x\in\Sigma} p(x) \log p(x).$$

L'entropie est exprimée en bits, et par convention $0 \log 0 = 0$.

Soit

$$X = \begin{cases} 0 \text{ avec probabilité } p \\ 1 \text{ avec probabilité } 1-p \end{cases}$$

Alors $H(X) = -p \log p - (1-p) \log(1-p) \stackrel{\text{déf}}{=} h(p)$.

Définition A.21. Soit (X, Y) une paire de variables aléatoires avec une distribution de probabilité $p(x, y)$. L'*entropie conjointe* de (X, Y), notée $H(X, Y)$, est définie par :

$$H(X,Y) \stackrel{\text{déf}}{=} -\sum_{x\in X}\sum_{y\in Y} p(x,y) \log p(x,y).$$

Définition A.22. L'*entropie conditionnelle* de Y sachant X, notée $H(Y|X)$, est définie par :

$$\begin{aligned} H(Y|X) &\stackrel{\text{déf}}{=} \sum_{x\in X} p(x) H(Y|X=x) \\ &= -\sum_{x\in X} p(x) \sum_{y\in Y} p(y|x) \log p(y|x). \end{aligned}$$

Le théorème A.23 permet de relier les trois définitions précédentes.

Théorème A.23.

$$H(X,Y) = H(X) + H(Y|X).$$

A New Operation on Sequences: The Boustrophedon Transform

ABSTRACT

A generalization of the Seidel-Entringer-Arnold method for calculating the alternating permutation numbers (or secant-tangent numbers) leads to a new operation on sequences, the boustrophedon transform.

This paper was published (in a somewhat different form) in
J. Combinatorial Theory, Series A, 76 (1996), pp. 44-54.

Iterations of Eccentric Digraphs

Mirka Miller, School of Electrical Engineering and Computer Science, The University of Newcastle, NSW, Australia.
Joan Gimbert, Departament de Mathematica, Universitat de Lleida, Spain.
Frank Ruskey, Department of Computer Science, University of Victoria, Canada.
Joseph Ryan, Information Systems Group, Department of Management, The University of Newcastle, NSW, Australia.

Abstract:

The *eccentricity* $e(u)$ of vertex u is the maximum distance of u to any other vertex of G. A vertex v is an *eccentric vertex* of vertex u if the distance from u to v is equal to $e(u)$. The *eccentric digraph* $ED(G)$ of a digraph G is the digraph that has the same vertex set as G and the arc set defined by: there is an arc from u to v if and only if v is an eccentric vertex of u. In this paper we consider the behaviour of an iterated sequence of eccentric graphs or digraphs of a graph or a digraph. The paper concludes with several open problems.

On enumeration problems in Lie--Butcher theory. With H. Munthe-Kaas. To appear (2003) in a special issue of FGCS (Future Generation Computer Systems)

Abstract:

The algebraic structure underlying non-commutative Lie-Butcher series is the free Lie algebra over ordered trees. In this paper we present a characterization of this algebra in terms of balanced Lyndon words over a binary alphabet. This yields a systematic manner of enumerating terms in non-commutative Lie-Butcher series.

Counting Permutations by their Rigid Patterns

A. N. Myers
anmyers@math.upenn.edu
University of Pennsylvania
Philadelphia, PA 19104-6395

September 20, 2002

Abstract

In how many permutations does the *pattern* τ occur exactly m times? In most cases, the answer is unknown. When we search for *rigid patterns*, on the other hand, we obtain exact formulas for the solution, in all cases considered.

keywords: pattern, rigid pattern, permutation, block

1 Introduction

The results of this paper generalize a fun, easy counting problem suggested by Herb Wilf. We begin by introducing and solving this problem. Given a permutation of the set $[n] = \{1, 2, \ldots, n\}$, an *n-permutation*, we consider sequences of consecutive integers which appear in consecutive positions. A maximal such sequence is called a *block*. For example, the 8-permutation 12678345 contains three blocks: 12, 678, and 345. Of the six 3-permutations, one contains one block (123), two contain two blocks (312 and 231), and three contain three blocks (132, 213, and 321). Figure 1 shows the 4-permutations grouped by number of blocks.

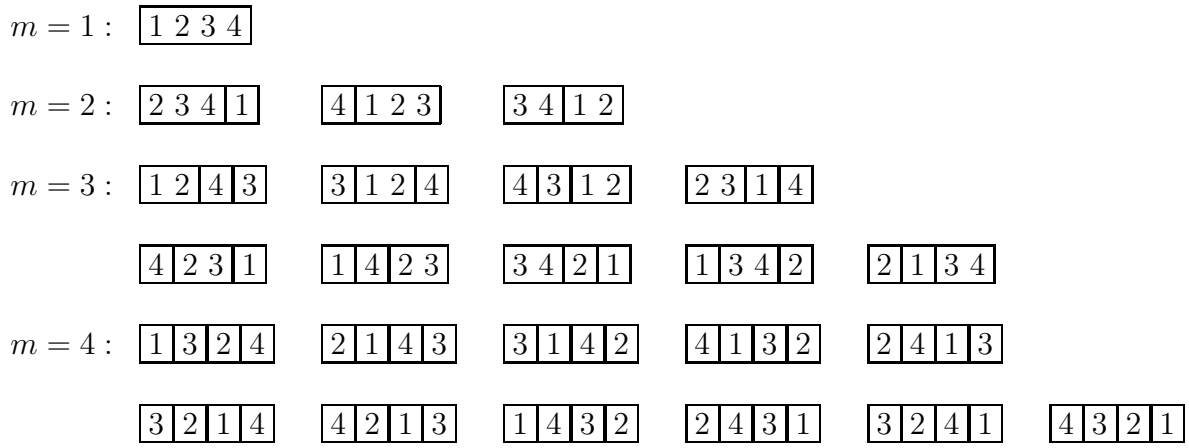

Figure 1. 4-permutations with m blocks.

Wilf posed the following question.

How many n-permutations contain exactly m blocks?

To solve this problem, we count, for each choice of m blocks, the number of n-permutations which contain exactly those blocks. To choose m blocks, we list the integers from 1 to n, and insert $m-1$ "dividers" into the $n-1$ spaces between integers. For example, the insertion of dividers, 12—345—678, yields blocks 12, 345, and 678. Each choice of $m-1$ spaces to place dividers from the set of $n-1$ possible spaces gives a distinct choice of blocks. Thus there are $\binom{n-1}{m-1}$ ways to choose the blocks.

Next we count the number of n-permutations which contain a given choice of m blocks. Suppose $n = 8$, $m = 3$, and we are given blocks $\beta_1 = 12$, $\beta_2 = 345$, and $\beta_3 = 678$. There are 3! ways to arrange three blocks, but not every arrangement yields a permutation with exactly the given blocks. For example, the arrangement $\beta_2\beta_3\beta_1$ gives the permutation 34567812. This permutation contains two blocks, 12 and 345678.

Let $F(m)$ denote the number of arrangements of m blocks which give n-permutations with exactly those blocks. Then $F(m)$ is the number of m-permutations with no two consecutive increasing integers in consecutive positions. For example, $F(3) = 3$ counts the 3-permutations 312, 213, and 321. We see that $F(m)$ is the number of m-permutations containing m blocks.

The answer to Wilf's question is given by $\binom{n-1}{m-1}F(m)$. We must determine $F(m)$. To do this, we observe every n-permutation contains m blocks for some choice of m. Thus

$$n! = \sum_m \binom{n-1}{m-1} F(m).$$

At this point we need the first of two versions of the binomial inversion formula quoted below. We include the second version of the formula for future reference.

$$a_n = \sum_k \binom{n}{k} b_k \quad (n = 0, 1, 2, \ldots) \iff b_n = \sum_k (-1)^{n-k} \binom{n}{k} a_k \quad (n = 0, 1, 2, \ldots) \tag{1}$$

and

$$a_k = \sum_n \binom{n}{k} b_n \quad (k = 0, 1, 2, \ldots) \iff b_k = \sum_n (-1)^{n-k} \binom{n}{k} a_n \quad (k = 0, 1, 2, \ldots). \tag{2}$$

The binomial inversion formula (**??**) tells us

$$F(m) = (m-1)! \sum_k (-1)^{m-k-1} \frac{k+1}{(m-k-1)!}.$$

The number of n-permutations which contain m blocks is therefore given by

$$\binom{n-1}{m-1} (m-1)! \sum_k (-1)^{m-k-1} \frac{(k+1)}{(m-k-1)!}. \tag{3}$$

We remark that the sequence $F(2), F(3), F(4), \ldots$ has been well studied. It is sequence A000255 in Sloane's On-Line Encyclopedia of Integer Sequences [**?**], and its exponential generating function is $e^{-x}/(1-x)^2$ (see Kreweras [**?**]).

So far, we have counted n-permutations with blocks that look like $i(i+1)(i+2)\cdots$. We now attempt to enumerate n-permutations with blocks having a more general form, for example, $i(i-1)(i+1)$ or $i(i-1)(i+2)$. To do so, we first generalize the notion of block.

We now define a *block* to be any sequence of values in a permutation which appear in consecutive positions. The number of values is the *length* of the block. We say a block $\beta = \beta_1\beta_2\ldots\beta_k$ has *type* $\tau = \tau_1\tau_2\ldots\tau_k$ when $\beta_i = \tau_i + c$ for all i, where c is some integer constant. In this case, we say β is a τ-*block*. For example, when $\tau = 213$, τ-blocks include 213, 324, 435, $\cdots$. When $\tau = 214$, τ-blocks include 214, 325, 436, $\cdots$.

With this new notion of block, the question of interest becomes the following.

How many n-permutations contain exactly m blocks with type τ?

This question is closely related to a big open problem in the theory of patterns of permutations. A *pattern* $\tau = \tau_1\tau_2\ldots\tau_k$ of *length* k is a fixed k-permutation. We say τ *occurs* in an n-permutation $\sigma = \sigma_1\sigma_2\ldots\sigma_n$ when there exist integers $1 \le i_1 < i_2 < \ldots < i_k \le n$ such

that $\sigma_{i_s} < \sigma_{i_t}$ if and only if $\tau_s < \tau_t$ for all $1 \le s < t \le k$. For example, the pattern $\tau = 213$ occurs exactly five times in the permutation $\sigma = 32415$ as illustrated below.

$$\underline{3}\,\underline{2}\,\underline{4}\,1\,5 \quad \underline{3}\,\underline{2}\,4\,1\,\underline{5} \quad \underline{3}\,2\,4\,\underline{1}\,\underline{5} \quad 3\,\underline{2}\,4\,\underline{1}\,\underline{5} \quad 3\,2\,\underline{4}\,\underline{1}\,\underline{5}$$

Figure 2. Five occurrences of the pattern $\tau = 213$ in the permutation $\sigma = 32415$.

A permutation σ *avoids* a pattern τ if τ does not occur in σ.

Recent results in pattern research establish partial answers to the following question.

In how many permutations does the pattern τ occur exactly m times?

When τ has length 3, and we look for permutations with $m = 0$ occurrences of the pattern τ (i.e., patterns which avoid τ), we can completely answer this question. Surprisingly, the answer does not depend on the particular pattern chosen. Schmidt and Simion [**?**] have shown that all patterns of length 3 are avoided by the same number of permutations, and this number is a Catalan number.

To obtain results for longer patterns when $m = 0$, we define an equivalence relation on patterns of length k by requiring that the numbers of permutations which avoid equivalent patterns be equal. In this sense, all patterns with length 3 are equivalent. Stankova [**?**] has shown there are three equivalence classes for patterns with length 4. In addition to the results involving equivalence classes, Bona [**?**] found the exact number of n-permutations avoiding 1342 and gave an ordinary generating function for them.

When $m > 0$ we also have a few results. Noonan and Zeilberger [**?**] found the number of permutations with exactly $m = 1$ occurrence of the pattern 132. Robertson, Wilf, and Zeilberger [**?**] found the number of n-permutations having exactly p occurrences of 123 and q occurrences of 132 in the form of a Maple program which returns the desired generating function.

Another interesting open problem concerns asymptotics for the number of n-permutations which avoid a given pattern τ. Let $f(n;\tau)$ denote the number of n-permutations which avoid τ. Stanley and Wilf have conjectured that the limit

$$\lim_{n\to\infty} f(n;\tau)^{1/n}$$

exists, is finite, and is nonzero. In all known cases, this limit is an integer.

Further results concern the maximum number of occurrences of τ in an n-permutation, and the permutations which achieve these maximums. For work on problems of this type, see [**?**], [**?**], and [**?**]. For a survey of results on patterns, see [**?**].

Counting occurrences of patterns in permutations is hard because patterns are so flexible. We have very few results for patterns of length greater than 4, and nonzero values of m. If we make the patterns more "rigid," then they are easier to count. In particular, we define a *rigid pattern* to be a sequence $\tau = \tau_1\tau_2\ldots\tau_k$ of k distinct positive integers, i.e., a block, and we say τ *occurs* in an n-permutation σ when σ contains a block with type τ. Note that all patterns are rigid patterns, but not all rigid patterns are patterns.

To illustrate the difference between patterns and rigid patterns, we note the *pattern* $\tau = 213$ occurs exactly five times in the permutation $\sigma = 32415$, as demonstrated above. The *rigid pattern* $\tau = 213$, on the other hand, occurs exactly once as the subsequence 324. Listed below are all 5-permutations in which the rigid pattern $\tau = 213$ occurs exactly one time.

$$\begin{array}{llllllllllllllllll}
\boxed{2\,1\,3}\,4\,5, & \boxed{2\,1\,3}\,5\,4, & 4\,\boxed{2\,1\,3}\,5, & 5\,\boxed{2\,1\,3}\,4, & 4\,5\,\boxed{2\,1\,3}, & 5\,4\,\boxed{2\,1\,3} \\
\boxed{3\,2\,4}\,1\,5, & \boxed{3\,2\,4}\,5\,1, & 1\,\boxed{3\,2\,4}\,5, & 5\,\boxed{3\,2\,4}\,1, & 1\,5\,\boxed{3\,2\,4}, & 5\,1\,\boxed{3\,2\,4} \\
\boxed{4\,3\,5}\,1\,2, & \boxed{4\,3\,5}\,2\,1, & 1\,\boxed{4\,3\,5}\,2, & 2\,\boxed{4\,3\,5}\,1, & 1\,2\,\boxed{4\,3\,5}, & 2\,1\,\boxed{4\,3\,5}
\end{array}$$

Figure 2. The rigid pattern $\tau = 213$ occurs exactly once in eighteen distinct 5-permutations.

In this paper, we consider the question analogous to that above for the more manageable rigid patterns.

In how many n-permutations does the rigid pattern τ occur exactly m times?

When we begin to investigate this question we notice an important difference between, for example, the rigid patterns 213 and 214. We observe that a permutation may contain overlapping blocks of type 214, but no permutation contains overlapping blocks of type 213. The 6-permutation 214365, for example, contains 214-blocks 214 and 436, which share the 4.

To account for this distinction, we say a rigid pattern τ is *nonextendible* if no permutation contains two overlapping blocks both with type τ. Otherwise τ is *extendible*.

When τ is a nonextendible rigid pattern satisfying certain conditions, we obtain the answer to our question from Theorem **??**. When the block is extendible, we can compute at least a lower bound, if not the answer itself, using Proposition **??**.

2 Nonextendible Blocks

In the previous section, we counted n-permutations with exactly m blocks by first selecting m blocks, then counting n-permutations with exactly those blocks. As a final step, we used binomial inversion to obtain a formula. To count n-permutations with exactly m occurrences of a given nonextendible rigid pattern τ, we follow a similar procedure.

We begin with the case where τ is a k-permutation. We again choose τ-blocks by inserting dividers, but now we do so more carefully. Not just any insertion of dividers will do. Consider the case $\tau = 213$. Here any three consecutive integers determine a τ-block. For example, the integers 3,4,5 determine the τ-block 435. Thus a choice of m τ-blocks corresponds to a choice of m disjoint sets of three consecutive integers each.

In how many ways can we choose m disjoint sets of three consecutive integers each from the set $[n]$? To answer this, we consider an equivalent question. In how many ways can we choose m sets of three consecutive integers each together with $n - 3m$ sets of one integer each from $[n]$ so that all sets are disjoint? Let $n = 10$ and $m = 2$. The insertion of dividers 123—456—7—8—9—10 demonstrates one such choice. We associate this particular insertion

of dividers with the composition $3+3+1+1+1+1$ of 10 with m parts size 3 and $n-3m$ parts size 1.

In this way we associate with each choice of m τ-blocks a composition of n with m parts size 3 and $n-3m$ parts size 1. Conversely, for each composition of n with m parts size 3 and $n-3m$ parts size 1, we have a choice of m τ-blocks with which the composition is associated. The number of distinct choices for m τ-blocks is therefore given by the number of distinct compositions of n with m parts size 3 and $n-3m$ parts size 1. There are $\frac{(m+(n-3m))!}{m!(n-3m)!} = \binom{m+(n-3m)}{m}$ such compositions. This observation generalizes naturally to the following.

Proposition 1 *Let τ be a nonextendible k-permutation. The number of ways to choose m disjoint τ-blocks from the set $[n]$ is given by $\binom{m+(n-km)}{m}$.*

Not all nonextendible rigid patterns are k-permutations. The rigid pattern $\tau = 1254$, for example, is nonextendible. To count the ways to choose m disjoint τ-blocks for more general nonextendible τ, we consider the *span* of τ.

The *span* of a rigid pattern $\tau = \tau_1\tau_2\ldots\tau_k$ is the block of consecutive increasing integers from $\min\{\tau_i\}$ to $\max\{\tau_i\}$. The span of 2154 is the block 12345. When disjoint τ-blocks necessarily have disjoint spans, we can choose τ-blocks by choosing their spans. Note that if τ is a permutation, then disjoint τ-blocks have disjoint spans.

Lemma 1 *Let τ be a nonextendible rigid pattern with the property that disjoint τ-blocks have disjoint spans. Suppose the span of τ has length l. The number of ways to choose m disjoint τ-blocks from the set $[n]$ is given by $\binom{m+(n-lm)}{m}$.*

Proof: We choose m disjoint τ-blocks from $[n]$ by choosing their disjoint spans. The number of ways to do this is given by the number of ways to choose m sets of l consecutive integers each together with $n-lm$ sets of one integer each from $[n]$. With each such choice we associate a composition of n with m parts size l and $n-lm$ parts size 1. The number of distinct choices for m τ-blocks is therefore given by the number of distinct compositions of n with m parts size l and $n-lm$ parts size 1. There are $\binom{m+(n-lm)}{m}$ such compositions. $\diamond$

The following theorem uses this lemma to enumerate n-permutations containing exactly m occurrences of a given nonextendible rigid pattern.

Theorem 1 *Let τ be a nonextendible rigid pattern of length k with the property that disjoint τ-blocks have disjoint spans. Suppose the span of τ has length l. Then the number of n-permutations in which τ occurs exactly m times is given by*

$$\sum_{m'}(-1)^{m-m'}\binom{m'}{m}\binom{m'+(n-lm')}{m'}[m'+(n-km')]! \tag{4}$$

Proof: We use Lemma **??** to count the number of ways to choose m disjoint τ-blocks from $[n]$. For each such choice we list the $[m+(n-km)]!$ arrangements of the m τ-blocks together with the $n-km$ blocks with length 1 not contained by any τ-block.

For example, suppose $\tau = 1254$, $n = 12$, $m = 2$, and we are given τ-blocks $\tau_1 = 1254$ and $\tau_2 = 67(10)9$. The blocks of length 1 not contained by either of these τ-blocks include $\tau_3 = 3, \tau_4 = 8, \tau_5 = (11)$, and $\tau_6 = (12)$. We list all 6! permutations of the blocks $\tau_1, \tau_2, \tau_3, \tau_4, \tau_5$, and τ_6.

In the end we obtain a list of $\binom{m+(n-lm)}{m}[m + (n - km)]!$ arrangements in total. This list includes all n-permutations with at least m τ-blocks.

Consider the case where $\tau = 1254$, $n = 12$, and $m = 1$. We list the n-permutation 125467(10)938(11)(12), with τ-blocks 1254 and 67(10)9, once when we arrange the blocks $\tau_1 = 1254$, $\tau_2 = 3, \tau_3 = 6, \tau_4 = 7, \tau_5 = 8, \tau_6 = 9, \tau_7 = (10), \tau_8 = (11)$, and $\tau_9 = (12)$, and once when $\tau_1 = 67(10)9$, $\tau_2 = 1, \tau_3 = 2, \tau_4 = 3, \tau_5 = 4, \tau_6 = 5, \tau_7 = 8, \tau_8 = (11)$, and $\tau_9 = (12)$.

Let $F_\tau^n(m)$ denote the number of n-permutations in which τ occurs exactly m times. Then $F_\tau^n(m)$ equals $\binom{m+(n-lm)}{m}[m+(n-km)]!$ take away the number of arrangements in the list in which τ occurs $m' > m$ times. There are $F_\tau^n(m')$ n-permutations in which τ occurs exactly m' times, each of which appears $\binom{m'}{m}$ times in the list above. Thus

$$F_\tau^n(m) = \binom{m + (n - lm)}{m}[m + (n - km)]! - \sum_{m'>m} \binom{m'}{m} F_\tau^n(m').$$

Now we apply a second form of the binomial inversion formula (**??**) to obtain

$$F_\tau^n(m) = \sum_{m'} (-1)^{m-m'} \binom{m'}{m} \binom{m' + (n - lm')}{m'} [m' + (n - km')]!.$$

◇

Note that application of this theorem depends on our ability to decide whether or not a given rigid pattern is extendible, and whether or not disjoint τ-blocks have disjoint spans. This is not difficult to do by inspection.

For example, suppose $\tau = 1254$. We first try to extend τ beginning with the 4. The τ-block starting with 4 is 4587. When we join the two τ-blocks by overlapping the 4's, we obtain 1254587. Since the 5 appears twice in this arrangement, we realize τ cannot be extended starting with the 4. Clearly it cannot be extended beginning with the 2 or the 5 either, and we easily conclude τ is nonextendible. It is similarly easy to determine that disjoint τ-blocks have disjoint spans.

For an example of a rigid pattern τ with the property that disjoint τ-blocks do *not* have disjoint spans, consider $\tau = 152$. In this case, 152 and 376, for example, are disjoint τ-blocks. Their spans, 12345 and 34567, on the other hand, are not disjoint.

When τ is an actual *pattern*, i.e., a k-permutation, we observe (as we would hope) that disjoint τ-blocks always have disjoint spans.

3 Extendible Blocks

If τ is a nonextendible block, then no permutation contains overlapping blocks with type τ, and it easy to count τ-blocks in a given permutation. How do we count blocks when τ

is extendible? Do the overlapping blocks 214 and 436 in the permutation 214365 count as two distinct τ-blocks, or should we count 21436 as one "extended" τ-block? Because we want to generalize the results of the introduction, we choose the latter method of counting occurrences of extendible rigid patterns.

Consider the 8-permutation $\sigma = 12678345$. With the original definition of a block as a maximal sequence of consecutive increasing integers, this permutation contains three blocks, 12, 345, and 678. To include this special case in the more general context in which we now find ourselves, we say σ contains three blocks with (extendible) type $\tau = 12$. The block 345 contains overlapping τ-blocks 34 and 45, and the block 678 contains overlapping τ-blocks 67 and 78. Thus to include the motivating problem in the current framework, we count each of the blocks 345 and 678 as one *extended* τ-block, rather than two.

When τ is an extendible rigid pattern, we count a maximal sequence of overlapping blocks with type τ as one (extended) τ-block. What do we do when τ-blocks overlap in different ways? Consider the extendible rigid pattern $\tau = 2154$. The τ-blocks $\beta = 4376$ and $\beta' = 5487$ both overlap the block τ. The blocks β and τ have one integer in common, while β' and τ have two integers in common. In fact, any pair of distinct τ-blocks have at most two integers in common. In this case, we say the block 215487, containing both τ and β', is a *proper* τ-block, and τ has *overlap length* equal to two.

In this section we enumerate n-permutations in which a given extendible rigid pattern occurs exactly m times. We say an extendible rigid pattern τ *occurs* exactly m times in a give n-permutation σ when σ contains exactly m proper blocks of type τ. To do this, we must know the possible lengths of τ-blocks and their spans. When $\tau = 2154$, for example, blocks of type τ include 2154, 215487, 215487(11)(10), $\cdots$. In this case, τ-blocks have lengths 4, 6, 8, and so on.

Lemma 2 *Suppose $\tau = \tau_1\tau_2\ldots\tau_k$ is an extendible rigid pattern with span length l. Let p denote the overlap length of τ, and set $q = \tau_{k-p+1} - \tau_1$. A proper τ-block in $[n]$ has length $k + r(k-p)$ and its span has length $l + rq$, where $0 \le r \le \lfloor \frac{n-l}{q} \rfloor$.*

Proof: Let β be a proper τ-block in $[n]$ with maximal length. The length of β is $k+r(k-p)$, where r is the greatest nonnegative integer for which the span of β has length at most n. The span of β has length $l + rq$. Thus $l + rq \le n$, which means $0 \le r \le \lfloor \frac{n-l}{q} \rfloor$. $\diamond$

When $\tau = 2154$, for example, we have $l = 5$, $p = 2$, and $q = 3$. In this case, the lemma tells us τ-blocks have lengths $4 + 2r$, where $0 \le r \le \lfloor \frac{n-5}{3} \rfloor$. In particular, when $n = 12$, τ-blocks in [12] have lengths 4, 6 and 8. Examples of such τ-blocks include 2154, 215487, and 2154(11)(10).

When τ is a nonextendible rigid pattern, each choice of m τ-blocks in $[n]$ is associated with a composition of n with m parts size l and $n - ml$ parts size 1. When τ is an extendible rigid pattern, on the other hand, the compositions associated with the various choices of m τ-blocks have parts of several sizes. As in the previous section, we consider only those τ-blocks for which any two disjoint τ-blocks have disjoint spans, and we choose disjoint τ-blocks by choosing their disjoint spans.

Lemma **??** tells us that blocks in [12] with type $\tau = 2154$ have spans with lengths 5, 8, and 11. To choose m disjoint spans in [12], we choose m disjoint sets of consecutive integers

in [12], where each set consists of either 5, 8, or 11 integers. We associate each choice of spans with lengths $s_1, s_2, \ldots, s_m$ with a composition of $[n]$ with parts sizes $s_1, s_2, \ldots, s_m$ and 1. There are $n - \sum s_i$ parts size 1. Let $C_\tau^n(m)$ denote the set of all such compositions.

For example, let $n = 12$ and $\tau = 2154$. Then $C_\tau^n(m)$ consists of compositions with exactly m parts in the set $\{5, 8, 11\}$, and remaining parts 1. We list compositions in $C_\tau^n(m)$ below.

$m = 0$: 1+1+1+1+1+1+1+1+1+1+1+1
$m = 2$: 5+5+1+1, 5+1+5+1, 5+1+1+5, 1+5+1+5, 1+1+5+5
8+1+1+1+1, 1+8+1+1+1, 1+1+8+1+1, 1+1+1+8+1, 1+1+1+1+8
1+11, 11+1

Figure 3. Compositions in $C_{2154}^{12}(m)$ for $m = 0, 2$.

We see that the number of ways to choose m τ-blocks in $[n]$ is given by the cardinality of the set $C_\tau^n(m)$. To determine this, we choose m (not necessarily distinct) span sizes $s_1, s_2, \ldots, s_m$ from the set $\{l + rq : 0 \leq r \leq \lfloor \frac{n-l}{q} \rfloor\}$ of possible span sizes (see Lemma **??**). For each choice of span sizes $s_1, s_2, \ldots, s_m$, we enumerate compositions of n with parts $s_1, s_2, \ldots, s_m$, and $n - \sum s_i$ parts 1. Suppose we have chosen s distinct span sizes. Let $t_1, t_2, \ldots, t_s$ denote the multiplicities of the s distinct span sizes (so $\sum t_i = m$). Then the number of ordered compositions with parts $s_1, s_2, \ldots, s_m$, and $n - \sum s_i$ parts 1 is given by

$$\frac{n}{\prod t_i!} = \binom{n}{t_1, t_2, \ldots, t_s}.$$

Each σ in $C_\tau^n(m)$ is associated with a choice of m disjoint τ-blocks in $[n]$. Let $s_n(\sigma)$ denote the number of integers in $[n]$ not contained by any of these τ-blocks. For example, consider $\sigma = 5+5+1+1$ in $C_{2154}^{12}(2)$. The composition σ is associated with the 2154-blocks 2154 and 76(10)9. In this case, $s_n(\sigma) = 4$ counts the integers 3, 8, 11, and 12 in [12].

We are now ready to count n-permutations with exactly m occurrences of an extendible rigid pattern.

Proposition 2 *Suppose τ is an extendible rigid pattern with the propertly that disjoint τ-blocks have disjoint spans. Let $F_\tau^n(m)$ denote the number of n-permutations in which τ occurs exactly m times. Then*

$$F_\tau^n(m) = \sum_{\sigma \in C_\tau^n(m)} [m + s_n(\sigma)]! - \sum_{m' > m} \binom{m'}{m} F_\tau^n(m') \tag{5}$$

Proof: Above we showed that each choice of m disjoint τ-blocks in $[n]$ is associated with a composition σ in $C_\tau^n(m)$. For each choice of τ-blocks we list the $[m + s_n(\sigma)]!$ arrangements of the m τ-blocks together with the $s_n(\sigma)$ integers not contained by any τ-block. We obtain a list of

$$\sum_{\sigma \in C_\tau^n(m)} [m + s_n(\sigma)]!$$

arrangements in total. This list includes all n-permutations with at least m τ-blocks.

Now $F_\tau^n(m)$ equals the number of permutations in the list above minus the number of arrangements in the list which contain $m' > m$ τ-blocks. There are $F_\tau^n(m')$ n-permutations which contain exactly m' τ-blocks, each of which appears $\binom{m'}{m}$ times in the list above. Thus equation (**??**) holds. $\diamond$

For example, when $\tau = 214$ and $n = 8$, $F_\tau^n(2) = 24$ counts the 4! 8-permutations of the blocks $\tau_1 = 214$, $\tau_2 = 658$, $\tau_3 = 3$, and $\tau_4 = 7$. Thus formula (**??**) for $m = 1$ becomes

$$F_\tau^n(1) = \sum_{\sigma \in C_\tau^n(1)} [1 + s(\sigma)]! - 24.$$

The set $C_\tau^n(1)$ contains ordered compostions $\sigma_1 = 8$, $\sigma_2 = 6+1+1$, $\sigma_3 = 1+6+1$, $\sigma_4 = 1+1+6$, $\sigma_5 = 4+1+1+1+1$, $\sigma_6 = 1+4+1+1+1$, $\sigma_7 = 1+1+4+1+1$, $\sigma_8 = 1+1+1+4+1$, and $\sigma_9 = 1+1+1+1+4$. Now $s(\sigma_1) = 1$, $s(\sigma_2) = s(\sigma_3) = 3$, and $s(\sigma_5) = s(\sigma_6) = s(\sigma_7) = s(\sigma_8) = s(\sigma_9) = 5$. Thus $F_\tau^n(1) = ([1+1]!+2[1+4]!+5[1+5]!) - 24 = 3,626$. Finally $F_\tau^n(0) = 8! - (3626 + 24) = 40,320$.

4 Conclusions

When we search for rigid patterns, we restrict the flexibility of (ordinary) patterns in two ways: 1) we require that values occur in consecutive positions, and 2) we insist that values in a τ-block β differ by exactly the difference between corresponding values in the rigid pattern, i.e., $\beta_i - \beta_j = \tau_i - \tau_j$. To bound the number of n-permutations in which an actual *pattern* occurs exactly m times, we would ideally eliminate these restrictions. With our approach, we're stuck with the first restriction, but we can at least reduce the second.

For example, consider enumerating n-permutations with exactly m occurrences of the *pattern* 213 in consecutive positions. To do this, we count n-permutations with exactly m occurrences of the *rigid* patterns 213, 214, 215, ..., 314, 315, ..., 324, 325, and so on. When the rigid pattern is nonextendible, and satisfies the span condition, we have the count from Theorem **??**. When the rigid pattern is extendible, we can compute at least a lower bound using Proposition **??**.

5 Open Problems

The alternating sums and binomial coefficients in (**??**) and (**??**) suggest a search for asymptotics.

> *For m a fixed constant or function of n, can we find asymptotics for* (**??**) *and* (**??**) *as $n \to \infty$? What is the probability that a rigid pattern τ occurs exactly m times in an n-permutation?*

Recall that when τ is an extendible rigid pattern, we count only those permutations in which every pair of overlapping τ-blocks overlap properly.

Can we extend the enumeration to include cases when blocks with a given rigid pattern do not overlap properly?

Given the connection with the theory of patterns, we would like to count overlapping blocks of extendible type individually.

If we count every block with a given type individually, regardless of overlapping, can we enumerate n-permutations which contain exactly m blocks with this type?

Finally, we would like to eliminate from our results the condition that disjoint blocks with the same type have disjoint spans.

Can we find results for a rigid pattern τ with the property that disjoint τ-blocks have nondisjoint spans?

6 Acknowledgments

I am grateful to Herb Wilf for stimulating discussions which initiated this study of rigid patterns.

7 Figures

I include all figures again here at the end as requested in the instructions for submission.

Computing Tournament Sequence Numbers Efficiently With Matrix Techniques

Abstract. We give a new, "almost explicit" formula for tournament numbers, representing them as upper left elements of the n-th power of a matrix with an explicit formula for elements of the original matrix. Using this representation, we show how to compute tournament numbers in time complexity O (n^6).

Catalan Traffic at the Beach

We design a lattice path problem in $\mathbf{Z}^2$ (the Catalan traffic) with step set $\{\rightarrow, \uparrow\}$ strictly above the line $y = (x-1)/2$, and with step set $\{\downarrow, \searrow\}$ below that same line, except for the gates at $(2y, y)$ (with $\{\uparrow, \downarrow, \searrow\}$-steps) and the closed intersections at $(2y+1, y)$ (no traffic). The step sets prevent any traffic from going below the diagonal $y = -x$ (the beach). If we denote by $t(n, m)$ the number of paths from the origin to (n, m), then the ubiquitous Catalan numbers $C_n = \binom{2n}{n}/(n+1)$ occur as $t(n, -n)$ along the beach. We prove this with the help of hypergeometric identities, and also by solving an equivalent lattice path problem. On the way we pick up several identities and discuss other known sequences of numbers occurring in the Catalan traffic scheme, like the Motzkin numbers in row $m = -1$, and the "Tri-Catalan numbers" $1, 1, 3, 12, 55, \ldots$ at the gates.

The Number Of Permutations Containing Exactly One Increasing Subsequence Of Length Three (1996)

John Noonan Temple University
DMATH: Discrete Mathematics

Abstract: . It is proved that the number of permutations on f1; 2; : : : ; ng with exactly one increasing subsequence of length 3 is 3 n \Gamma 2n n +3 \Delta [0; 0; 1; 6; 27; 110;429; : : : (Sloane A3517)]. Given oe 2 Sn , an abc subsequence is a set of three elements of a permutation, oe(i), oe(j), oe(k) with oe(i) ! oe(j) ! oe(k) and i ! j ! k. It is known[2,3,4] that the number of permutations on f1; 2; : : :; ng with no abc subsequences is given by the Catalan number 1 n+1 \Gamma 2n n... (Update)

RÉSUMÉ. Le degré de retournement est une caractéristique des graphes planaires topologiques. Dans cet article nous proposons un algorithme amélioré pour calculer le degré de retournement d'un graphe planaire topologique. Cet algorithme explore les différents cas possibles suivant une méthode descendante. Son implémentation sur machine a donné lieu à des tests sur des cas pratiques, ceci en des temps de calcul tout à fait raisonnables, sur des graphes dont l'un comporte plus d'une cinquantaine de sommets intérieurs de degré impair.

ABSTRACT. One characteristic of planar topological graphs is the reversal degree. In this paper, we propose an improve algorithm for calculating the reversal degree of a planar topological graphs. This algorithm explores various possible cases following the descending method. Practical tests carried out on machine, using graphs with more than fifty internal vertices of odd degree, have been realized within reasonable computing time.

MOTS-CLÉS graphe planaire topologique, degré de retournement, algorithme, carte, SIG.

KEYWORDS: planar topological graph, reversal degree, algorithm, map, GIS.

1. Introduction

Dans les pays en développement, bien que l'apport des Systèmes d'Informations Géographiques (SIG) soit indéniable comme partout ailleurs [10],[11],[18],[17], surtout dans ses aspects d'aide à la décision et maîtrise de l'environnement, le manque de matériel adapté à la saisie des données spatiales constitue un véritable frein à l'introduction de cette nouvelle branche de l'informatique. Le problème du calcul du degré de retournement d'un graphe dont une solution est présentée ici s'est posé lors de l'acquisition, pour un logiciel de SIG, de cartes par une méthode n'utilisant pas les outils traditionnels comme le scanner ou la table à digitaliser. Cette méthode appelée Digitalisation au Millimètre (DIMI) a été expérimentée sur la carte du Cameroun ([3],[9]) et a donné des résultats satisfaisants, particulièrement dans le cadre des applications en cartographie thématique. La méthode et les résultats obtenus ont été présentés dans [13],[14]. Précisons que le degré de retournement est un minimum sur un ensemble de valeurs et le problème pratique ici est de trouver une orientation des arêtes du graphe planaire topologique qui réalise ce minimum. La connaissance de cette orientation pour une carte (qui est un graphe planaire topologique particulier) facilite son acquisition par la DIMI. La connaissance de cette orientation est aussi intéressante dans les SIG fonctionnant selon le modèle vecteur topologique [10] où les coordonnées des points constituant chaque arc sont rangées une seule fois dans la base, mais doivent être lues dans un sens ou dans un autre selon la face que délimite cet arc.

Nous avons étudié le problème de la recherche du degré de retournement d'un graphe en utilisant la théorie des graphes et nous sommes arrivés à des formules et une méthode algorithmique de calcul de cette caractéristique que nous présentons ci-dessous après quelques définitions. Cet algorithme est mis en œuvre et testé sur des exemples pratiques de difficulté graduée.

2. Définitions

Dans cette partie nous rappelons quelques définitions de la théorie des graphes [1], [8], [21] et nous précisons la notion de profondeur d'un sommet et de degré de retournement d'un graphe.

G est un **graphe planaire** s'il est possible de le représenter sur un plan de sorte que les sommets soient des points distincts, les arêtes des courbes simples et que deux arêtes ne se rencontrent pas en dehors de leurs extrémités. Sa représentation sur un plan est appelée **graphe planaire topologique**. Dans la suite de l'exposé nous nous intéresserons uniquement aux graphes planaires topologiques sans isthme. Un isthme

est une arête dont la suppression augmente le nombre de composantes connexes. Quand nous parlerons d'un graphe G il s'agira toujours d'un graphe planaire topologique G sans isthme.

Une face d'un graphe G est une région du plan limitée par des arêtes et telle que deux points arbitraires dans cette région peuvent toujours être reliés par un trait continu ne rencontrant ni sommets ni arêtes.

le **degré d'un sommet** est le nombre d'arêtes issues de ce sommet. Nous dirons qu'un sommet S de G appartient à une face f si et seulement si S est incident à deux arêtes appartenant à la frontière de f.

Nous dirons qu'un sommet de degré n de G est intérieur s'il appartient à n faces finies. Le terme **sidi** sera utilisé pour désigner un sommet intérieur de degré impair.

Un sommet intérieur sera dit de **profondeur 1** s'il est adjacent à au moins un sommet extérieur. Un sommet intérieur sera dit de **profondeur n** (n>1) s'il est adjacent à au moins un sommet de profondeur n-1 et n'est adjacent à aucun sommet de profondeur inférieur à n-1. Pour un sommet intérieur S de profondeur n il existe donc au moins une chaîne de n arêtes reliant S à un sommet extérieur. Par la suite nous appellerons **chaîne minimale** associée à S toute chaîne constituée de n arêtes et reliant S à un sommet extérieur.

Nous désignerons par **chaîne minimale** reliant deux sommets intérieurs toute chaîne reliant ces deux sommets et ayant le minimum d'arêtes.

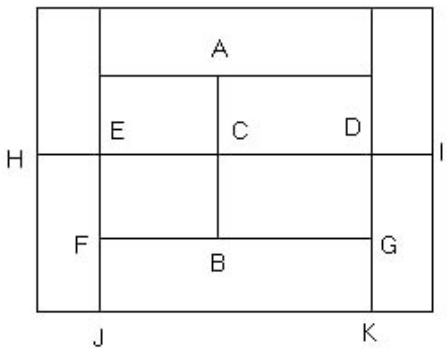

Figure 1. *Exemple de graphe planaire topologique sans isthme*

La figure 1 présente un exemple de graphe. Les sommets H, I, J et K par exemple, sont des sommets extérieurs. Les sommets A, B, C, D, E, F et G sont intérieurs. Les sommets D, E, F et G sont de profondeur 1. Les sommets A, B et C sont de profondeur

2. La chaîne constituée des arêtes AC et CB constitue la chaîne minimale reliant les sommets A et B. La chaîne constituée des arêtes BF et FJ est une chaîne minimale associée au sommet intérieur B. La chaîne constituée des arêtes BG et GK est une autre chaîne minimale associée au même sommet B.

Nous dirons que G est à **zéro retournement** si on peut orienter dans un seul sens les arêtes de G de telle sorte que chaque face finie soit délimitée par un circuit. Nous dirons que G est **à n retournements** (n>0) s'il faut orienter au moins n de ses arêtes dans les deux sens pour que chaque face finie de G soit délimitée par un circuit. Les graphes planaires topologiques à zéro et à un retournement ont été entièrement caractérisés dans [14] et [15]. Il en ressort qu'une condition nécessaire et suffisante pour que G soit à zéro retournement est que G ne possède aucun sommet intérieur de degré impair. De même une condition nécessaire et suffisante pour que G soit à un retournement est qu'il ait un seul sidi de profondeur 1 ou qu'il ait deux sidis adjacents.

Nous dirons que G est entièrement orienté si chacune de ses faces finies est délimitée par un circuit, certaines arêtes étant éventuellement orientées dans les deux sens.

Nous dirons qu'une chaîne est orientée dans les deux sens si chaque arête constituant cette chaîne est orientée dans les deux sens. Un sidi sera dit isolé si sa chaîne minimale est orientée dans les deux sens. Un sidi sera dit apparié à un autre si la chaîne minimale les reliant est orientée dans les deux sens.

3. Calcul du degré de retournement d'un graphe Planaire topologique

3.1. Théorème 1

Une condition suffisante pour que G soit entièrement orientable est que chaque sidi de G soit ou isolé ou apparié à un autre sidi de G.

Remarquons d'abord que pour orienter les arêtes des n faces auxquelles appartient un sommet intérieur de degré pair de telle sorte que chaque face soit délimitée par un circuit, il suffit d'imposer une orientation à l'une des arêtes issues de ce sommet, l'orientation des autres arêtes issues du même sommet s'en déduit automatiquement (figure 2 a). En ce qui concerne un sommet de degré impair, nous allons d'abord orienter une arête issue de ce sommet dans les deux sens avant d'imposer une orientation à l'une des arêtes restantes. L'orientation des autres arêtes s'en déduit aussi automatiquement (figure 2 b). Autrement dit, dès que les arêtes d'une face contenant un

sommet sont orientées de telle sorte que cette face soit délimitée par un circuit, l'orientation des autres faces s'en déduit automatiquement.

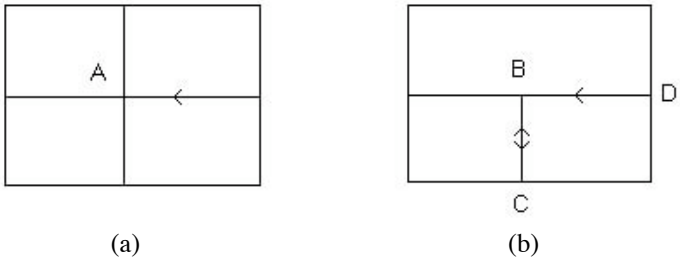

Figure 2. *Exemples d'orientation initiale des arêtes*

Pour démontrer le théorème nous supposons donc que G est un graphe planaire topologique possédant n sidis. Chaque sidi est soit isolé soit apparié à un autre. Précisons qu'un sidi isolé n'est pas apparié à un autre et inversement un sidi apparié à un autre n'est pas isolé. Au départ seules les arêtes appartenant aux différentes chaînes minimales sont orientées dans les deux sens. Les autres arêtes de G n'ont aucune orientation. Nous allons maintenant montrer comment il faut procéder pour orienter les différentes arêtes restantes de G pour que chaque face soit délimitée par un circuit.

Pour cela nous allons partir de l'un des sidis S de G et imposer une orientation à l'une des arêtes non déjà orientées de S. D'après la remarque faite plus haut, ce sens permet d'orienter les arêtes des différentes faces auxquelles appartient S de telle sorte que chacune de ces faces soit un circuit. Ce premier travail permet d'imposer une orientation à des arêtes appartenant à des faces ne contenant pas S. Nous utilisons ce sens pour orienter ces nouvelles faces et de proche en proche pour orienter entièrement G. En fait nous pouvons commencer l'orientation sur n'importe quelle arête non encore orientée puisqu'en définitive chaque arête aura un seul sens d'orientation.

Dans cette orientation nous n'avons pris que les chaînes minimales ce qui veut dire qu'il peut exister d'autres orientations de G avec plus d'arêtes orientées dans les deux sens. C'est pour cela que notre condition n'est pas nécessaire. Comme le degré de retournement que nous recherchons est un minimum, nous ne sommes pas intéressés par les cas d'orientations comportant un plus grand nombre d'arêtes orientées dans les deux sens.

Calculer le degré de retournement de G revient donc à éliminer l'effet de chaque sidi soit en l'isolant, soit en l'appariant à un autre sidi. Cette approche permet non seulement de trouver le degré de retournement mais aussi de trouver les différentes orientations des arêtes pour que chaque face soit un circuit.

3.2. Exemple□ Graphe planaire topologique à 3 sidis

Considérons le schéma simplifié d'un graphe planaire topologique à trois sidis S_1, S_2 et S_3 (figure 3). Chaque sidi S_i a une profondeur P_i. Entre deux sidis S_i et S_j il y a une chaîne minimale composée de h_{ij} arêtes. Pour éliminer l'effet de ces trois sidis, nous avons quatre possibilités : isoler chacun des trois sidis (une possibilité), isoler un des trois sidis et apparier les deux autres (trois possibilités). Le degré de retournement de ce graphe est alors donné par la formule suivante :

$$D = \min(p_1 + p_2 + p_3, p_1 + h_{23}, p_2 + h_{13}, p_3 + h_{12})$$

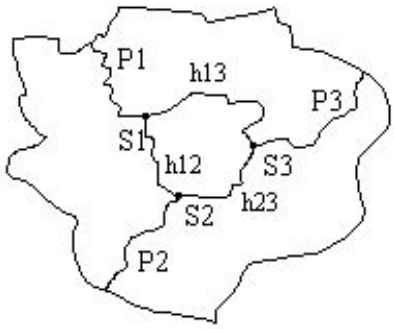

Figure 3. *Schéma simplifié d'un graphe planaire topologique à trois sidis*

La première expression (P_1+P_2+P_3) représente le poids du cas où les arêtes reliant chaque sidi au sommet extérieur le plus proche ont été orientées dans les deux sens. Les trois sidis sont isolés. La deuxième expression (P_1+h_{23}), quant à elle, représente le poids du cas où S_1 est isolé et les deux autres sidis sont appariés. Les deux dernières expressions se déduisent de la deuxième par permutation des rôles joués par les trois sidis.

Si nous avons par exemple P_1=1, P_2=1, P_3=3, h_{12}=1, h_{13}=3 et h_{23}=2, alors le degré de retournement de la carte sera de 3.

Cette analyse montre que le degré de retournement d'un graphe est inférieur ou égal à la somme des profondeurs de ses sidis. Il est aussi supérieur ou égal à la moitié du nombre de sidis. Ce minimum est atteint quand on a un nombre pair de sidis appariés deux à deux de chaîne minimale égale à un. Le degré de retournement D d'un graphe possédant n sidis vérifie donc la relation suivante :

$$\frac{n}{2} \leq D \leq \sum_{i=1}^{n} p_i$$

Le graphe planaire topologique de la figure 4 est à deux degrés de retournement avec trois sidis A, B et C. Ce degré de retournement est obtenu en isolant le sidi A (ce qui revient à orienter dans les deux sens l'arête AD) et en appariant les sidis B et C (ce qui revient à orienter dans les deux sens l'arête BC).

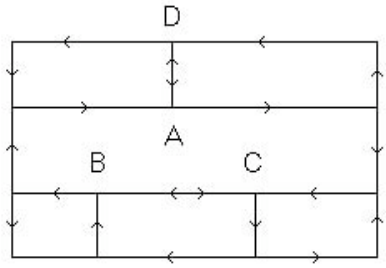

Figure 4. *Exemple de graphe à 3 sidis et 2 degrés de retournement*

3.3. Graphe planaire topologique à n sidis

Considérons un graphe planaire topologique G possédant n sidis. Nous utiliserons le terme «cas possible» pour désigner une façon d'éliminer les n sidis. A chaque cas possible correspond un poids qui est le nombre d'arêtes orientées dans les deux sens pour ce cas. Adoptons la notation suivante :

α_n désigne le nombre de cas possibles quand on dispose d'un graphe ayant n sidis.

α_n^i désigne le nombre de cas dans lesquels on a exactement i paires de sidis appariés.

α_i désigne le poids associé au cas i.

C_i désigne le nombre de paires de sidis appariés contenus dans le cas i.

D désigne le degré de retournement du graphe G.

Nous avons les formules suivantes :

$$\alpha_n = \sum_{i=0}^{ent(n/2)} \alpha_n^i \qquad (1)$$

ent(n/2) représentant la partie entière de la division de n par 2.

$$\Pi_i = \sum_{j=1}^{c_i} h_j + \sum_{j=1}^{n-2c_i} p_j \qquad (2)$$

$$D = \min(\Pi_i), i = 1,2,...\Pi_n \qquad (3)$$

La relation (1) traduit simplement le fait que l'ensemble des cas possibles est la somme des cas possibles contenant zéro paire de sidis appariés, une paire de sidis appariés, …, ent(n/2) paires de sidis appariés.

La relation (2) donne le poids de chaque cas possible. Par h_j on désigne le nombre d'arêtes dans une chaîne minimale séparant les sidis de la paire j. p_j désigne quant à lui la profondeur du sidi j. La relation (3) en déduit le degré de retournement par calcul du minimum sur les différents poids. Plusieurs cas possibles peuvent avoir le poids minimum. Ce sont alors des solutions équivalentes.

3.4. Théorème 2

Pour un graphe qui a n sidis, le nombre de cas possibles dans lequel on a i paires de sidis appariés (1<i<=ent(n/2)) est donné par la formule suivante :

$$\Pi_n^i = \Pi_{n-1}^i + (n-1)\Pi_{n-2}^{i-1}$$

Les cas possibles de i paires contenant une paire de la forme (S_1,S_a) avec 1<a<=n sont au nombre de (n-1) Π^{i-1}_{n-2} les cas possibles de i paires ne contenant aucune paire de la forme (S_1,S_a) avec 1<a<=n sont au nombre de Π^i_{n-1}, d'où le théorème [22].

Il existe un seul cas dans lequel tous les sidis sont isolés. Il n'y a pas de paire de sidi. D'où la relation :

$$\Pi_n^0 = 1 \quad \forall n > 0$$

Avec un seul sidi on ne peut constituer de paire, d'où la relation :

$$\Pi_1^i = 0 \quad \forall i > 0$$

Pour constituer i paires de sidis il faut que 2i soit au plus égal à n, d'où la relation:

$$\Pi_n^i = 0 \quad \textit{pour tout i tel que } 2i > n$$

Le nombre de cas possibles contenant une paire avec n sidis est donné par la formule classique des combinaisons suivante :

$$\Pi_n^1 = C_n^2 = \frac{n(n-1)}{2}$$

Le tableau 1 ci-après présente quelques valeurs de Ω_n^i et du nombre de cas possibles pour n variant de 1 à 14. La première colonne donne les différentes valeur de n. La première ligne donne le nombre de paires dans chaque cas. Les deux dernières colonnes donnent le nombre de cas possibles Ω_n comparé à 2^n. Pour n=5 par exemple on lit sur cette ligne du tableau qu'il y a un cas possible avec 0 paire de sidis, 10 cas avec une paire de sidis et 15 cas avec 2 paires de sidis.

	Nombre de paires par cas									
N	**0**	**1**	**2**	**3**	**4**	**5**	**6**	**7**	Ω_n	2^n
1	1	0	0	0	0	0	0	0	1	2
2	1	1	0	0	0	0	0	0	2	4
3	1	3	0	0	0	0	0	0	4	8
4	1	6	3	0	0	0	0	0	10	16
5	1	10	15	0	0	0	0	0	26	32
6	1	15	45	15	0	0	0	0	76	64
7	1	21	105	105	0	0	0	0	232	128
8	1	28	210	420	105	0	0	0	764	256
9	1	36	378	1 260	945	0	0	0	2 620	512
10	1	45	630	3 150	4 725	945	0	0	9 496	1 024

Tableau 1. *Valeur de Ω_n pour n inférieur à 15.*

Comme le montre le tableau 1, la croissance est plus qu'exponentielle. Ce résultat ne peut être utilisé tel quel que pour des graphes avec peu de sidis (une dizaine environ). Nous sommes en présence d'un problème d'explosion combinatoire [12] ou d'optimisation combinatoire [21]. En effet si on désigne par C l'ensemble des cas possibles et par $f: C \rightarrow N$ l'application de C dans l'ensemble des entiers N qui à chaque cas possible associe son poids, il s'agit de trouver $\_ \in C$ tel que:

$$f(\_) = \mathrm{Min}_{c \in C} [f(c)]$$

Pour des graphes possédant un nombre élevé de sidis il convient donc d'utiliser une approche algorithmique et des méthodes appropriées afin de pouvoir évaluer le degré de

retournement dans un temps acceptable sans forcément passer par tous les cas possibles. C'est ce que nous nous proposons d'examiner dans la suite de ce travail.

4. Algorithme de calcul du degré de retournement

Dans cette partie nous présentons une méthode algorithmique pour déterminer le degré de retournement d'un graphe dans le cas général. Cet algorithme est basé sur les méthodes par séparation et évaluation [21] et utilise un parcours en profondeur [4], [12]. Nous allons d'abord présenter en général la méthode utilisée pour effectuer la séparation et l'évaluation ensuite nous présenterons l'algorithme qui en découle.

4.1 Méthode de séparation et d'évaluation

Le degré de retournement est un minimum parmi un grand nombre de poids associés aux différents cas possibles. Nous connaissons un majorant et un minorant pour cette quantité. Un graphe G peut avoir plusieurs cas possibles associés au degré de retournement, c'est-à-dire associés au poids minimum. L'algorithme s'arête s'il trouve un cas possible réalisant ce minimum. G n'a qu'un seul degré de retournement qui est un entier. Le nombre de cas possibles est très élevé. C'est un problème d'optimisation combinatoire [21]. Les méthodes de séparation et évaluation vont nous permettre de trouver ce degré sans examiner systématiquement tous les cas possibles. Pour cela nous allons décomposer par étape l'ensemble des cas possibles comme indiqué dans la figure 5. A la première étape nous apparions le sidi 1 à l'un des n-1 sidis restants ou bien nous l'isolons. A la seconde étape nous apparions deux sidis parmi les n-2 restant et ainsi de suite jusqu'à ce qu'il ne soit plus possible de faire des appariements. Les branches de l'extrême droite correspondent aux sidis isolés.

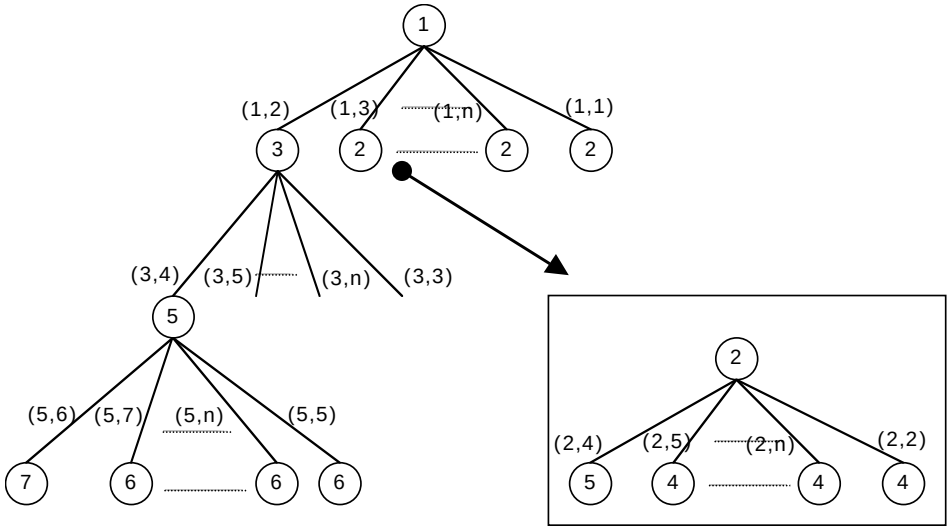

Figure 5. *Exemple de décomposition de l'ensemble des cas possibles*

Sur la figure 5 la notation (n,m), avec n différent de m, indique que le sidi n est apparié au sidi m et la notation (n,n) indique que le sidi n est isolé. Dans le cas où les sidis sont adjacents les uns aux autres il est évident que le degré de retournement sera donné par un cas possible contenant un grand nombre de sommets appariés et très peu de sommets isolés. Quand le sidi 1 est apparié au sidi 3 (deuxième branche issue de la racine à partir de la gauche), le sidi 2 à son tour peut être apparié soit à 4, soit à 5, …, soit à n. Il peut même être isolé. C'est ce que montre le sous-arbre développé au bout de la flèche issue du petit rond contenant 2.

La condition suivante (condition d'éligibilité) nous permet d'éliminer, sans aller jusqu'au bout, les cas possibles ne pouvant conduire à un minimum□

Si à une étape donnée, le sidi n ne peut pas être apparié au sidi m (chaîne minimale trop longue par rapport au maximum imposé par l'utilisateur par exemple), le parcours du sous-arbre issue de cette paire est abandonné.

La méthode de parcours en profondeur de l'arbre [4] est utilisée pour explorer les différents cas possibles. Elle permet de descendre plus profondément dans l'arbre chaque fois que c'est nécessaire et d'examiner systématiquement tous les cas possibles. Pour un cas possible donné, l'évaluation se fait en calculant son poids. Si ce poids est plus petit que le minimum trouvé jusque là, il devient le minimum, sinon on le rejette.

4.2 Présentation de l'algorithme

Cet algorithme reçoit en entrée l'ensemble des n sidis du graphe avec pour chacun sa profondeur et pour chaque paire de sidis la chaîne minimale les reliant. Les profondeurs sont présentées dans un vecteur de n éléments dit vecteur de profondeur. Les chaînes minimales sont présentées dans une matrice triangulaire à diagonale nulle dite matrice de chaîne minimale. Il met en sortie un cas possible de poids minimum qui est le degré de retournement cherché.

Bien que cet algorithme puisse générer tous les cas possibles (pour un petit nombre de sidis par exemple), son paramétrage peut permettre, comme nous le verrons plus loin, de trouver le degré de retournement en examinant très peu de cas possibles.

Cet algorithme a connu d'importantes améliorations par rapport à celui présenté au Colloque Africain sur la Recherche en Informatique (CARI' 2000) [16]. Ces améliorations nous ont permis de calculer en quelques minutes le degré de retournement de cartes qui ont un nombre élevé de sidis comme celles de l'Afrique et des Etats Unis avec leur découpage en états.

Nous présentons cet algorithme à travers cinq procédures :

- Une procédure principale
- Une procédure d'initialisation (Procédure INIT) qui lit les paramètres c'est-à-dire entre autres le nombre de sidis, le vecteur de profondeur et la matrice de chaîne minimale.
- Une procédure de calcul du poids (fonction à minimiser) de chaque cas possible (Procédure POIDS) qui retient aussi le poids minimum. Elle utilise pour ce calcul le vecteur de profondeur et la matrice de chaîne minimale.
- Une procédure (Procédure FIXER) qui fixe les m-1 paires pour une valeur de m donnée supérieure ou égale à deux. La paire m est ensuite calculée dans la procédure COMBINE en utilisant les combinaisons.
- Une procédure COMBINE qui calcule la paire m (une fois que les m-1 paires sont fixées) en utilisant les combinaisons.

Nous présentons ci-après ces différentes procédures. Pour faciliter cette présentation, nous supposons que toutes les variables utilisées sont des variables communes à l'ensemble des procédures.

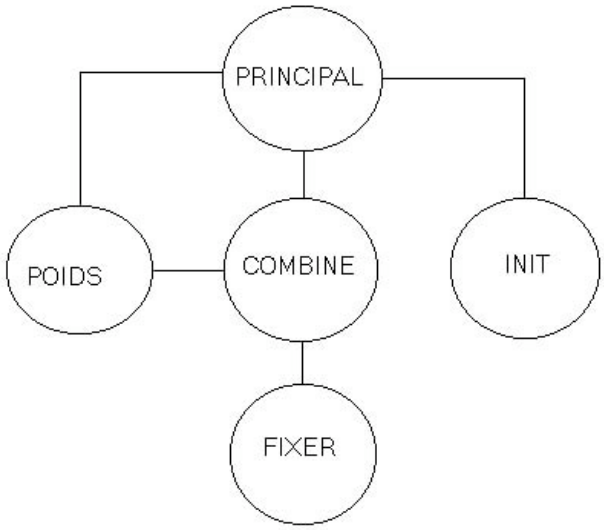

Figure 6. *Interconnexion entre les cinq procédures*

4.2.1. Procédure Principale

Début
Appeler la procédure INIT pour la lecture des paramètres;
in := 0;
Appeler la procédure POIDS pour l'initialisation;
in := 1;
Appeler la procédure COMBINE pour générer les différents cas possibles;
Imprimer le degré de retournement et le cas possible correspondant;
Fin.

La procédure principale appelle la procédure INIT pour la lecture des paramètres et la procédure POIDS pour l'initialisation de C0 et p0 (cas possible de départ et poids associé). Elle appelle ensuite la procédure COMBINE. A la fin de l'algorithme, la procédure principale imprime p0 et C0 qui représentent respectivement le poids minimum (degré de retournement du graphe proposé) et un cas possible ayant ce poids minimum. Le cas possible qui minimise la fonction poids permet d'orienter les arêtes de telle sorte que chaque face soit un circuit avec un nombre minimum d'arêtes orientées dans les deux sens.

4.2.2. Procédure INIT

Début
Lecture du nombre n de sidis;
Lecture du vecteur Vp de profondeur des n sidis;
Lecture de la matrice Mcm de chaîne minimale;
Lecture de Cmax, chaîne maximale autorisée entre 2 sidis à apparier;
Pour i=1 **jusqu'à** n;
C1(i) := i;
C2(i) := i;
Vi(i) := 0;
FinPour;
Fin;

Vp est un vecteur tel que Vp(i) désigne la profondeur du sidi i. Mcm est la matrice symétrique à diagonale nulle de chaîne minimale. Mcm(i,j) désigne donc la chaîne minimale (en terme de nombre d'arêtes) reliant les sidis i et j. Cmax est un nombre qui représente la chaîne maximale autorisée entre deux sidis à apparier. Si la chaîne minimale entre deux sidis est supérieure à Cmax, les deux sidis ne seront pas appariés par l'algorithme. Le sous-arbre correspondant n'est pas exploré. Cette approche permet d'éliminer d'office, comme nous le verrons plus loin, un grand nombre de cas qui dans certaines situations ne peuvent conduire à un minimum. Pour une carte de géographie par exemple, les sommets intérieurs sont souvent des sidis de degré trois. On peut, dans ce cas, donner à Cmax la valeur 1 pour que seuls les sidis adjacents soient effectivement appariés. La détermination des éléments de la matrice Mcm s'en trouve simplifiée. Mcm(i,j) vaut 1 si les deux sidis i et j sont adjacents et par exemple 2 (ou toute autre valeur supérieure à 1) dans les autres cas.

Les variables C1 et C2 utilisées ici sont des vecteurs contenant au départ les entiers de 1 à n. Pendant le déroulement de l'algorithme, C2 restera inchangé. Il sert uniquement à reconstituer C1 quand on passe d'un cas possible contenant m paires de sidis appariés à un autre contenant m+1 paires de sidis appariés. La variable C1, par contre contiendra le dernier cas possible généré. Le vecteur Vi quant à lui, indique les sidis isolés au milieu de C1, ceci par opposition, comme nous le verrons plus loin, aux sidis qui peuvent être isolés soit au début soit à la fin de C1. Supposons que C1 et Vi contiennent par exemple les valeurs suivantes pour n=10 sidis et m=3 paires de sidis appariés□

C1□	-1	2	3	4	-5	6	-7	8	9	10
Vi □	0	0	1	1	0	0	0	0	0	0

Cette configuration traduit le fait que les sidis 3 et 4 sont isolés au milieu de C1. Les sidis 1 et 2 sont appariés. Il en est de même des sidis 5 et 6 ainsi que des sidis 7 et 8. Les sidis 9 et 10 sont isolés à la fin de C1 car le nombre de paires (3 ici) est déjà atteint. Pour un souci de clarté dans l'exposé, nous avons fait précéder le premier sidi d'une paire par le signe moins. Ainsi –1 signifie que le sidi 1 est apparié au sidi 2, de même, -5 signifie que le sidi 5 est apparié au sidi 6. il n'est donc pas nécessaire de faire placer ce signe par l'algorithme. Cette configuration est représentée dans l'arbre de la figure 7.

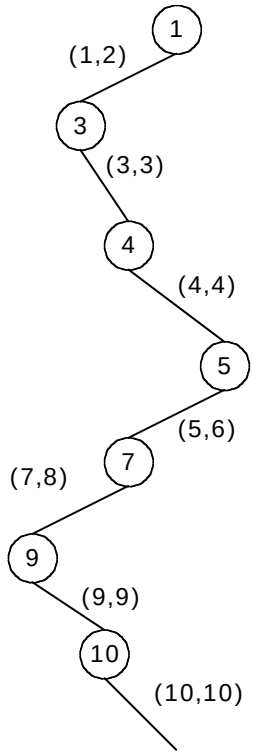

Figure 7. *Représentation d'un cas possible dans l'arbre.*

4.2.3.Procédure POIDS

La procédure POIDS calcule le poids d'un cas possible. Ce poids est la somme des profondeurs des sidis isolés de ce cas possible ajoutée à la somme des chaînes

minimales des paires composant ce même cas possible. Pour un cas possible contenu dans le vecteur C1, elle calcule d'abord la somme des profondeurs d'éventuels sidis isolés au début de C1, sidis de numéro inférieur à la valeur de la variable dpp (début première paire en partant de la gauche). Elle ajoute à cette somme les chaînes minimales des différentes paires ainsi que les profondeurs des sidis isolés tant au milieu de C1 qu'à la fin.

```
Début
    Si in=0  Alors   /* Initialisation du poids et des éléments pour l'impression du
                     résultat */
                     p0 := sommes des profondeurs des n sidis;
                     C0 := C2;
                     Vi0□= Vi;   /* Pas d'élément isolé au milieu du vecteur C0 */
                     dpp0□= 0;   /* Pas d'élément isolé au début de C0 */
                     m0□= 0;     /* Aucune paire de sidis */
             Sinon
                     /* Calcul du poids du cas possible qui est dans C1 */
                     d□=1;
                     p□=0;
                      /* Calcul du poids des sidis isolés au début de C1 */
             Tant que d<dpp Faire
                     p□= p+Vp(d);
                     d := d+1;
             Fin Tant que
                     np := 1;  /* compteur du nombre de paires */
            /* Ajout des poids des paires et des sidis isolés au milieu de C1 */
             Tant que  np<=m Faire
                     p1□= C1(d)□
                     Si Vi(d)=1 Alors p□= p + Vp(p1)□d□= d + 1□
                     Sinon p2□= C1(d+1); p□=p + Mcm(p1,p2);
                                  d□= d + 2; np□= np+1;
                     FinSi
             Fin Tant que
             /*  Ajout des poids des sidis  isolés à la fin */
             Tant que d<=n Faire
                     p1□= C1(d)□
                     p□= p + Vp(p1)□
                     d := d + 1;
             Fin Tant que
              /* Si le nouveau poids est plus petit il remplace l'ancien */
             Si p<p0 Alors
```

```
                    p0 := p;
                    C0 := C1;
                    Vi0 := Vi;
                    m0 := m;
                    dpp0 := dpp;
                FinSi;
            FinSi;
    Fin;
```

Les variables p0, C0, Vi0, dpp0 et m0 servent de variables de sauvegarde respectivement pour les variables p (poids d'un cas possible), C1, Vi, dpp et m. Elles permettent à la fin de l'algorithme d'imprimer le degré de retournement et le cas possible associé.

La variable C0 qui est un vecteur comme C1 et C2, contient le cas possible de poids minimum. La variable p0 contient le poids minimum associé à ce cas possible. La variable C0 est initialisée avec C2 c'est-à-dire le cas possible où tous les sidis sont isolés. Le poids p0 correspondant est tout simplement la somme des profondeurs de l'ensemble des n sidis. Cette initialisation est faite lors du premier appel avec in=0. Quand la variable in est non nulle, un nouveau cas possible vient remplacer C0 si son poids est inférieur à l'ancien p0.

4.2.4. Procédure COMBINE

```
Début
    /* Génération des cas possibles ne contenant qu'une paire */
    Pour k=1 jusqu'à  n-1  Faire
        Pour r=k+1 jusqu'à  n  Faire
            Si Mcm(k,r)<=Cmax Alors
            Appeler POIDS avec la paire (Sk, Sr),
            les autres sidis étant isolés;
            FinSi;
        FinPour;
    FinPour;
    /* Génération des cas possibles contenant plus d'une paire */
    nei := 0                    /* Nombre d'éléments isolés au milieu */
    dpp := 1;                   /* Début première paire  */
    fini := faux;
    pr_appel := vrai;
    m :=  2;                    /* Nombre de paire par cas */
    Tant que (m<= Ent(n/2) et fini=faux) Faire
```

```
                Appeler la procédure FIXER□;
                Si fini=faux Alors
                        /* Génération de la dernière paire par combinaison */
                        Pour k=2(m-1)+dpp+nei  jusqu'à  n-1 Faire
                                Pour r=k+1 jusqu'à  n  Faire
                                        p1□=C1(k); p2□=C1(r);
                                        Si Mcm(p1,p2) <= Cmax Alors
                                        Appeler la procédure POIDS;
                                        FinSi;
                                FinPour;
                        FinPour;
                FinSi;
        FinTant que;
Fin.
```

La variable **pr_appel** a la valeur **vrai** lors du premier appel de la procédure FIXER et a la valeur **faux** lors des autres appels. La variable **m** donne le nombre de paires par cas possible. La variable **dpp** qui veut dire début de la première paire, donne l'indice du début de la première paire en partant de la gauche. La variable **nei** donne le nombre total de sidis isolés au milieu du vecteur C1.

Pour générer les cas possibles contenant m paires de sidis (m>1), la procédure COMBINE fixe à l'aide de la procédure FIXER les m-1 premières paires et génère la dernière paire en utilisant les combinaisons. Comme dans le cas d'une paire, elle appelle chaque fois la procédure POIDS pour mettre à jour C0 et p0.

4.2.5. Procédure FIXER

```
Début
        cas_bon := faux;
        Tant que (ca_bon=faux et fini=faux) Faire
                Si pr_appel Alors
                        C1 := C2;
                        pr_appel :=faux ;
                Sinon
                        j := 0;
                        i : = m - 1;
                        Tant que (i > 0 et j = 0) Faire
                                r := pgep(i) +1;
                                reste := n-dpp-nei;
                                /* nombre d'éléments restant pour l'appariement */
                                Si r>n Alors Si reste >= 2*m Alors
```

```
                        /* on isole au milieu de C1 */
                        nei:=nei+1;
                        Isoler le 1° élément de la paire i et trier les
                        autres à droite;
                        j:=1;
                        Sinon   Libérer l'éventuelle plage
                                d'isolement avant la paire i;
                                i=i-1;
                        FinSi;
                Sinon Si r se trouve à droite Alors
                        Permuter r et pgep(i);
                        Trier à droite de la paire i;
                        j := 1;
                        Sinon r := r + 1;
                        FinSi;
                FinSi;
        Fin Tant que;
        Si i = 0 Alors
                /* On décale d'un élément vers la droite si possible */
                C1 : = C2;
                dpp := dpp + 1;
                Si n-dpp+1<2m Alors
                        /* On augmente le nombre de paire par cas */
                        m := m + 1;
                        dpp := 1;
                        Si  2m>n  Alors fini := vrai;

```

Cette procédure fixe les m-1 premières paires de sidis (m>1). Elle vérifie ensuite que chaque paire est telle que la chaîne minimale séparant ses deux sidis est inférieure à Cmax avant de renvoyer ces m-1 paires à la procédure COMBINE. Dans le cas contraire, elle continue la recherche. Nous allons d'abord décrire cette procédure sans tenir compte de cet aspect que nous appelons contrôle de validité. Nous y reviendrons un peu plus loin.

Pour illustrer la démarche décrite par cette procédure, nous allons prendre le cas de n=10 sidis et m=3 paires. La première fois que cette procédure est appelée avec m=3 elle renvoie dans les vecteurs C1 et Vi les éléments suivants:

C1□	-1	2	-3	4	5	6	7	8	9	10
Vi□	0	0	0	0	0	0	0	0	0	0

Ceci traduit le fait que C1 contient deux paires de sidis (S_1,S_2) et (S_3,S_4). Aucun sidi n'étant isolé au milieu, Vi ne contient que des zéros. La procédure COMBINE va, au retour, générer la dernière paire par combinaison des sidis 5 à 10. Quand elle aura généré tous les cas possibles contenant les paires (S_1,S_2) et (S_3,S_4), elle va à nouveau appeler la procédure FIXER. Cette dernière va renvoyer dans C1 et Vi les éléments suivants:

C1□	-1	2	-3	5	4	6	7	8	9	10
Vi□	0	0	0	0	0	0	0	0	0	0

Dans cette nouvelle configuration de C1, 5 est venu remplacer 4 dans la deuxième paire et 4 est allé à l'ancienne place de 5. Dans l'algorithme **pgep(i)** désigne le plus grand élément de la paire i. Dans ce cas il s'agit du plus grand élément de la paire 2 qui est 4. En ajoutant 1 à cet élément nous obtenons 5 qui se trouve effectivement à droite de la paire i dans C1. On permute pgep(i) et r, c'est-à-dire 4 et 5. Ici le tri ne change pas grand chose. En positionnant la variable j à 1, cela nous permet de sortir de la boucle **Tant que** et de revenir à la procédure COMBINE pour la génération de la dernière paire.

Au huitième appel, en ajoutant 1 au plus grand élément de la deuxième paire, c'est-à-dire à 10 on trouve 11 qui est plus grand que n. On isole 3 et les deux premières paires seront constituées de (S_1,S_2) et de (S_4,S_5). L'isolement du sidi 3 se traduit par un «□□ à la position correspondante du vecteur d'isolement Vi comme indiqué ci-après.

C1□	-1	2	3	-4	5	6	7	8	9	10
Vi□	0	0	1	0	0	0	0	0	0	0

On recommence le processus d'isolement quand la deuxième paire sera (S_4,S_{10}). Le sidi 4 sera à son tour isolé, puis le sidi 5 et le sidi 6. La variable **nei** donne le nombre total d'éléments ainsi isolés. La configuration suivante donne la situation des vecteurs C1 et Vi après l'isolement du sidi 6.

C1⊡	-1	2	3	5	4	6	-7	10	8	9
Vi⊡	0	0	1	1	1	1	0	0	0	0

La première paire est toujours formée des sidis 1 et 2. la deuxième paire est formée des sidi 7 et 10 et la dernière paire est formée des sidis 8 et 9. Le deuxième élément de la deuxième paire est au maximum. On devrait isoler le sidi 7, mais si on l'isole le nombre de sidis non isolés est de 5 (les sidis 1, 2, 8, 9 et 10), ce qui ne permet pas de former trois paires. On ne peut donc continuer à isoler.

On procède à la libération des éléments isolés pour permettre leur appariement avec les autres. On diminue alors i de 1 ce qui permet de passer à la paire immédiatement à gauche (la première paire dans notre cas). On applique l'algorithme sur la première paire et la procédure FIXER renvoie dans C1 les éléments suivants :

-1	3	-2	4	5	6	7	8	9	10

Les appels suivants vont permettre de générer les cas possibles contenant les paires (S_1,S_3) et (S_2,S_i) pour i >3. On passera ensuite aux cas contenant les paires (S_1,S_4) et (S_2,S_i) avec i>2 et i≠4 et ainsi de suite.

Au bout d'un certain nombre d'appels, la procédure FIXER va recevoir en entrée la configuration suivante :

C1⊡	-1	10	2	3	4	5	-6	9	7	8
Vi⊡	0	0	1	1	1	1	0	0	0	0

Dans cette configuration, nous avons les paires (S_1,S_{10}) et (S_6,S_9), les sidis 2 à 5 étant isolés au milieu de C1. En ajoutant 1 au plus grand élément de la deuxième paire on trouve 10 qui n'est pas à droite. On ajoute à nouveau 1 et le résultat est supérieur à n. On libère les sidis isolés, on passe à la paire immédiatement à gauche (la première paire). Ici, il faut à nouveau passer à la paire immédiatement à gauche. Il n'y a pas de paire à gauche. La variable i a pris la valeur zéro. On sort de la boucle **Tant que**. Dans la partie qui suit de la procédure FIXER, quand cette situation arrive, on décale d'un élément vers la droite. La variable **dpp** qui donne l'indice de la première paire en partant de la

gauche est incrémentée de 1. Ce qui permet d'isoler un sidi à gauche (le sidi 1 dans ce cas). Cette situation marque dans notre exemple la fin des cas possibles contenant une paire de la forme (S_1,S_i) avec $i \neq 1$. La procédure FIXER renvoie dans C1 les éléments suivants :

C1	1	-2	3	-4	5	6	7	8	9	10
Vi	0	0	0	0	0	0	0	0	0	0

La variable dpp a pris la valeur 2 pour dire que la première paire de sidis commence au deuxième élément du vecteur C1. Comme nous l'avons mentionné plus haut, les sidis à gauche de cette première paire (comme le sidi 1 dans cet exemple) sont des sidis isolés au début de C1. Les éléments du vecteur d'isolement Vi ne sont pas positionnés à 1 pour ces sidis isolés au début du vecteur C1. Ils ne sont pas non plus positionnés pour les sidis isolés à la fin de ce même vecteur. Plus loin, la procédure FIXER recevra en entrée après plusieurs décalages à droite les éléments suivants avec dpp = 5 :

C1	1	2	3	4	-5	10	-6	9	7	8
Vi	0	0	0	0	0	0	0	0	0	0

La première paire de sidi est donc constituée des sidis 5 et 10 et la deuxième des sidi 6 et 9. Les sidis 1 à 4 sont isolés au début de C1. On va sortir de la boucle **Tant que** avec i nulle. En voulant décaler à nouveau vers la droite on va s'apercevoir que les éléments qui resteront à droite ne permettront pas de constituer les trois paires qu'il faut. C'est la fin des cas possibles contenant trois paires de sidis. En augmentant m de 1 on passe à la génération des cas possibles contenant 4 paires de sidis. En augmentant m on repart sans sommet isolé à gauche. Si en augmentant m il n'est plus possible de générer m paires avec les n sidis, la variable **fini** prend la valeur **vrai**, c'est la fin de l'algorithme. Le retour à la procédure principale provoque l'impression du cas possible de poids minimum.

4.2.6. Remarque

A un moment donné, le vecteur d'isolement peut avoir plusieurs plages de sidis isolés au milieu. Si nous prenons par exemple n=16 et m=4, on aura à un moment donné la configuration suivante avec dpp =2 :

C1	1	-2	3	4	5	-6	7	8	9	10	-11	12	13	14	15	16
Vi	0	0	0	1	1	0	0	1	1	1	0	0	0	0	0	0

Le sidi 1 est isolé puisque la première paire commence à 2. Cette première paire est constituée des sidis 2 et 3. les sidis 4 et 5 sont isolés au milieu de C1 et constituent la première plage d'isolement. Les sidis 6 et 7 sont appariés. Les sidis 8, 9 et 10 sont aussi isolés au milieu de C1 et constituent la deuxième plage d'isolement. Les sidis 11 et 12 sont appariés. La quatrième paire est constituée des sidis 13 et 14. Les sidis 15 et 16 sont isolés à la fin de C1. Plus le nombre de sidis est élevé, plus il peut y avoir de plages d'isolement distinctes.

4.2.7. Contrôle de validité des cas générés

La description, faite ci-dessus de la procédure FIXER s'est faite en supposant que les m-1 paires chaque fois générées par cette procédure remplissaient la condition d'éligibilité. C'est-à-dire que pour chaque paire, la chaîne minimale séparant les deux sidis qui la composent était inférieure ou égale à Cmax. Dans la pratique, et tel que le montre la dernière partie de cette procédure, les m-1 premières paires ne sont renvoyées à la procédure COMBINE que si cette condition est remplie. La procédure COMBINE génère alors la dernière paire et vérifie que la même condition est remplie pour cette paire.

Si par exemple Mcm(1,2) est supérieur à Cmax, la procédure FIXER ne renverra à la procédure FIXER aucun cas possible contenant la paire (S_1,S_2).

Elle va directement passer aux cas possibles contenant la paire (S_1,S_3). Evaluons pour n=10 par exemple le nombre de cas possibles ainsi éliminés. Nous avons dit plus haut au niveau du théorème 1 que les cas possibles de i paires contenant une paire de type (S_1,S_a) avec 1<a<=n sont au nombre de (n-1) Γ^{i-1}_{n-2}. Notons $A_{1,n}$ le nombre de cas possibles contenant une paire de type (S_1,S_a). Nous aurons□

$$A_{11,n} = \sum_{i=1}^{ent(n/2)} (n-1)\Gamma^{i-1}_{n-2}$$

$$A_{1,10} = 9\left(\Gamma^{0}_{8} + \Gamma^{1}_{8} + \Gamma^{2}_{8} + \Gamma^{3}_{8} + \Gamma^{4}_{8}\right) = 9 \text{ x } 764 = 6876$$

Les différentes valeurs sont données par le tableau 1 présenté plus haut. Pour n=10 un tel passage élimine donc l'examen de 6 876 cas possibles. Ce qui représente plus de 72 % de l'ensemble des cas. Ce pourcentage est assez élevé pour qu'il soit intéressant de recenser et de noter dans la matrice de chaîne minimale les sidis qu'il ne faut pas apparier. Le tableau 2 donne en dernière ligne les différents pourcentages pour n variant de 2 à 14. La deuxième ligne de ce tableau donne le nombre de cas éliminés, la troisième ligne donne le nombre de cas au total (Γ_n) comme précisé dans le tableau 1. Ce

tableau montre que le pourcentage croît en fonction de n et se trouve au dessus de cinquante pour les valeurs examinées.

	$A_{1,2}$	$A_{1,3}$	$A_{1,4}$	$A_{1,5}$	$A_{1,6}$	$A_{1,7}$	$A_{1,8}$	$A_{1,9}$	$A_{1,10}$	$A_{1,11}$	$A_{1,12}$	$A_{1,13}$	$A_{1,14}$
Nb cas	1	2	6	16	50	156	532	1 856	6 876	26 200	104 456	428 352	1 821 846
Total	2	4	10	26	76	232	764	2 620	9 496	35 696	140 142	568 504	2 255 345
%	50	50	60,0	61,5	65,8	67,2	69,6	70,8	72,4	73,4	74,5	75,3	80,8

Tableau 2. *Pourcentage des cas éliminés par la condition d'éligibilité.*

4.2.8. Autre paramétrage

Dans la démarche que nous venons de présenter, nous avons proposé une recherche du degré de retournement par examen des différents cas possibles en commençant par ceux contenant une paire de sidis et en allant vers ceux contenant le plus grand nombre de paires. Un paramétrage approprié permet de faire une recherche locale d'un poids minimum, c'est-à-dire un poids minimum pour des cas possibles contenant un nombre donné de paires de sidi. Il suffit pour cela de préciser comme paramètre le nombre de paires minimum par cas possible, le nombre maximum par cas possible et le sens de la recherche (croissant ou décroissant).

5. Exemples d'application

L'algorithme présenté plus haut a été implémenté en langage Pascal et nous l'avons testé sur des exemples. Nous en présentons deux dans cette partie.

5.1 Exemple 1

Le graphe de la figure 8 présente le plan simplifié d'une ville avec ses rues et carrefours. Ce graphe planaire possède 16 sidis numérotés de 1 à 16 sur la figure. Combien de rues au minimum (degré de retournement de ce plan) faut-il mettre dans les deux sens et les autres en sens unique pour que chaque habitant puisse faire le tour de son quartier en respectant les sens imposés? L'algorithme proposé trouve neuf rues (neuf degrés de retournement) avec les sept paires de sidis suivantes :

(1,2); (3,4), (5,10), (6,7), (8,9), (11,16), (12,13) et deux sidis isolés à savoir 14 et 15.

Sur le plan les flèches indiquent les rues à double sens. Une solution équivalente consiste à apparié aussi les sidis 14 et 15. On obtient ainsi huit paires de sidis appariés. La chaîne minimale de la dernière paire de sidis étant égale à deux cela ne change pas le degré de retournement.

Le vecteur de profondeur associé au graphe de la figure 8 est présenté dans le tableau 3.

Numéro du Sidi	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**	**13**	**14**	**15**	**16**
Profondeur	1	1	2	1	1	1	2	3	2	2	1	1	2	1	1	1

Tableau 3. *Profondeur des sidis du graphe de la figure 8*

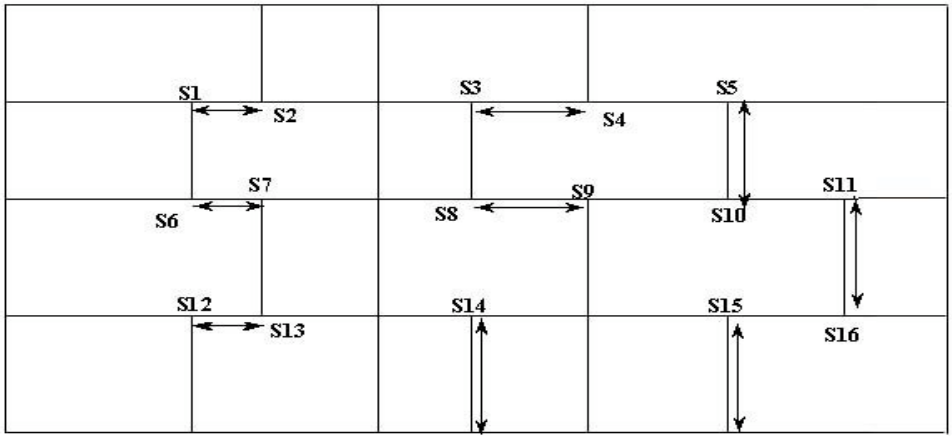

Figure 8. *Plan d'une ville*

La matrice de chaîne minimale associée au plan de la figure 8 est présentée dans le tableau 4.

	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**	**13**	**14**	**15**
2	1														
3	3	2													
4	4	3	1												
5	5	4	2	1											
6	1	2	4	5	6										
7	2	3	3	4	5	1									
8	4	3	1	2	3	3	2								
9	5	4	2	3	2	4	3	1							
10	6	5	3	2	1	5	4	2	1						
11	7	6	4	3	2	6	5	3	2	1					
12	4	5	5	6	7	3	2	4	5	6	7				
13	3	4	4	5	6	2	1	3	4	5	6	1			
14	5	4	4	5	4	4	3	3	2	3	4	3	2		
15	7	6	4	5	4	6	5	3	2	3	2	5	4	2	
16	8	7	5	4	3	7	6	4	3	2	1	6	5	3	1

Tableau 4. *Matrice de chaîne minimale des sidis du graphe de la figure 8*

5.2 Exemple 2

Le deuxième exemple concerne la carte de la France avec son découpage en régions. Cette carte possède 23 sidis. L'algorithme a trouvé comme degré de retournement douze ainsi que le montrent les flèches placées sur la carte. Il suffit d'imposer une orientation à n'importe quelle arête non orientée dans les deux sens pour en déduire l'orientation des autres arêtes et aboutir au fait que chaque face est délimitée par un circuit.

Les temps de calcul sont élevés. Le cas de la carte de la France a nécessité plus de 23 heures de calcul sur un Pentium 333 Mhz avec l'algorithme non optimisé et une recherche systématique qui a examiné tous les cas possibles. Avec l'algorithme optimisé qui ne prend en compte que les cas possibles ne contenant que des paires éligibles, le calcul prend à peine deux minutes.

Dans le cas pratique de la carte de la France, le minimum absolu pour le degré de retournement est atteint (12 degré pour 23 sidis). On peut modifier la procédure POIDS pour que l'algorithme s'arête automatiquement quand le minimum absolu est atteint. Ce qui évite de continuer inutilement les recherches quand un cas possible de ce poids est trouvé.

Figure 9. *Carte de la France avec le découpage en régions.*

5.3 Exemple 3

Avant de présenter cet exemple nous allons donner quelques résultats permettant de mieux l'illustrer.

Théorème 3

Soit E l'ensemble des cas éligibles tel que Cmax = 1 et tout sidi isolé est de profondeur 1. Alors tout élément de E ayant un nombre maximal de paires est de poids minimum dans E.

Soit x un élément de E contenant m paires de sidis. Le poids associé à x est n–m ou n désigne le nombre de sidis. Pour un autre cas y contenant m – 1 paires, le poids

associé est n–(m-1) = n-m+1. Le poids de x est donc inférieur au poids de y donc au poids de tout cas contenant moins de paires de sidis.

La condition d'éligibilité d'un cas possible énoncée dans ce théorème 3 est surtout intéressante pour les graphes qui sont comme les cartes de géographie. En effet les cartes de géographie contiennent des sidis de degré trois et très rarement des sidis de degré pair.

La carte de la figure 10 est celle de l'Afrique avec son découpage en états. Cette carte possède 55 sidis. Pour évaluer son degré de retournement il a fallu en plus de l'algorithme optimisé choisir un sens de recherche à partir du nombre maximum de paires possibles (27 dans ce cas) et en allant vers 1. Nous avons aussi imposé la condition d'éligibilité énoncée dans le théorème 3. L'algorithme n'a trouvé aucun cas possible éligible avec 27 paires de sidis. Le premier cas éligible a 26 paires de sidis et donc trois sidis isolés tous de profondeur 1. Le poids correspondant à ce cas est de 29. Le degré de retournement de cette carte de l'Afrique est donc inférieur ou égal à 29. Mais comme aucun cas possible éligible ne possède 27 paires, 29 est effectivement le degré de retournement de cette carte. Ceci vient du simple fait que tout cas ayant 27 paires de sidis contient au moins une paire de chaîne minimale supérieure à 1 ou contient un sidi isolé de profondeur supérieur à 1.

C0 qui résume le cas possible associé au degré de retournement est le suivant⊡

-1	2	-3	9	-4	7	-5	10	-6	11	-8	12
-13	27	-14	15	-16	17	18	-19	20	-21	22	23
-24	25	-26	33	-28	29	30	-31	32	-34	37	-35
36	-38	55	-39	41	-40	48	-42	49	-43	44	-45
47	-46	54	-50	51	-52	53					

Les sidis isolés sont les sidis 18, 23 et 30. Ce résultat est obtenu en moins d'une minute. Pour examiner tous les 3 140 cas éligibles il faut cependant plus d'une heure sur un Pentium 133 MHZ. Parmi ces cas éligibles il y a plusieurs cas de poids égal à 29.

On peut se rendre compte que la numérotation initiale des sidis n'influence pas le résultat. Le sidi 3 est apparié au sidi 9, le sidi 26 au sidi 33 et le sidi 38 au sidi 55 par exemple.

Figure 10. *Carte d'Afrique avec le découpage en pays.*

Avec l'examen de ces trois exemples on se rend compte que d'autres améliorations peuvent encore être faites sur l'algorithme. Particulièrement en affinant la notion de cas éligible. On peut aussi modifier la procédure COMBINE pour qu'elle ne fasse les combinaisons que dans le cas où le poids des m-1 paires est au plus égal à p0-2. Si le poids des m-1 premières paires est au moins égal à p0-1, aucun des poids du nouveau cas à obtenir dans la procédure COMBINE ne peut être inférieur au minimum. En effet la dernière paire à constituer aura comme chaîne minimale au moins un.

6. Conclusion

Nos précédents travaux ont montré que la connaissance du degré de retournement d'une carte avec l'orientation des différentes arêtes associée permet de minimiser le nombre de retournement à effectuer dans la confection des contours lors de la digitalisation au millimètre. Le degré de retournement intervient aussi, comme nous l'avons signalé, dans les SIG fonctionnant selon le modèle vecteur topologique.

Dans ce présent document nous avons rappelé des formules permettant de calculer le degré de retournement d'un graphe dans le cas général. De ces formules, il ressort qu'il faut examiner un nombre de cas qui est une fonction croissante du nombre de sommets intérieurs de degré impair du graphe considéré. A partir de 6 sommets intérieurs de degré impair, cette fonction croît plus vite que la fonction exponentielle. C'est un problème d'explosion ou d'optimisation combinatoire. Pour examiner dans un temps acceptable tous ces cas possibles il faut utiliser des méthodes appropriées comme celles de séparation et d'évaluation.

Nous avons proposé un algorithme permettant de générer toutes les situations ou cas possibles et d'en déduire le degré de retournement pour tout graphe planaire topologique donné. Nous avons utilisé pour cela une méthode de séparation et d'évaluation avec un parcours en profondeur de l'arbre associé. Des améliorations de cet algorithme nous ont permis de l'appliquer en des temps d'exécution tout à fait raisonnables sur trois exemples pratiques de difficulté graduée. L'un des cas comporte cinquante cinq sommets intérieurs de degré impair. Les résultats sont présentés ici. Une analyse plus approfondie permettra de mieux optimiser l'approche et de réduire davantage les temps de calcul tout en abordant des graphes ayant un nombre de sommets intérieurs de degré impair toujours plus important.

Asymptotic Enumeration Methods

A. M. Odlyzko

AT&T Bell Laboratories
Murray Hill, New Jersey 07974

1. Introduction

Asymptotic enumeration methods provide quantitative information about the rate of growth of functions that count combinatorial objects. Typical questions that these methods answer are: (1) How does the number of partitions of a set of n elements grow with n? (2) How does this number compare to the number of permutations of that set?

There do exist enumeration results that leave nothing to be desired. For example, if a_n denotes the number of subsets of a set with n elements, then we trivially have $a_n = 2^n$. This answer is compact and explicit, and yields information about all aspects of this function. For example, congruence properties of a_n reduce to well-studied number theory questions. (This is not to say that all such questions have been answered, though!) The formula $a_n = 2^n$ also provides complete quantitative information about a_n. It is easy to compute for any value of n, its behavior is about as simple as possible, and it holds uniformly for all n. However, such examples are extremely rare. Usually, even when there is a formula for the function we are interested in, it is a complicated one, involving summations or recurrences. The purpose of asymptotic methods is to provide simple explicit formulas that describe the behavior of a sequence for large values of indices. There is no satisfactory definition of what is meant by "simple" or by "explicit." However, we can illustrate this concept by some examples. The number of permutations of n letters is given by $b_n = n!$. This is a compact notation, but only in the sense that factorials are so widely used that they have a special symbol. The symbol $n!$ stands for $n \cdot (n-1) \cdot (n-2) \cdot \ldots \cdot 2 \cdot 1$, and it is the latter formula that has to be used to answer questions about the number of permutations. If one is after arithmetic information, such as the highest power of 7, say, that divides $n!$, one can obtain it from the product formula, but even then some work has to be done. For most quantitative purposes, however, $n! = n \cdot (n-1) \cdot \ldots \cdot 2 \cdot 1$ is inadequate. Since this formula is a product of n terms, most of them large, it is clear that $n!$ grows rapidly, but it is not obvious just how rapidly. Since all but the last term are ≥ 2, we have $n! \geq 2^{n-1}$, and since all but the last two terms are ≥ 3, we have $n! \geq 3^{n-2}$, and so on. On the other hand, each term is $\leq n$, so $n! \leq n^n$. Better bounds can clearly be obtained with

greater care. The question such estimates raise is just how far can one go? Can one obtain an estimate for $n!$ that is easy to understand, compute, and manipulate? One answer provided by asymptotic methods is Stirling's formula: $n!$ is asymptotic to $(2\pi n)^{1/2}(n/e)^n$ as $n \to \infty$, which means that the limit as $n \to \infty$ of $n!(2\pi n)^{-1/2}(n/e)^{-n}$ exists and equals 1. This formula is concise and gives a useful representation of the growth rate of $n!$. It shows, for example, that for n large, the number of permutations on n letters is considerably larger than the number of subsets of a set with $\lfloor \frac{1}{2} n \log n \rfloor$ elements.

Another simple example of an asymptotic estimate occurs in the "problème des rencontres" [81]. The number d_n of *derangements* of n letters, which is the number of ways of handing back hats to n people so that no person receives his or her own hat, is given by

$$d_n = \sum_{k=0}^{n} (-1)^k \frac{n!}{k!} \ . \tag{1.1}$$

This is a nice formula, yet to compute d_n exactly with it requires substantial effort, since the summands are large, and at first glance it is not obvious how large d_n is. However, we can obtain from (1.1) the asymptotic estimate

$$\frac{d_n}{n!} \to e^{-1} \quad \text{as} \quad n \to \infty \ . \tag{1.2}$$

To prove (1.2), we factor out $n!$ from the sum in (1.1). We are then left with a sum of rapidly decreasing terms that make up the initial segment of the series

$$e^{-1} = \sum_{k=0}^{\infty} \frac{(-1)^k}{k!} \ ,$$

and (1.2) follows easily. It can even be shown that d_n is the nearest integer to $e^{-1}n!$ for all $n \geq 1$, see [81]. The estimate (1.2) does not allow us to compute d_n, but combined with the estimate for $n!$ cited above it shows that d_n grows like $(2\pi n)^{1/2} n^n e^{-n-1}$. Further, (1.2) shows that the fraction of all ways of handing out hats that results in every person receiving somebody else's hat is approximately $1/e$. Results of this type are often exactly what is desired.

Asymptotic estimates usually provide information only about the behavior of a function as the arguments get large. For example, the estimate for $n!$ cited above says only that the ratio of $n!$ to $(2\pi n)^{1/2}(n/e)^n$ tends to 1 as n gets large, and says nothing about the behavior of this ratio for any specific value of n. There are much sharper and more precise bounds for $n!$, and they will be presented in Section 3. However, it is generally true that the simpler the estimate, the weaker and less precise it is. There seems to be an unavoidable tradeoff

between conciseness and precision. Just about the simplest formula that exactly expresses $n!$ is $n \cdot (n-1) \cdot \ldots \cdot 2 \cdot 1$. (We have to be careful, since there is no generally accepted definition of simplicity, and in many situations it is better to use other exact formulas for $n!$, such as the integral formula $n! = \int_0^\infty t^n e^{-t} dt$ for the Γ-function. There are also methods for evaluating $n!$ that are somewhat more efficient than the straightforward evaluation of the product.) Any other formula is likely to involve some loss of accuracy as a penalty for simplicity.

Sometimes, the tradeoffs are clear. Let $p(n)$ denote the number of partitions of an integer n. The Rademacher convergent series representation [13, 23] for $p(n)$ is valid for any $n \geq 1$:

$$p(n) = \pi^{-1} 2^{-1/2} \sum_{m=1}^{\infty} A_m(n) m^{1/2} \frac{d}{dv} (\lambda_v^{-1} \sinh(C m^{-1} \lambda_v)) \Big|_{v=n} , \tag{1.3}$$

where

$$C = \pi (2/3)^{1/2}, \quad \lambda_v = (v - 1/24)^{1/2} , \tag{1.4}$$

and the $A_m(n)$ satisfy

$$A_1(n) = 1, \quad A_2(n) = (-1)^n \quad \text{for all} \quad n \geq 1 ,$$

$$|A_m(n)| \leq m, \qquad\qquad \text{for all} \quad m, n \geq 1 ,$$

and are easy to compute. Remarkably enough, the series (1.3) does yield the exact integer value of $p(n)$ for every n, and it converges rapidly. (Although this is not directly relevant, we note that using this series to compute $p(n)$ gives an algorithm for calculating $p(n)$ that is close to optimal, since the number of bit operations is not much larger than the number of bits of $p(n)$.) By taking more and more terms, we obtain better and better approximations. The first term in (1.3) shows that

$$p(n) = \pi^{-1} 2^{-1/2} \frac{d}{dv} (\lambda_v^{-1} \sinh(C \lambda_v)) \Big|_{v=n} + O(n^{-1} \exp(C n^{1/2}/2)) , \tag{1.5}$$

and if we don't like working with hyperbolic sines, we can derive from (1.5) the simpler (but less precise) estimate

$$p(n) = \frac{1 + O(n^{-1/2})}{4 \cdot 3^{1/2} n} e^{C n^{1/2}} , \tag{1.6}$$

valid for all $n \geq 1$. Unfortunately, exact and rapidly convergent series such as (1.3) occur infrequently in enumeration, and in general we have to be content with poorer approximations.

The advantage of allowing parameters to grow large is that in surprisingly many cases, even when there do exist explicit expressions for the functions we are interested in, this procedure does yield simple asymptotic approximations, when the influence of less important factors falls

off. The resulting estimates can then be used to compare numbers of different kinds of objects, decide what the most common objects in some category are, and so on. Even in situations where bounds valid for all parameter values are needed, asymptotic estimates can be used to suggest what form those bounds should take. Usually the error terms in asymptotic estimates can be made explicit (although good bounds often require substantial work), and can be used together with computations of small values to obtain universal estimates. It is common that already for n not much larger than 10 (where n is the basic parameter) the asymptotic estimate is accurate to within a few percent, and for $n \geq 100$ it is accurate to within a fraction of a percent, even though known proofs do not guarantee results as good as this. Therefore the value of asymptotic estimates is much greater than if they just provided a picture of what happens at infinity.

Under some conditions, asymptotic results can be used to prove completely uniform results. For example, if there were any planar maps that were not four-colorable, then almost every large planar map would not be four-colorable, as it would contain one of those small pathological maps. Therefore if it could be proved that most large planar maps are four-colorable, we would obtain a new proof of the four-color theorem that would be more satisfactory to many people than the original one of Haken and Appel. Unfortunately, while this is an attractive idea, no proof of the required asymptotic estimate for the normal chromatic number of planar maps has been found so far.

Asymptotic estimates are often useful in deciding whether an identity is true. If the growth rates of the two functions that are supposed to be equal are different, then the coincidence of initial values must be an accident. There are also more ingenious ways, such as that of Example 13.1, for deducing nonexistence of identities in a wide class from asymptotic information. Sometimes asymptotics is used in a positive way, to suggest what identities might hold.

Simplicity is an important advantage of asymptotic estimates. They are even more useful when no explicit formulas for the function being studied are available, and one has to deal with indirect relations. For example, let T_n be the number of rooted unlabeled trees with n vertices, so that $T_0 = 0$, $T_1 = T_2 = 1$, $T_3 = 2$, $T_4 = 4, \ldots$. No explicit formula for the T_n is known. However, if

$$T(z) = \sum_{n=1}^{\infty} T_n z^n \tag{1.7}$$

is the ordinary generating function of T_n, then Cayley and Pólya showed that

$$T(z) = z \exp\left(\sum_{k=1}^{\infty} T(z^k)/k\right) . \tag{1.8}$$

This functional equation can be derived using the general Pólya-Redfield enumeration method, an approach that is sketched in Section 15. Example 15.1 shows how analytic methods can be used to prove, starting with Eq. (1.8), that

$$T_n \sim C r^{-n} n^{-3/2} \quad \text{as} \quad n \to \infty , \tag{1.9}$$

where

$$C = 0.4399237\ldots , \quad r = 0.3383219\ldots , \tag{1.10}$$

are constants that can be computed efficiently to high precision. For $n = 20$, $T_n = 12,826,228$, whereas $Cr^{-20}20^{-3/2} = 1.274\ldots \times 10^7$, so asymptotic formula (1.9) is accurate to better than 1%. Thus this approximation is good enough for many applications. It can also be improved easily by adding lower order terms.

Asymptotic enumeration methods are a subfield of the huge area of general asymptotic analysis. The functions that occur in enumeration tend to be of restricted form (often nonnegative and of regular growth, for example) and therefore the repertoire of tools that are commonly used is much smaller than in general asymptotics. This makes it possible to attempt a concise survey of the most important techniques in asymptotic enumeration. The task is not easy, though, as there has been tremendous growth in recent years in combinatorial enumeration and the closely related field of asymptotic analysis of algorithms, and the sophistication of the tools that are commonly used has been increasing rapidly.

In spite of its importance and growth, asymptotic enumeration has seldom been presented in combinatorial literature at a level other than that of a research paper. There are several books that treat it [43, 81, 175, 177, 235, 236, 237, 377], but usually only briefly. The only comprehensive survey that is available is the excellent and widely quoted paper of Bender [33]. Unfortunately it is somewhat dated. Furthermore, the last two decades have also witnessed a flowering of asymptotic analysis of algorithms, which was pioneered and popularized by Knuth. Combinatorial enumeration and analysis of algorithms are closely related, in that both deal with counting of particular structures. The methods used in the two fields are almost the same, and there has been extensive cross-fertilization between them. The literature on theoretical computer science, especially on average case analysis of algorithms, can therefore

be used fruitfully in asymptotic enumeration. One notable survey paper in that area is that of Vitter and Flajolet [371]. There are also presentations of relevant methods in the books [177, 209, 235, 236, 237, 223]. Section 18 is a guide to the literature on these topics.

The aim of this chapter is to survey the most important tools of asymptotic enumeration, point out references for the results and methods that are discussed, and to mention additional relevant papers that have other techniques that might be useful. It is intended for a reader who has already used combinatorial, algebraic, or probabilistic methods to reduce a problem to that of estimating sums, coefficients of a generating function, integrals, or terms in a sequence satisfying some recursion. How such a reduction is to be accomplished will be dealt with sparingly, since it is a large subject that is already covered extensively in other chapters, especially [**?**]. We will usually assume that this task has been done, and will discuss only the derivation of asymptotic estimates.

The emphasis in this chapter is on elementary and analytic approaches to asymptotic problems, relying extensively on explicit generating functions. There are other ways to solve some of the problems we will discuss, and probabilistic methods in particular can often be used instead. We will only make some general remarks and give references to this approach in Section 16.

The only methods that will be discussed in detail are fully rigorous ones. There are also methods, mostly from classical applied mathematics (cf. [31]) that are powerful and often give estimates when other techniques fail. However, we do not treat them extensively (aside from some remarks in Section 16.4) since many of them are not rigorous.

Few proofs are included in this chapter. The stress is on presentation of basic methods, with discussions of their range of applicability, statements of general estimates derivable from them, and examples of their applications. There is some repetitiveness in that several functions, such as $n!$, are estimated several times. The purpose of doing this is to show how different methods compare in their power and ease of use. No attempt is made to present derivations starting from first principles. Some of the examples are given with full details of the asymptotic analysis, to explain the basic methods. Other examples are barely more than statements of results with a brief explanation of the method of proof and a reference to where the proof can be found. The reader might go through this chapter, possibly in a random order, looking for methods that might be applicable to a specific problem, or can look for a category of methods that might fit the problem and start by looking at the corresponding sections.

There are no prerequisites for reading most of this chapter, other than acquaintance with advanced calculus and elementary asymptotic estimates. Many of the results are presented so that they can be used in a cookbook fashion. However, many of the applications require knowledge of complex variables.

Section 2 presents the basic notation used throughout the chapter. It is largely the standard one used in the literature, but it seemed worthwhile summarizing it in one place. Section 3 is devoted to a brief discussion of identities and related topics. While asymptotic methods are useful and powerful, they can often be either augmented or entirely replaced by identities, and this section points out how to use them.

Section 4 summarizes the most important and most useful estimates in combinatorial enumeration, namely those related to factorials and binomial coefficients. Section 5 is the first one to feature an in-depth discussion of methods. It deals with estimates of sums in terms of integrals, summation formulas, and the inclusion-exclusion principle. However, it does not present the most powerful tool for estimation of sums, namely generating functions. These are introduced in Section 6, which presents some of the basic properties of, and tools for dealing with generating functions. While most generating functions that are used in combinatorial enumeration converge at least in some neighborhood of the origin, there are also many nonconvergent ones. Section 7 discusses some estimates that apply to all formal series, but are especially useful for nonconvergent ones.

Section 8 is devoted to estimates for convergent power series that do not use complex variables. While not as powerful as the analytic methods presented later, these techniques are easy to use and suffice in many applications.

Section 9 presents a variety of techniques for determining the asymptotics of recurrence relations. Many of these methods are based on generating functions, and some use analytic methods that are discussed later in the chapter. They are presented at this point because they are basic to combinatorial enumeration, and they also provide an excellent illustration of the power of generating functions.

Section 10 is an introduction to the analytic methods for estimating generating functions. Many of the results mentioned here are common to all introductory complex analysis courses. However, there are also many, especially those in Sections 10.4 and 10.5, are not as well known, and are of special value in asymptotics.

Sections 11 and 12 present the main methods used in estimation of coefficients of analytic

functions in a single variable. The basic principle is that the singularities of the generating function that are closest to the origin determine the growth rate of the coefficients. If the function does not grow too fast as it approaches those singularities, the methods of Section 11 are usually applicable, while if the growth rate is high, methods of Section 12 are more appropriate.

Sections 13–15 discuss extensions of the basic methods of Sections 10–12 to multivariate generating functions, integral transforms, and problems that involve a combination of methods.

Section 16 is a collection of miscellaneous methods and results that did not easily fit into any other section, yet are important in asymptotic enumeration. Section 17 discusses the extent to which computer algebra systems can be used to derive asymptotic information. Finally, Section 18 is a guide to further reading on asymptotics, since this chapter does not provide complete coverage of the topic.

2. Notation

The symbols O, o, and $\sim$ will have the usual meaning throughout this paper:

$$f(z) = O(g(z)) \text{ as } z \to w \text{ means } f(z)/g(z) \text{ is bounded as } z \to w ;$$

$$f(z) = o(g(z)) \text{ as } z \to w \text{ means } f(z)/g(z) \to 0 \text{ as } z \to w ;$$

$$f(z) \sim g(z) \text{ as } z \to w \text{ means } f(z)/g(z) \to 1 \text{ as } z \to w .$$

When an asymptotic relation is stated for an integer variable n instead of z, it will implicitly be taken to apply only for integer values of $n \to w$, and then we will always have $w = \infty$ or $w = -\infty$. An introduction to the use of this notation can be found in [175]. Only a slight acquaintance with it is assumed, enough to see that $(1 + O(n^{-1/3}))^n = \exp(O(n^{2/3}))$ and $\log(n + n^{1/2}) = \log(n) + n^{-1/2} - (2n)^{-1} + O(n^{-3/2})$.

The notation $x \to w^-$ for real w means that x tends to w only through values $x < w$.

Some asymptotic estimates refer to *uniform convergence*. As an example, the statement that $f(z) \sim (1-z)^{-2}$ as $z \to 1$ uniformly in $|\mathrm{Arg}(1-z)| < 2\pi/3$ means that for every $\epsilon > 0$, there is a $\delta < 0$ such that

$$|f(z)(1-z)^2 - 1| \le \epsilon$$

for all z with $0 < |1-z| < \delta$, $|\mathrm{Arg}(1-z)| < 2\pi/3$. This is an important concept, since lack of uniform convergence is responsible for many failures of asymptotic methods to yield useful results.

Generating functions will usually be written in the form

$$f(z) = \sum_{n=0}^{\infty} f_n z^n \ , \tag{2.1}$$

and we will use the notation $[z^n]f(z)$ for the coefficient of z^n in $f(z)$, so that if $f(z)$ is defined by (2.1), $[z^n]f(z) = f_n$. For multivariate generating functions, $[x^m y^n]f(x,y)$ will denote the coefficient of $x^m y^n$, and so on. If a_n denotes a sequence whose asymptotic behavior is to be studied, then in combinatorial enumeration one usually uses either the *ordinary generating function* $f(z)$ defined by (2.1) with $f_n = a_n$, or else the *exponential generating function* $f(z)$ defined by (2.1) with $f_n = a_n/n!$. In this chapter we will not be concerned with the question of which type of generating function is best in a given context, but will assume that a generating function is given, and will concentrate on methods of extracting information about the coefficients from the form we have.

Asymptotic series, as defined by Poincaré, are written as

$$f_n \sim \sum_{k=0}^{\infty} a_k n^{-k} \ , \tag{2.2}$$

and mean that for every $K \geq 0$,

$$f_n = \sum_{k=0}^{K} a_k n^{-k} + O(n^{-K-1}) \quad \text{as} \quad n \to \infty \ . \tag{2.3}$$

The constant implied by the O-notation may depend on K. It is unfortunate that the same symbol is used to denote an asymptotic series as well as an asymptotic relation, defined in the first paragraph of this section. Confusion should be minimal, though, since asymptotic relations will always be written with an explicit statement of the limit of the argument.

The notation $f(z) \approx g(z)$ will be used to indicate that $f(z)$ and $g(z)$ are in some vague sense close together. It is used in this chapter only in cases where a precise statement would be cumbersome and would not help in explaining the essence of the argument.

All logarithms will be natural ones to base e unless specified otherwise, so that $\log 8 = 2.0794\ldots$, $\log_2 8 = 3$. The symbol $\lfloor x \rfloor$ denotes the greatest integer $\leq x$. The notation $x \to 1^-$ means that x tends to 1, but only from the left, and similarly, $x \to 0^+$ means that x tends to 0 only from the right, through positive values.

3. Identities, indefinite summations, and related approaches

Asymptotic estimates are useful, but often they can be avoided by using other methods. For example, the asymptotic methods presented later yield estimates for $\binom{n}{k}2^k$ as k and n vary,

which can be used to estimate accurately the sum of $\binom{n}{k}2^k$ for n fixed and k running over the full range from 0 to n. That is a general and effective process, but somewhat cumbersome. On the other hand, by the binomial theorem,

$$\sum_{k=0}^{n} \binom{n}{k} 2^k = (1+2)^n = 3^n \ . \tag{3.1}$$

This is much more satisfactory and simpler to derive than what could be obtained from applying asymptotic methods to estimate individual terms in the sum. However, such identities are seldom available. There is nothing similar that can be applied to

$$\sum_{k \le n/5} \binom{n}{k} 2^k \ , \tag{3.2}$$

and we are forced to use asymptotic methods to estimate this sum.

Recognizing when some combinatorial identity might apply is not easy. The literature on this subject is huge, and some of the references for it are [172, 174, 186, 216, 336]. Many of the books listed in the references are useful for this purpose. Generating functions (see Section 6) are one of the most common and powerful tools for proving identities. Here we only mention two recent developments that are of significance for both theoretical and practical reasons. One is Gosper's algorithm for indefinite hypergeometric summation [171, 175]. Given a sequence $a_1, a_2, \ldots$, Gosper's algorithm determines whether the sequence of partial sums

$$b_n = \sum_{k=1}^{n} a_k \ , \quad n = 1, 2, \ldots \tag{3.3}$$

has the property that b_n/b_{n-1} is a rational function of n, and if it is, it gives an explicit form for b_n. We note that if b_n/b_{n-1} is a rational function of n, then so is

$$\frac{a_n}{a_{n-1}} = \frac{b_n/b_{n-1} - 1}{1 - b_{n-2}/b_{n-1}} \ . \tag{3.4}$$

Therefore Gosper's algorithm should be applied only when a_n/a_{n-1} is rational.

The other recent development is the Wilf-Zeilberger method for proving combinatorial identities [379, 380]. Given a conjectured identity, it provides an algorithmic procedure for verifying it. This method succeeds in a surprisingly wide range of cases. Typically, to prove an identity of the form

$$\sum_{k} U(n,k) = S(n) \ , \quad n \ge 0 \ , \tag{3.5}$$

where $S(n) \neq 0$, Wilf and Zeilberger define $F(n,k) = U(n,k)/S(n)$ and search for a rational function $R(n,k)$ such that if $G(n,k) = R(n,k)F(n,k-1)$, then

$$F(n+1,k) - F(n,k) = G(n,k+1) - G(n,k) \tag{3.6}$$

holds for all integers n, k with $n \geq 0$, and such that

1) for each integer k, the limit

$$f_k = \lim_{n\to\infty} F(n,k) \tag{3.7}$$

exists and is finite.

2) for each integer $n \geq 0$, $\lim_{k\to\pm\infty} G(n,k) = 0$.

3) $\lim_{k\to-\infty} \sum_{n=0}^{\infty} G(n,k) = 0$.

If all these conditions are satisfied, and Eq. (3.5) holds for $n = 0$, then it holds for all $n \geq 0$.

Example 3.1. *Dixon's binomial sum identity.* This identity states that

$$\sum_k (-1)^k \binom{n+b}{n+k}\binom{b+c}{b+k}\binom{n+c}{c+k} = \frac{(n+b+c)!}{n!\,b!\,c!}\ . \tag{3.8}$$

This can be proved by the Wilf-Zeilberger method by taking

$$R(n,k) = \frac{(b+1-k)(c+1-k)}{2(n+k)(n+b+c+1)} \tag{3.9}$$

and verifying that the conditions above hold. ■

The Wilf-Zeilberger method requires finding a rational function $R(n,k)$ that satisfies the properties listed above. This is often hard to do, especially by hand. Gosper's algorithm leads to a systematic procedure for constructing such $R(n,k)$.

To conclude this section, we mention that a useful resource when investigating sequences arising in combinatorial settings is the book of Sloane [345, 346], which lists several thousand sequences and gives references for them. Section 17 mentions some software systems that are useful in asymptotics.

4. Basic estimates: factorials and binomial coefficients

No functions in combinatorial enumeration are as ubiquitous and important as the factorials and the binomial coefficients. In this section we state some estimates for these quantities, which will be used throughout this chapter and are of widespread applicability. Several different proofs of some of these estimates will be sketched later.

The basic estimate, from which many others follow, is that for the factorial. As was mentioned in the introduction, the basic form of Stirling's formula is

$$n! \sim (2\pi n)^{1/2} n^n e^{-n} \quad \text{as} \quad n \to \infty \; . \tag{4.1}$$

This is sufficient for many enumeration problems. However, when necessary one can draw on much more accurate estimates. For example Eq. 6.1.38 in [297] gives

$$n! = (2\pi n)^{1/2} n^n \exp(-n + \theta/(12n)) \tag{4.2}$$

for all $n \geq 1$, where $\theta = \theta(n)$ satisfies $0 < \theta < 1$. More generally, there is Stirling's asymptotic expansion:

$$\log\{n!(2\pi n)^{-1/2} n^{-n} e^n\} \sim \frac{1}{12n} - \frac{1}{360n^3} + \cdots \; . \tag{4.3}$$

(This is an asymptotic series in the sense of Eq. (2.2), and there is no convergent expansion for $\log\{n!(2\pi n)^{-1/2} n^{-n} e^n\}$ as a power series in n^{-1}.) Further terms in the expansion (4.3) can be obtained, and they involve Bernoulli numbers. In most references, such as Eq. 6.1.37 or 6.1.40 of [297], Stirling's formula is presented for $\Gamma(x)$, where Γ is Euler's gamma function. Expansions for $\Gamma(x)$ translate readily into ones for $n!$ because $n! = \Gamma(n+1)$.

Stirling's approximation yields the expansion

$$\binom{2n}{n} = \frac{4^n}{(\pi n)^{1/2}} \left\{ 1 - \frac{1}{8n} + \frac{1}{128n^2} + \frac{5}{1024n^3} + O(n^{-4}) \right\} \; . \tag{4.4}$$

A less precise but still useful estimate is

$$\binom{n}{\lfloor n/2 \rfloor} \sim \left(\frac{2}{\pi n} \right)^{1/2} 2^n \quad \text{as} \quad n \to \infty \; . \tag{4.5}$$

This estimate is used frequently. The binomial coefficients are *symmetric*, so that $\binom{n}{k} = \binom{n}{n-k}$ and *unimodal*, so that for a fixed n and k varying, the $\binom{n}{k}$ increase monotonically up to a peak at $k = \lfloor n/2 \rfloor$ (which is unique for n even and has two equal high points at $k = (n \pm 1)/2$ for n odd) and then decrease.

More important than Eq. (4.5) are expansions for general binomial coefficients. Eq. (4.2) shows that for $1 \le k \le n-1$,

$$\binom{n}{k} = \frac{n!}{k!(n-k)!} = \left\{\frac{n}{2\pi k(n-k)}\right\}^{1/2} \frac{n^n}{k^k(n-k)^{n-k}} \exp\left(O\left(\frac{1}{k}+\frac{1}{n-k}\right)\right)$$
$$= \left\{\frac{n}{2\pi k(n-k)}\right\}^{1/2} \exp\left(nH\left(\frac{k}{n}\right) + O\left(\frac{1}{k}+\frac{1}{n-k}\right)\right) , \quad (4.6)$$

where

$$H(x) = -x\log x - (1-x)\log(1-x) \quad (4.7)$$

is the entropy function. (We set $H(0) = H(1) = 0$ to make $H(x)$ continuous for $0 \le x \le 1$.) Simplifying further, we obtain

$$\binom{n}{k} = \exp(nH(k/n) + O(\log n)) , \quad (4.8)$$

an estimate that is valid for all $0 \le k \le n$. In many situations it suffices to use the weaker but simpler bound

$$\binom{n}{k} \le \left(\frac{ne}{k}\right)^k , \quad 0 \le k \le n . \quad (4.9)$$

Approximations of this form are used frequently in information theory and other fields.

A general estimate that can be derived by totally elementary methods, without recourse to Stirling's formula, is

$$\binom{n}{k}\binom{n}{\lfloor n/2\rfloor}^{-1} = \exp(-2(k-n/2)^2/n + O(|k-n/2|^3/n^2)) , \quad (4.10)$$

valid for $|k-n/2| \le n/4$, say. It is most useful for $|k-n/2| = o(n^{2/3})$, since the error term is small then. Similarly,

$$\binom{n}{k+r} \sim \binom{n}{k}\left(\frac{n-k}{k}\right)^r \quad \text{as} \quad n \to \infty , \quad (4.11)$$

uniformly in k provided r (which may be negative) satisfies $r^2 = o(k)$ and $r^2 = o(n-k)$. Further, we have

$$(n+k)! \sim n^k \exp(k^2/(2n))n! \quad \text{as} \quad n \to \infty , \quad (4.12)$$

again uniformly in k provided $k = o(n^{2/3})$.

5. Estimates of sums and other basic techniques

When encountering a combinatorial sum, the first reaction should always be to check whether it can be simplified by use of some identity. If no identity for the sum is found, the

next step should be to try to transform the problem to eliminate the sum. Usually we are interested not in single isolated sums, but parametrized families of them, such as

$$b_n = \sum_k a_n(k) \ , \tag{5.1}$$

and it is the asymptotic behavior of the b_n as $n \to \infty$ that is desired. A standard and well-known technique (named the "snake-oil" method by Wilf [377]) for handling such cases is to form a generating function $f(z)$ for the b_n, use the properties of the $a_n(k)$ to obtain a simple form for $f(z)$, and then obtain the asymptotics of the b_n from the properties of $f(z)$. This method will be presented briefly in Section 6. In this section we discuss what to do if those two approaches fail. Sometimes the methods to be discussed can also be used in a preliminary phase to obtain a rough estimate for the sum. This estimate can then be used to decide which identities might be true, or what generating functions to form.

There are general methods for dealing with sums (cf. [234]), many of which are used in asymptotic enumeration. A basic technique of this type is summation by parts. Often sums to be evaluated can be expressed as

$$\sum_{j=1}^{n} a_j b_j \quad \text{or} \quad \sum_{j=1}^{\infty} a_j b_j \ ,$$

where the b_j, say, are known explicitly or behave smoothly, while the a_j by themselves might not be known well, but the asymptotics of

$$A(k) = \sum_{j=1}^{k} a_j \tag{5.2}$$

are known. Summation by parts relies on the identity

$$\sum_{j=1}^{n} a_j b_j = \sum_{k=1}^{n-1} A(k)(b_k - b_{k+1}) + A(n) b_n \ . \tag{5.3}$$

Example 5.1. *Sum of primes.* Let

$$S_n = \sum_{p \le n} p \ , \tag{5.4}$$

where p runs over the primes $\le n$. The Prime Number Theorem [23] states that the function

$$\pi(x) = \sum_{p \le x} 1 \tag{5.5}$$

satisfies

$$\pi(x) \sim \frac{x}{\log x} \quad \text{as} \quad x \to \infty \ . \tag{5.6}$$

(More precise estimates are available, but we will not use them.) We rewrite

$$S_n = \sum_{j=1}^{n} a_j b_j \ , \tag{5.7}$$

where

$$a_j = \begin{cases} 1 & j \text{ is prime} \ , \\ \\ 0 & \text{otherwise} \ , \end{cases} \tag{5.8}$$

and $b_j = j$ for all j. Then $A(k) = \pi(k)$ and summation by parts yields

$$S_n = \sum_{k=1}^{n-1} -\pi(k) + \pi(n)n \ . \tag{5.9}$$

Since

$$\sum_{k=1}^{n-1} \pi(k) \sim \sum_{k=2}^{n-1} \frac{k}{\log k} \sim \frac{n^2}{2 \log n} \quad \text{as} \quad n \to \infty \ , \tag{5.10}$$

we have

$$S_n \sim \frac{n^2}{2 \log n} \quad \text{as} \quad n \to \infty \ . \tag{5.11}$$

■

Summation by parts is used most commonly in situations like those of Example 5.1, to obtain an estimate for one sum from that of another.

Summation by parts is often easiest to carry out, both conceptually and notationally, by using integrals. If we let

$$A(x) = \sum_{k \le x} a_k \ , \tag{5.12}$$

then $A(x) = A(n)$ for $n \le x < n+1$. Suppose that $b_k = b(k)$ for some continuously differentiable function $b(x)$. Then

$$b_k - b_{k+1} = -\int_k^{k+1} b'(x) dx \ , \tag{5.13}$$

and we can rewrite Eq. (5.3) as

$$\sum_{j=1}^{n} a_j b_j = A(n)b(n) - \int_1^n A(x) b'(x) dx \ . \tag{5.14}$$

(One can apply similar formulas even when the b_j are not smooth, but this usually requires Riemann-Stieltjes integrals, cf. [14].) The approximation of sums by integrals that appears in (5.14) is common, and will be treated at length later.

5.1. Sums of positive terms

Sums of positive terms are extremely common. They can usually be handled with only a few basic tools. We devote substantial space to this topic because it is important and because the simplicity of the methods helps in illustrating some of the basic principles of asymptotic estimation, such as approximation by integrals, neglecting unimportant terms, and uniform convergence. For readers not familiar with asymptotic methods, working through the examples of this section is a good exercise that will make it easier to learn other techniques later.

Typical sums are of the form

$$b_n = \sum_k a_n(k) \ , \qquad a_n(k) \geq 0 \ , \tag{5.15}$$

where k runs over some range of summation, often $0 \leq k \leq n$ or $0 \leq k < \infty$, and the $a_n(k)$ may be given either explicitly or only through an asymptotic approximation. What is desired is the asymptotic behavior of b_n as $n \to \infty$. Usually the $a_n(k)$ for n fixed are unimodal, so that either i) $a_n(k) \leq a_n(k+1)$ for all k in the range, or ii) $a_n(k) \geq a_n(k+1)$ for all k, or iii) $a_n(k) \leq a_n(k+1)$ for $k \leq k_0$, and $a_n(k) \geq a_n(k+1)$ for $k > k_0$. The single most important task in estimating b_n is usually to find the maximal $a_n(k)$. This can be done either by combinatorial means (involving knowledge of where the $a_n(k)$ come from), by asymptotic estimation of the $a_n(k)$, or (most common when the $a_n(k)$ are expressed in terms of factorials or binomial coefficients) by finding where the ratio $a_n(k+1)/a_n(k)$ is close to 1. If $a_n(k+1)/a_n(k) < 1$ for all k, then we are in case ii) above, and if $a_n(k+1)/a_n(k) > 1$ for all k, we are in case i). If there is a k_0 in the range of summation such that $a_n(k_0+1)$ is close to $a_n(k_0)$, then we are almost certainly in case iii) and the peak occurs at some k close to k_0. The different cases are illustrated in the examples presented later in this section.

Once $\max a_n(k) = a_n(k_0)$ has been found, the next task is to show that most of the terms in the sum are insignificant. For example, if the sum in Eq. (5.15) is over $0 \leq k \leq n$, and if $a_n(0) = 1$ is the largest term, then

$$\sum_{\substack{k=0 \\ a_n(k) < n^{-2}}}^{n} a_n(k) < n^{-1} \ ,$$

which is negligible if we are only after a rough approximation to b_n, say of the form $b_n \sim c_n$ as $n \to \infty$, or even $b_n = c_n(1 + O(n^{-1}))$ as $n \to \infty$. Once the small terms have been discarded, we are usually left with a short range of summation. It can happen that this range

is extremely short, and the maximal term $a_n(k_0)$ is much larger than any of its neighbors to the extent that $b_n \sim a_n(k_0)$ as $n \to \infty$. More commonly, the number of terms that contribute significantly to b_n does grow as $n \to \infty$, but slowly. Their contribution, relative to that of the maximal term $a_n(k_0)$, can usually be estimated by some simple function of $k - k_0$, and the sum of all of them approximated by an explicit integral. This method is sometimes referred to as Laplace's method for sums (in analogy to Laplace's method for estimating integrals, mentioned in Section 5.5, which proceeds in a similar spirit). There is extensive discussion of this method in [63].

Example 5.2. *Sums of the partition function.* We estimate

$$U_n = \sum_{k=1}^{n} p(k)^k \ , \tag{5.16}$$

where $p(k)$ is the number of partitions of k. Since any partition of $m-1$, say one with c_j parts of size j, can be transformed into a partition of m with $c_1 + 1$ parts of size 1, and c_j of size j for $j \geq 2$, we have $p(m) \geq p(m-1)$ for all $m \geq 2$. Therefore the largest term in the sum in (5.16) is the one with $k = n$. If the only estimate for $p(k)$ that we have is the one given by (1.6), then

$$p(n)^n = \exp(Cn^{3/2} - n\log(4 \cdot 3^{1/2}n) + O(n^{1/2})) \ . \tag{5.17}$$

Since the constant implied by the O-symbol is not specified, this estimate is potentially larger than $p(n)^n$ by a factor of $\exp(cn^{1/2})$, so we can only obtain asymptotics of $\log p(n)^n$, not of $p(n)^n$ itself. This also means that rough estimates of U_n follow easily from (5.17). Since $p(k)^k \leq p(n)^n$ for all $k < n$, and there are n terms in the sum, we have $p(n)^n \leq U_n \leq np(n)^n$, and because of the large error term in (5.17), we obtain

$$U_n = \exp(Cn^{3/2} - n\log(4 \cdot 3^{1/2}n) + O(n^{1/2})) \ . \tag{5.18}$$

Thus the use of the poor estimate (1.6) for $p(n)$ means that we can obtain only a crude estimate for U_n, and there is no need for careful analysis.

Instead of (1.6) we can use the more refined estimate (1.5). Let q_n denote first term on the right side of (1.5). Then we have

$$p(n) = q_n + O(n^{-1}\exp(Cn^{1/2}/2)) = q_n(1 + O(\exp(-Cn^{1/2}/2))) \ , \tag{5.19}$$

so

$$p(n)^n = q_n^n(1 + O(n\exp(-Cn^{1/2}/2))) = q_n^n(1 + O(\exp(-Cn^{1/2}/3))) \ , \tag{5.20}$$

say. Also, for some $\epsilon > 0$ we find from Eq. (1.5) (or Eq. 1.6) that for large n

$$q_{n-1} < q_n - \epsilon n^{-1/2} q_n \ .$$

Thus for large n,

$$\begin{aligned} q_{n-1}^{n-1} &< q_n^{n-1}(1-\epsilon n^{-1/2})^{n-1} \\ &< q_n^n \exp(-\epsilon n^{1/2}/2) \ , \end{aligned}$$

and therefore

$$\sum_{k=1}^{n-1} p(k)^k \le (n-1)p(n-1)^{n-1} < q_n^n \exp(-\epsilon n^{1/2}/3) \ .$$

Thus we obtain

$$U_n = q_n^n(1 + O(\exp(-\delta n^{1/2}))) \tag{5.21}$$

for some $\delta > 0$.

The estimates of U_n presented above relied on the observation that the last term in the sum (5.16) defining U_n is much larger than the sum of all the other terms. This does not happen often. A more typical example is presented by

$$T_n = \sum_{k=1}^{n} p(k) \ . \tag{5.22}$$

As was noted before, $p(n)$ is larger than any of the other terms, but not by enough to dominate the sum. We therefore try the other approaches that were listed at the beginning of this section. We use only the estimate (1.6). Since $(1-x)^{1/2} < 1 - x/2$ for $0 \le x \le 1$, we find that for large n,

$$\begin{aligned} \sum_{k<n-n^{2/3}} p(k) &\le np(n - \lceil n^{2/3} \rceil) \\ &\le \exp(C(n - \lceil n^{2/3} \rceil)^{1/2}) \\ &\le \exp(Cn^{1/2} - Cn^{1/6}/2) \\ &= O(p(n)\exp(-Cn^{1/6}/3)) \ . \end{aligned} \tag{5.23}$$

Thus most of the values of k contribute a negligible amount to the sum. For $k = n - j$, $0 \le j \le n^{2/3}$, we find that

$$p(n-j)/p(n) = (1 + O(n^{-1/3}))\exp(C(n-j)^{1/2} - Cn^{1/2}) \ .$$

Since

$$\begin{aligned} (n-j)^{1/2} &= n^{1/2} - jn^{-1/2}/2 + O(j^2 n^{-3/2}) \ , \\ p(n-j)/p(n) &= \exp(-Cjn^{-1/2}/2 + O(n^{-1/6})) \\ &= (1 + O(n^{-1/6}))\exp(-Cjn^{-1/2}/2) \ . \end{aligned} \tag{5.24}$$

Thus the ratios $p(n-j)/p(n)$ decrease geometrically, and so

$$p(n)^{-1} \sum_{0 \le j \le n^{2/3}} p(n-j) = \frac{(1+O(n^{-1/6}))}{1-\exp(-Cn^{-1/2}/2)} = 2C^{-1}n^{1/2}(1+O(n^{-1/6})) \ . \tag{5.25}$$

Therefore, combining all the estimates,

$$T_n = \sum_{k=1}^{n} p(k) = \frac{1+O(n^{-1/6})}{2 \cdot C \cdot 3^{1/2} \cdot n^{1/2}} \ e^{Cn^{1/2}} \ . \tag{5.26}$$

The $O(n^{-1/6})$ error term above can easily be improved with a little more care to $O(n^{-1/2})$, even if we continue to rely only on (1.6). ■

Before presenting further examples, we discuss some of the problems that can arise even in the simple setting of estimating positive sums. We then introduce the basic technique of approximating sums by integrals.

The lack of uniform convergence is a frequent cause of incorrect estimates. If $a_n(k) \sim c_n(k)$ for each k as $n \to \infty$, it does not necessarily follow that

$$b_n = \sum_k a_n(k) \sim \sum_k c_n(k) \quad \text{as} \quad n \to \infty \ . \tag{5.27}$$

A simple counterexample is given by $a_n(k) = \binom{n}{k}$ and $c_n(k) = \binom{n}{k}(1+k/n)$. To conclude that (5.27) holds, it is usually necessary to know that $a_n(k) \sim c_n(k)$ as $n \to \infty$ uniformly in k. Such uniform convergence does hold if we replace $c_n(k)$ in the counterexample above by $c'_n(k) = \binom{n}{k}(1+k/n^2)$, for example.

There is a general principle that sums of terms that vary smoothly with the index of summation should be replaced by integrals, so that for $\alpha > 0$, say,

$$\sum_{k=1}^{n} k^\alpha \sim \int_1^{n+1} u^\alpha du \quad \text{as} \quad n \to \infty \ . \tag{5.28}$$

The advantage of replacing a sum by an integral is that integrals are usually much easier to handle. Many more closed-form expressions are available for definite and indefinite integrals than for sums. We will discuss extensions of this principle of replacing sums by integrals further in Section 5.3, when we present the Euler-Maclaurin summation formula. Usually, though, we do not need anything sophisticated, and the application of the principle to situations like that of (5.28) is easy to justify. If $a_n = g(n)$ for some function $g(x)$ of a real argument x, then

$$\left| g(n) - \int_n^{n+1} g(u)du \right| \le \max_{n \le u \le n+1} |g(u) - g(n)| \ , \tag{5.29}$$

and so

$$\left|\sum_n g(n) - \int g(u)du\right| \le \sum_n \max_{n\le u\le n+1} |g(u) - g(n)| \ , \tag{5.30}$$

where the integral is over $[a, b+1]$ if the sum is over $a \le n \le b$, $a, b \in Z$. If $g(u)$ is continuously differentiable, then $|g(u) - g(n)| \le \max_{n\le v\le n+1} |g'(v)|$ for $n \le u \le n+1$. This gives the estimate

$$\left|\sum_{n=a}^{b} g(n) - \int_a^{b+1} g(u)du\right| \le \sum_{n=a}^{b} \max_{n\le v\le n+1} |g'(v)| \ . \tag{5.31}$$

Often one can find a simple explicit function $h(w)$ such that $|g'(v)| \le h(w)$ for any v and w with $|v - w| \le 1$, in which case Eq. (5.31) can be replaced by

$$\left|\sum_{n=a}^{b} g(n) - \int_a^{b+1} g(u)du\right| \le \int_a^{b+1} h(v)dv \ . \tag{5.32}$$

For good estimates to be obtained from integral approximations to sums, it is usually necessary for individual terms to be small compared to the sum.

Example 5.3. *Sum of* $\exp(-\alpha k^2)$. In the final stages of an asymptotic approximation one often encounters sums of the form

$$h(\alpha) = \sum_{k=-\infty}^{\infty} \exp(-\alpha k^2) \ , \qquad \alpha > 0 \ . \tag{5.33}$$

There is no closed form for the indefinite integral of $\exp(-\alpha u^2)$ (it is expressible in terms of the Gaussian error function only), but there is the famous evaluation of the definite integral

$$\int_{-\infty}^{\infty} \exp(-\alpha u^2)du = (\pi/\alpha)^{1/2} \ . \tag{5.34}$$

Thus it is natural to approximate $h(\alpha)$ by $(\pi/\alpha)^{1/2}$. If $g(u) = \exp(-\alpha u^2)$, then $g'(u) = -2\alpha u g(u)$, and so for $n \ge 0$,

$$\max_{n\le v\le n+1} |g'(v)| \le 2\alpha(n+1)g(n) \ . \tag{5.35}$$

For the integral in Eq. (5.30) to yield a good approximation to the sum we must show that the error term is smaller than the integral. The largest term in the sum occurs at $n = 0$ and equals 1. The error bound (5.35) that comes from approximating $g(0) = 1$ by the integral of $g(u)$ over $0 \le u \le 1$ is 2α. Therefore we cannot expect to obtain a good estimate unless $\alpha \to 0$. We find that

$$2\alpha(n+1)g(n) \le 4\alpha u g(u/2) \quad \text{for} \quad n \ge 1, \quad n \le u \le n+1 \ ,$$

so (integral approximation again!)

$$\begin{aligned} \sum_{n=1}^{\infty} 2\alpha(n+1)g(n) &\leq 4\alpha \int_1^{\infty} ug(u/2)du \\ &\leq 4\alpha \int_0^{\infty} ug(u/2)du = (8\alpha)^{1/2} \ . \end{aligned} \tag{5.36}$$

Therefore, taking into account the error for $n = 0$ which was not included in the bound (5.36), we have

$$\begin{aligned} h(\alpha) &= \sum_{n=-\infty}^{\infty} \exp(-\alpha n^2) = \int_{-\infty}^{\infty} \exp(-\alpha u^2)du + O(\alpha^{1/2} + \alpha) \\ &= (\pi/\alpha)^{1/2} + O(\alpha^{1/2}) \quad \text{as} \quad \alpha \to 0^+ \ . \end{aligned} \tag{5.37}$$

For this sum much more precise estimates are available, as will be shown in Example 5.9. For many purposes, though, (5.37) is sufficient. ■

Example 5.3 showed how to use the basic tool of approximating a sum by an integral. Moreover, the estimate (5.37) that it provides is ubiquitous in asymptotic enumeration, since many approximations reduce to it. This is illustrated by the following example.

Example 5.4. *Bell numbers* (cf. [63]). The Bell number, $B(n)$, counts the partitions of an n-element set. It is given by [81]

$$B(n) = e^{-1} \sum_{k=1}^{\infty} \frac{k^n}{k!} \ . \tag{5.38}$$

In this sum no single term dominates. The ratio of the $(k+1)$-st to the k-th term is

$$\frac{(k+1)^n}{(k+1)!} \cdot \frac{k!}{k^n} = \frac{1}{k+1} \left(1 + \frac{1}{k}\right)^n \ . \tag{5.39}$$

As k increases, this ratio strictly decreases. We search for the point where it is about 1. For $k \geq 2$,

$$\left(1 + \frac{1}{k}\right)^n = \exp\left(n \log\left(1 + \frac{1}{k}\right)\right) = \exp(n/k + O(n/k^2)) \ , \tag{5.40}$$

so the ratio is close to 1 for n/k close to $\log(k+1)$. We choose k_0 to be the closest integer to w, the solution to

$$n = w \log(w+1) \ . \tag{5.41}$$

For $k = k_0 + j$, $1 \le j \le k_0/2$, we find, since $\log(1 + i/k_0) = i/k_0 - i^2/(2k_0^2) + O(i^3/k_0^3)$,

$$\begin{aligned} \frac{k^n}{k!} &= \frac{k_0^n}{k_0!} \frac{(1 + j/k_0)^n}{k_0^j \Pi_{i=1}^j (1 + i/k_0)} \\ &= \frac{k_0^n}{k_0!} \exp\left(jn/k_0 - j \log k_0 - j^2(n + k_0)/(2k_0^2) + O(nj^3/k_0^3 + j/k_0) \right) . \end{aligned} \tag{5.42}$$

The same estimate applies for $-k_0/2 \le j \le 0$. The term $jn/k_0 - j \log k_0$ is small, since $|k_0 - w| \le 1/2$ and w satisfies (5.41). We find

$$\begin{aligned} n/k_0 - \log k_0 &= n/w - \log(w + 1) + O(n/w^2 + 1/w) \\ &= O(n/w^2 + 1/w) . \end{aligned} \tag{5.43}$$

By (5.41), $w \sim n/\log n$ as $n \to \infty$. We now further restrict j to $|j| \le n^{1/2} \log n$. Then (5.42) and (5.43) yield

$$\frac{k^n}{k!} = \frac{k_0^n}{k_0!} \exp(-j^2(n + k_0)/(2k_0^2) + O((\log n)^6 n^{-1/2})) . \tag{5.44}$$

Approximating the sum by an integral, as in Example 5.3, shows that

$$\sum_{\substack{k \\ |j| \le n^{1/2} \log n}} \frac{k^n}{k!} = \frac{k_0^n}{k_0!} k_0 (2\pi)^{1/2} (n + k_0)^{-1/2} (1 + O((\log n)^6 n^{-1/2})) . \tag{5.45}$$

(An easy way to obtain this is to apply the estimate of Example 5.3 to the sum from $-\infty$ to ∞, and show that the range $|j| > n^{1/2} \log n$ contributes little.) To estimate the contribution of the remaining summands, with $|j| > n^{1/2} \log n$, we observe that the ratio of successive terms is ≤ 1, so the range $1 \le k \le k_0 - \lfloor n^{1/2} \log n \rfloor$ contributes at most k_0 (the number of terms) times the largest term, which arises for $k = k_0 - \lfloor n^{1/2} \log n \rfloor$. By (5.44), this largest term is

$$O(k_0^n (k_0!)^{-1} \exp(-(\log n)^3)) .$$

For $k \ge k_1 \ge k_0 + \lfloor n^{1/2} \log n \rfloor$, we find that the ratio of the $(k+1)$-st to the k-th term is, for large n,

$$\begin{aligned} \le \frac{1}{k_1 + 1} \left(1 + \frac{1}{k_1} \right)^n &= \exp(n/k_1 - \log(k_1 + 1) - n/(2k_1^2) + O(n/k_1^3)) \\ &\le \exp(-(k_1 - k_0)n/k_1^2 + O(n/k_1^3)) \\ &\le \exp(-2n^{-1/2}) \ \le \ 1 - n^{-1/2} , \end{aligned} \tag{5.46}$$

and so the sum of these terms, for $k_1 \le k < \infty$, is bounded above by $n^{1/2}$ times the term for $k = k_1$. Therefore the estimate on the right-hand side of (5.45) applies even when we sum on all k, $1 \le k < \infty$.

To obtain an estimate for $B(n)$, it remains only to estimate $k_0^n/k_0!$. To do this, we apply Stirling's formula and use the property that $|k_0 - w| \le 1/2$ to deduce that

$$B(n) \sim (\log w)^{1/2} w^{n-w} e^w \quad \text{as} \quad n \to \infty \ , \tag{5.47}$$

where w is given by (5.41).

There is no explicit formula for w in terms of n, and substituting various asymptotic approximations to w, such as

$$w = \frac{n}{\log n} + O\left(\frac{n}{(\log n)^2}\right) \tag{5.48}$$

(see Example 5.10) yields large error terms in (5.47), so for accuracy it is usually better to use (5.47) as is. There are other approximations to $B(n)$ in the literature (see, for example, [33, 63]). They differ slightly from (5.47) because they estimate $B(n)$ in terms of roots of equations other than (5.41).

Other methods of estimating $B(n)$ are presented in Examples 12.5 and 12.6. ■

5.2. Alternating sums and the principle of inclusion-exclusion

At the beginning of Section 5, the reader was advised in general to search for identities and transformations when dealing with general sums. This advice is even more important when dealing with sums of terms that have alternating or irregularly changing coefficients. Finding the largest term is of little help when there is substantial cancellation among terms. Several general approaches for dealing with this difficulty will be presented later. Generating function methods for dealing with complicated sums are discussed in Section 6. Contour integration methods for alternating sums are mentioned in Section 10.3. The summation formulas of the next section can sometimes be used to estimate sums with regularly varying coefficients as well. In this section we present some basic elementary techniques that are often sufficient.

Sometimes it is possible to obtain estimates of sums with positive and negative summands by approximating separately the sums of the positive and of the negative summands. Methods of the preceding section or of the next section are useful in such situations. However, this approach is to be avoided as much as possible, because it often requires extremely precise estimates of the two sums to obtain even rough bounds on the desired sums. One method that often works and is much simpler consists of a simple pairing of adjacent positive and negative terms.

Example 5.5. *Alternating sum of square roots.* Let

$$S_n = \sum_{k=1}^{n} (-1)^k k^{1/2} \ . \tag{5.49}$$

We have

$$\begin{aligned} (2m)^{1/2} - (2m-1)^{1/2} &= (2m)^{1/2} \left\{ 1 - \left(1 - \frac{1}{2m} \right)^{1/2} \right\} \\ &= (2m)^{1/2} \left\{ 1 - \left(1 - \frac{1}{4m} + O(m^{-2}) \right) \right\} \\ &= (8m)^{-1/2} + O(m^{-3/2}) \ , \end{aligned} \tag{5.50}$$

so

$$\begin{aligned} \sum_{k=1}^{2\lfloor n/2 \rfloor} (-1)^k k^{1/2} &= \sum_{m=1}^{\lfloor n/2 \rfloor} (8m)^{-1/2} + O(1) \\ &= n^{1/2}/2 + O(1) \ . \end{aligned} \tag{5.51}$$

Hence

$$S_n = \begin{cases} n^{1/2}/2 + O(1) & \text{if } n \text{ is even} \ , \\ -n^{1/2}/2 + O(1) & \text{if } n \text{ is odd} \ . \end{cases} \tag{5.52}$$

■

In Example 5.5, the sums of the positive terms and of the negative terms can easily be estimated accurately (for example, by using the Euler-Maclaurin formula of the next section) to obtain (5.52). In other cases, though, the cancellation is too extensive for such an approach to work. This is especially true for sums arising from the principle of inclusion-exclusion.

Suppose that X is some set of objects and P is a set of properties. For $R \subseteq P$, let $N_=(R)$ be the number of objects in X that have exactly the properties in R and none of the properties in $P \setminus R$. We let $N_\geq(R)$ denote the number of objects in X that have all the properties in R and possibly some of those in $P \setminus R$. The principle of inclusion-exclusion says that

$$N_=(R) = \sum_{R \subseteq Q \subseteq P} (-1)^{|Q \setminus R|} N_\geq(Q) \ . \tag{5.53}$$

(This is a basic version of the principle. For more general results, proofs, and references, see [81, 173, 351].)

Example 5.6. *Derangements of n letters.* Let X be the set of permutations of n letters, and suppose that P_i, $1 \le i \le n$, is the property that the i-th letter is fixed by a permutation, and $P = \{P_1, \dots, P_n\}$. Then d_n, the number of derangements of n letters, equals $N_=(\phi)$, where ϕ is the empty set, and so by (5.53)

$$d_n = \sum_{Q \subseteq P} (-1)^{|Q|} N_\ge(Q) \ . \tag{5.54}$$

However, $N_\ge(Q)$ is just the number of permutations that leave all letters specified by Q fixed, and thus

$$\begin{aligned} d_n &= \sum_{Q \subseteq P} (-1)^{|Q|} (n - |Q|)! \\ &= \sum_{k=0}^{n} (-1)^k (n-k)! \binom{n}{k} = \sum_{k=0}^{n} (-1)^k \frac{n!}{k!} \ , \end{aligned} \tag{5.55}$$

which is Eq. (1.1). ■

The formula (1.1) for derangements is easy to use because the terms decrease rapidly. Moreover, this formula is exceptionally simple, largely because $N_\ge(Q)$ depends only on $|Q|$. In general, the inclusion-exclusion principle produces complicated sums that are hard to estimate. A frequently helpful tool is provided by the *Bonferroni inequalities* [81, 351]. One form of these inequalities is that for any integer $m \ge 0$,

$$N_=(R) \ge \sum_{\substack{Q \\ R \subseteq Q \subseteq P \\ |Q \setminus R| \le 2m}} (-1)^{|Q \setminus R|} N_\ge(Q) \tag{5.56}$$

and

$$N_=(R) \le \sum_{\substack{Q \\ R \subseteq Q \subseteq P \\ |Q \setminus R| \le 2m+1}} (-1)^{|Q \setminus R|} N_\ge(Q) \ . \tag{5.57}$$

Thus in general

$$\Big| N_=(R) - \sum_{\substack{Q \\ R \subseteq Q \subseteq P \\ |Q \setminus R| \le k}} (-1)^{|Q \setminus R|} N_\ge(Q) \Big| \le \sum_{\substack{Q \\ R \subseteq Q \subseteq P \\ |Q \setminus R| \le k+1}} N_\ge(Q) \ . \tag{5.58}$$

These inequalities are frequently applied for $n = |X|$ increasing. Typically one chooses k that increases much more slowly than n, so that the individual terms $N_\ge(Q)$ in (5.58) can be estimated asymptotically, as the interactions of the different properties counted by $N_\ge(Q)$ is not too complicated to estimate. Bender [33] presents some useful general principles to be used in such estimates (especially the asymptotically Poisson distribution that tends to occur when the method is successful). We present an adaptation of an example from [33].

Example 5.7. *Balls and cells.* Given n labeled cells and m labeled balls, let $a_h(m,n)$ be the number of ways to place the balls into cells so that exactly h of the cells are empty. We consider h fixed. Let X be the ways of placing the balls into the cells (n^m in total), and $P = \{P_1, \dots, P_n\}$, where P_i is the property that the i-th cell is empty. If $R = \{P_1, \dots, P_h\}$, then $a_h(m,n) = \binom{n}{h} N_=(R)$. Now

$$N_\geq(Q) = (n - |Q|)^m \ , \tag{5.59}$$

so

$$\begin{aligned} \sum_{\substack{Q \\ R \subseteq Q \subseteq P \\ |Q \setminus R| = t}} N_\geq(Q) &= \tbinom{n-h}{t}(n-h-t)^m \\ &= n^m e^{-mh/n}(ne^{-m/n})^t (t!)^{-1}(1 + O((t^2+1)mn^{-2} + (t^2+1)n^{-1})) \ , \end{aligned} \tag{5.60}$$

provided $t^2 \leq n$ and $mt^2n^{-2} \leq 1$, say. In the range $0 \leq t \leq \log n$, $n \log n \leq m \leq n^2(\log n)^{-3}$, we find that the right-hand side of (5.60) is

$$n^m e^{-mh/n}(ne^{-m/n})^t (t!)^{-1}(1 + O(mn^{-2}(\log n)^2)) \ .$$

We now apply (5.58) with $k = \lfloor \log n \rfloor$, and obtain

$$\begin{aligned} a_h(m,n) &= \tbinom{n}{h} N_=(R) \sim \tbinom{n}{h} n^m \exp(-mh/n - ne^{-m/n}) \\ &\sim n^m (h!)^{-1} (ne^{-m/n})^h \exp(-ne^{-m/n}) \end{aligned} \tag{5.61}$$

as $m, n \to \infty$, provided $n \log n \leq m \leq n^2(\log n)^{-3}$. Since $a_h(m,n)n^{-m}$ is the probability that there are exactly h empty cells, the relation (5.61) (which we have established only for fixed h) shows that this probability is asymptotically distributed like a Poisson random variable with parameter $n \exp(-m/n)$.

Many additional results on random distributions of balls into cells, and references to the extensive literature on this subject can be found in [241]. ■

Bonferroni inequalities include other methods for estimating $N_=(R)$ by linear combinations of the $N_\geq(Q)$. Recent approaches and references (phrased in probabilistic terms) can be found in [152]. For bivariate Bonferroni inequalities (where one asks for the probability that at least one of two sets of events occurs) see [153, 249].

The Chen-Stein method [75] is a powerful technique that is often used in place of the principle of inclusion-exclusion, especially in probabilistic literature. Recent references are [17, 27].

5.3. Euler-Maclaurin and Poisson summation formulas

Section 5.0 showed that sums can be successfully approximated by integrals if the summands are all small compared to the total sum and vary smoothly as functions of the summation index. The approximation (5.29), though crude, is useful in a wide variety of cases. Sometimes, though, more accurate approximations are needed. An obvious way is to improve the bound (5.29). If $g(x)$ is really smooth, we can expect that the difference

$$a_n - \int_n^{n+1} g(u)du$$

will vary in a regular way with n. This is indeed the case, and it is exploited by the Euler-Maclaurin summation formula. It can be found in many books, such as [63, 175, 297, 298]. There are many formulations, but they do not differ much.

Euler-Maclaurin summation formula. Suppose that $g(x)$ has $2m$ continuous derivatives in $[a,b]$, $a,b \in Z$. Then

$$\begin{aligned}\sum_{k=a}^{b} g(k) &= \int_a^b g(x)dx + \sum_{r=1}^{m} \frac{B_{2r}}{(2r)!}\left\{g^{(2r-1)}(b) - g^{(2r-1)}(a)\right\} \\ &\quad + \frac{1}{2}\{g(a)+g(b)\} + R_m \ ,\end{aligned} \tag{5.62}$$

where

$$R_m = -\int_a^b g^{(2m)}(x)\frac{B_{2m}(x-\lfloor x\rfloor)}{(2m)!}dx \ , \tag{5.63}$$

and so

$$|R_m| \le \int_a^b |g^{(2m)}(x)|\frac{|B_{2m}(x-\lfloor x\rfloor)|}{(2m)!}dx \ . \tag{5.64}$$

In the above formulas, the $B_n(x)$ denote the Bernoulli polynomials, defined by

$$\frac{ze^{xz}}{e^z-1} = \sum_{n=0}^{\infty} B_n(x)\frac{z^n}{n!} \ . \tag{5.65}$$

The B_n are the Bernoulli numbers, defined by

$$\frac{z}{e^z-1} = \sum_{n=0}^{\infty} B_n\frac{z^n}{n!} \ , \tag{5.66}$$

so that $B_n = B_n(0)$, and

$$\begin{aligned} B_0 &= 1 \ , \quad B_1 = -1/2 \ , \quad B_2 = 1/6 \ , \\ B_3 &= B_5 = B_7 = \cdots = 0 \ , \\ B_4 &= -1/30 \ , \quad B_6 = 1/42 \ , \quad B_8 = -1/30, \ \ldots \ . \end{aligned} \tag{5.67}$$

It is known that

$$|B_{2m}(x - \lfloor x \rfloor)| \le |B_{2m}| \ , \tag{5.68}$$

so we can simplify (5.64) to

$$|R_m| \le |B_{2m}|((2m)!)^{-1} \int_a^b |g^{(2m)}(x)| dx \ . \tag{5.69}$$

There are many applications of the Euler-Maclaurin formula. One of the most frequently cited ones is to estimate factorials.

Example 5.8. *Stirling's formula.* We transform the product in the definition of $n!$ into a sum by taking logarithms, and find that for $g(x) = \log x$ and $m = 1$ we have

$$\log n! = \sum_{k=1}^{n} \log k = \int_1^n (\log x) dx + \frac{1}{2} \log n + \frac{1}{2} B_2 \left\{ \frac{1}{n} - 1 \right\} + R_1 \ , \tag{5.70}$$

where

$$R_1 = \int_1^n \frac{B_2(x - \lfloor x \rfloor)}{2x^2} dx = C + O(n^{-1}) \tag{5.71}$$

for

$$C = \int_1^\infty \frac{B_2(x - \lfloor x \rfloor)}{2x^2} dx \ . \tag{5.72}$$

Therefore

$$\log n! = n \log n - n + \frac{1}{2} \log n + C + 13/12 + O(n^{-1}) \ , \tag{5.73}$$

which gives

$$n! \sim C' n^{1/2} n^n e^{-n} \quad \text{as} \quad n \to \infty \ . \tag{5.74}$$

To obtain Stirling's formula (4.1), we need to show that $C' = (2\pi)^{1/2}$. This can be done in several ways (cf. [63]). In Examples 12.1, 12.4, and 12.5 we will see other methods of deriving (4.1). ■

There is no requirement that the function $g(x)$ in the Euler-Maclaurin formula be positive. That was not even needed for the crude approximation of a sum by an integral given in Section 5.0. The function $g(x)$ can even take complex values. (After all, Eq. (5.62) is an identity!) However, in most applications this formula is used to derive an asymptotic estimate with a small error term. For that, some high order derivatives have to be small, which means that $g(x)$ cannot change sign too rapidly. In particular, the Euler-Maclaurin formula usually is not very useful when the $g(k)$ alternate in sign. In those cases one can sometimes use

the differencing trick (cf. Example 5.5) and apply the Euler-Maclaurin formula to $h(k) = g(2k) + g(2k+1)$. There is also Boole's summation formula for alternating sums that can be applied. (See Chapter 2, §3 and Chapter 6, §6 of [298], for example.) Generalizations to other periodic patterns in the coefficients have been derived by Berndt and Schoenfeld [47].

The bounds for the error term R_m in the Euler-Maclaurin formula that were stated above can often be improved by using special properties of the function $g(x)$. For example, when $g(x)$ is analytic in x, there are contour integrals for R_m that sometimes give good estimates (cf. [315]).

The Poisson summation formula states that

$$\sum_{n=-\infty}^{\infty} f(n+a) = \sum_{m=-\infty}^{\infty} \exp(2\pi i m a) \int_{-\infty}^{\infty} f(y) \exp(-2\pi i m y) dy \tag{5.75}$$

for "nice" functions $f(x)$. The functions for which (5.75) holds include all continuous $f(x)$ for which $\int |f(x)| dx < \infty$, which are of bounded variation, and for which $\sum_n f(n+a)$ converges for all a. For weaker conditions that ensure validity of (5.75), we refer to [63, 365]. The Poisson summation formula often converts a slowly convergent sum into a rapidly convergent one. Generally it is not as widely applicable as the Euler-Maclaurin formula as it requires extreme regularity for the Fourier coefficients to decrease rapidly. On the other hand, it can be applied in some situations that are not covered by the Euler-Maclaurin formula, including some where the coefficients vary in sign.

Example 5.9. *Sum of* $\exp(-\alpha k^2)$. We consider again the function $h(\alpha)$ of Example 5.3. We let $f(x) = \exp(-\alpha x^2)$, $a = 0$. Eq. (5.15) then gives

$$h(\alpha) = \sum_{n=-\infty}^{\infty} \exp(-\alpha n^2) = (\pi/\alpha)^{1/2} \sum_{m=-\infty}^{\infty} \exp(-\pi^2 m^2/\alpha) \ . \tag{5.76}$$

This is an identity, and the sum on the right-hand side above converges rapidly for small α. Many applications require the evaluation of the sum on the left in which α tends to 0. Eq. (5.76) offers a method of converting a slowly convergent sum into a tractable one, whose asymptotic behavior is explicit. ■

5.4. Bootstrapping and other basic methods

Bootstrapping is a useful technique that uses asymptotic information to obtain improved estimates. Usually we start with some rough bounds, and by combining them with the relations defining the function or sequence that we are studying, we obtain better bounds.

Example 5.10. *Approximation of Bell numbers.* Example 5.4 obtained the asymptotics of the Bell numbers B_n, but only in terms of w, the solution to Eq. (5.41). We now show how to obtain asymptotic expansions for w. As n increases, so does w. Therefore $\log(w+1)$ also increases, and so $w < n$ for large n. Thus

$$n = w\log(w+1) < w\log(n+1) \ ,$$

and so

$$n(\log(n+1))^{-1} < w < n \ . \tag{5.77}$$

Therefore

$$\log(w+1) = \log n + O(\log\log n) \ , \tag{5.78}$$

and so

$$w = \frac{n}{\log(w+1)} = \frac{n}{\log n} + O\left(\frac{n\log\log n}{(\log n)^2}\right) \ . \tag{5.79}$$

To go further, note that by (5.79),

$$\begin{aligned} \log(w+1) &= \log\left(\frac{n}{\log n}\left(1 + O\left(\frac{\log\log n}{\log n}\right)\right)\right) \\ &= \log n - \log\log n + O((\log\log n)(\log n)^{-1}) \ , \end{aligned} \tag{5.80}$$

and so by applying this estimate in Eq. (5.41), we obtain

$$w = \frac{n}{\log n} + \frac{n\log\log n}{(\log n)^2} + \frac{n(\log\log n)^2}{(\log n)^3} + O\left(\frac{n\log\log n}{(\log n)^3}\right) \ . \tag{5.81}$$

This procedure can be iterated indefinitely to obtain expansions for w with error terms $O(n(\log n)^{-\alpha})$ for as large a value of α as desired. ■

In the above example, w can also be estimated by other methods, such as the Lagrange-Bürmann inversion formula (cf. Example 6.7). However, the bootstrapping method is much more widely applicable and easy to apply. It will be used several times later in this chapter.

5.5. Estimation of integrals

In some of the examples in the preceding sections integrals were used to approximate sums. The integrals themselves were always easy to evaluate. That is true in most asymptotic enumeration problems, but there do occur situations where the integrals are more complicated. Often the hard integrals are of the form

$$f(x) = \int_\alpha^\beta g(t)\exp(xh(t))dt \ , \tag{5.82}$$

and it is necessary to estimate the behavior of $f(x)$ as $x \to \infty$, with the functions $g(t)$, $h(t)$ and the limits of integration α and β held fixed. There is a substantial theory of such integrals, and good references are [54, 63, 100, 315]. The basic technique is usually referred to as Laplace's method, and consists of approximating the integrand by simpler functions near its maxima. This approach is similar to the one that is discussed at length in Section 5.1 for estimating sums. The contributions of the approximations are then evaluated, and it is shown that the remaining ranges of integration, away from the maxima, contribute a negligible amount. By breaking up the interval of integration we can write the integral (5.82) as a sum of several integrals of the same type, with the property that there is a unique maximum of the integrand and that it occurs at one of the endpoints. When $\alpha > 0$, the maximum of the integrand occurs for large x at the maximum of $h(t)$ (except in rare cases where $g(t) = 0$ for that t for which $h(t)$ is maximized). Suppose that the maximum occurs at $t = \alpha > 0$. It often happens that

$$h(t) = h(\alpha) - c(t-\alpha)^2 + O(|t-\alpha|^3) \tag{5.83}$$

for $\alpha \le t \le \beta$ and $c = -h''(\alpha)/2 > 0$, and then one obtains the approximation

$$f(x) \sim g(\alpha) \exp(xh(\alpha))[-\pi/(4xh''(\alpha))]^{1/2} \quad \text{as} \quad x \to \infty \ , \tag{5.84}$$

provided $g(\alpha) \neq 0$. For precise statements of even more general and rigorous results, see for example Chapter 3, §7 of [315]. Those results cover functions $h(t)$ that behave near $t = \alpha$ like $h(\alpha) - c(t-\alpha)^\mu$ for any $\mu > 0$.

When the integral is highly oscillatory, as happens when $h(t) = iu(t)$ for a real-valued function $u(t)$, still other techniques (such as the stationary phase method), are used. We will not present them here, and refer to [54, 63, 100, 315] for descriptions and applications. In Section 12.1 we will discuss the saddle point method, which is related to both Laplace's method and the stationary phase method.

Laplace integrals

$$F(x) = \int_0^\infty f(t) \exp(-xt) dt \tag{5.85}$$

can often be approximated by integration by parts. We have (under suitable conditions on $f(t)$)

$$\begin{aligned} F(x) &= x^{-1} f(0) + x^{-1} \int_0^\infty f'(t) \exp(-xt) dt \\ &= x^{-1} f(0) + x^{-2} f'(0) + x^{-2} \int_0^\infty f''(t) \exp(-xt) dt \ , \end{aligned} \tag{5.86}$$

and so on. There are general results, usually associated with the name of Watson's Lemma, for deriving such expansions. For references, see [100, 315].

6. Generating functions

6.1. A brief overview

Generating functions are a wonderfully powerful and versatile tool, and most asymptotic estimates are derived from them. The most common ones in combinatorial enumeration are the ordinary and exponential generating functions. If $a_0, a_1, \ldots$, is any sequence of real or complex numbers, the *ordinary generating function* is

$$f(z) = \sum_{n=0}^{\infty} a_n z^n \ , \tag{6.1}$$

while the *exponential generating function* is

$$f(z) = \sum_{n=0}^{\infty} \frac{a_n z^n}{n!} \ . \tag{6.2}$$

Doubly-indexed arrays, for example $a_{n,k}$, $0 \le n < \infty$, $0 \le k \le n$, are encoded as two-variable generating functions. Depending on the array, sometimes one uses

$$f(x,y) = \sum_{n=0}^{\infty} \sum_{k=0}^{n} a_{n,k} x^k y^n \ , \tag{6.3}$$

and sometimes other forms that might even mix ordinary and exponential types, as in

$$f(x,y) = \sum_{n=0}^{\infty} \frac{y^n}{n!} \sum_{k=0}^{n} a_{n,k} x^k \ . \tag{6.4}$$

For example, the Stirling numbers of the first kind, $s(n,k)$ ($(-1)^{n+k} s(n,k)$ is the number of permutations on n letters with k cycles) have the generating function (see pp. 50, 212–213, and 234–235 in [81])

$$1 + \sum_{n=1}^{\infty} \frac{y^n}{n!} \sum_{k=1}^{n} s(n,k) x^k = (1+y)^x \ . \tag{6.5}$$

In general, a generating function is just a formal power series, and questions of convergence do not arise in the definition. However, some of the main applications of generating functions in asymptotic enumeration do rely on analyticity or other convergence properties of those functions, and there the domain of convergence is important.

A generating function is just another form for the sequence that defines it. There are many reasons for using it. One is that even for complicated sequences, generating functions are

frequently simple. This might not be obvious for the partition function $p(n)$, which has the ordinary generating function

$$f(z) = \sum_{n=0}^{\infty} p(n) z^n = \prod_{k=1}^{\infty} (1 - z^k)^{-1} \ . \tag{6.6}$$

The sequence $p(n)$, which is complicated, is encoded here as an infinite product. The terms in the product are simple and vary in a regular way with the index, but it is not clear at first what is gained by this representation. In other cases, though, the advantages of generating functions are clearer. For example, the exponential generating function for derangements (Eq. (1.1) and Example 5.6) is

$$\begin{aligned} f(z) &= \sum_{n=0}^{\infty} \frac{d_n}{n!} z^n = \sum_{n=0}^{\infty} \frac{z^n}{n!} \sum_{n=0}^{n} (-1)^k \frac{n!}{k!} \\ &= \sum_{k=0}^{\infty} \frac{(-1)^k}{k!} \sum_{n=k}^{\infty} z^n = \frac{e^{-z}}{1-z} \ , \end{aligned} \tag{6.7}$$

which is extremely compact.

Reasons for using generating functions go far beyond simplicity. The one that matters most for this chapter in that generating functions can be used to obtain information about the asymptotic behavior of sequences they encode, information that often cannot be obtained in any other way, or not as easily. Methods such as those of Section 10.2 can be used to obtain immediately from Eq. (6.7) the asymptotic estimate $d_n \sim e^{-1} n!$ as $n \to \infty$. This estimate can also be derived easily by elementary methods from Eq. (1.1), so here the generating function is not essential. In other cases, though, such as that of the partition function $p(n)$, all the sharp estimates, such as that of Hardy and Ramanujan given in (1.5), are derived by exploiting the properties of the generating function. If there is any main theme to this chapter, it is that generating functions are usually the easiest, most versatile, and most powerful way to study asymptotic behavior of sequences. Especially when the generating function is analytic, its behavior at the dominant singularities (a term that will be defined in Section 10) determines the asymptotics of the sequence. When the generating function is simple, and often even when it is not simple, the contribution of the dominant singularity can often be determined easily, although the sequence itself is complicated.

There are many applications of generating functions, some related to asymptotic questions. Averages can often be studied using generating functions. Suppose, for example, that $a_{n,k}$, $0 \le k \le n$, $0 \le n < \infty$, is the number of objects in some class of size n, which have weight k

(for some definition of size and weight), and that we know, either explicitly or implicitly, the generating function $f(x,y)$ of $a_{n,k}$ given by (6.4). Then

$$g(y) = f(1,y) = \sum_{n=0}^{\infty} \frac{y^n}{n!} \sum_{k=0}^{n} a_{n,k} \tag{6.8}$$

is the exponential generating function of the number of objects of size n, while

$$h(y) = \frac{\partial}{\partial x} f(x,y)\Big|_{x=1} = \sum_{n=0}^{\infty} \frac{y^n}{n!} \sum_{k=0}^{n} k a_{n.k} \tag{6.9}$$

is the exponential generating function of the sum of the weights of objects of size n. Therefore the average weight of an object of size n is

$$\frac{[y^n]h(y)}{[y^n]g(y)} \ . \tag{6.10}$$

The wide applicability and power of generating functions come primarily from the structured way in which most enumeration problems arise. Usually the class of objects to be counted is derived from simpler objects through basic composition rules. When the generating functions are chosen to reflect appropriately the classes of objects and composition rules, the final generating function is derivable in a simple way from those of the basic objects. Suppose, for example, that each object of size n in class C can be decomposed uniquely into a pair of objects of sizes k and $n-k$ (for some k) from classes A and B, and each pair corresponds to an object in C. Then c_n, the number of objects of size n in C, is given by the convolution

$$c_n = \sum_{k=0}^{n} a_k b_{n-k} \ , \tag{6.11}$$

(where a_k is the number of objects of size k in A, etc.). Hence if $A(z) = \sum a_n z^n$, $B(z) = \sum b_n z^n$, $C(z) = \sum c_n z^n$ are the ordinary generating functions, then

$$C(z) = A(z)B(z) \ . \tag{6.12}$$

Thus ordered pairing of objects corresponds to multiplication of ordinary generating functions. If $A(z) = \sum a_n z^n$ and

$$b_n = \sum_{k=0}^{n} a_k \ ,$$

then $B(z) = \sum b_n z^n$ is given by

$$B(z) = \frac{A(z)}{1-z} \ , \tag{6.13}$$

so that the ordinary generating function of cumulative sums of coefficients is obtained by dividing by $1 - z$. There are many more such general correspondences between operations on combinatorial objects and on the corresponding generating functions. They are present, implicitly or explicitly, in most books that cover combinatorial enumeration, such as [81, 173, 351, 377]. The most systematic approach to developing and using general rules of this type has been carried out by Flajolet and his collaborators [139]. They develop ways to see immediately (cf. [134]) that if we consider mappings of a set of n labeled elements to itself, so that all n^n distinct mappings are considered equally likely, then the generating function for the longest path length is given by

$$f(z) = \sum_{k=0}^{\infty} \left(\frac{1}{1 - t(z)} - e^{v_k(z)} \right) , \tag{6.14}$$

where

$$v_k(z) = t_{k-1}(z) + \frac{1}{2} t_{k-2}(z)^2 + \cdots + \frac{1}{k} t_0(k)^k , \tag{6.15}$$

with

$$t_0(z) = z , \quad t_{h+1}(z) = z \exp(t_h(z)) , \tag{6.16}$$

and $t(z) = \lim_{h \to \infty} t_h(z)$ (in the sense of formal power series, so convergence is that of coefficients). Furthermore, as is mentioned in Section 17, many of these rules for composition of objects and generating functions can be implemented algorithmically, automating some of the chores of applying them.

We illustrate some of the basic generating function techniques by deriving the generating function for rooted labeled trees, which will occur later in Examples 6.6 and 10.8. (The rooted unlabeled trees, with generating function given by (1.8), are harder.)

Example 6.1. *Rooted labeled trees.* Let t_n be the number of rooted labeled trees on n vertices, so that $t_1 = 1$, $t_2 = 2$, $t_3 = 9$. (It will be shown in Example 6.6 that $t_n = n^{n-1}$.) Let

$$t(z) = \sum_{n=1}^{\infty} t_n \frac{z^n}{n!} \tag{6.17}$$

be the exponential generating function. If we remove the root of a rooted labeled tree with n vertices, we are left with $k \geq 0$ rooted labeled trees that contain a total of $n - 1$ vertices. The total number of ways of arranging an ordered selection of k rooted trees with a total of $n - 1$ vertices is

$$[z^{n-1}] t(z)^k .$$

Since the order of the trees does not matter, we have

$$\frac{1}{k!}[z^{n-1}]t(z)^k$$

different trees of size n that have exactly k subtrees, and so

$$\begin{aligned} t_n &= \sum_{k=0}^{\infty} \frac{1}{k!}[z^{n-1}]t(z)^k \\ &= [z^{n-1}]\sum_{k=0}^{\infty} t(z)^k/k! \;=\; [z^n]z\exp(t(z)) \;, \end{aligned} \tag{6.18}$$

which gives

$$t(z) = z\exp(t(z)) \;. \tag{6.19}$$

As an aside, the function $t_h(z)$ of Eq (6.16) is the exponential generating function of rooted labeled trees of height $\leq h$. ■

The key to the successful use of generating functions is to use a generating function that is of the appropriate form for the problem at hand. There is no simple rule that describes what generating function to use, and sometimes two are used simultaneously. In combinatorics and analysis of algorithms, the most useful forms are the ordinary and exponential generating functions, which reflects how the classes of objects that are studied are constructed. Sometimes other forms are used, such as the double exponential form

$$f(z) = \sum_{n=0}^{\infty} \frac{a_n z^n}{(n!)^2} \tag{6.20}$$

that occurs in Section 7, or the Newton series

$$f(z) = \sum_{n=0}^{\infty} a_n z(z-1)\cdots(z-n+1) \;. \tag{6.21}$$

Also frequently encountered are various q-analog generating functions, such as the Eulerian

$$f(z) = \sum_{n=1}^{\infty} \frac{a_n z^n}{(1-q)(1-q^2)\cdots(1-q^n)} \;. \tag{6.22}$$

In multiplicative number theory, the most common are Dirichlet series

$$f(z) = \sum_{n=1}^{\infty} a_n n^{-z} \;, \tag{6.23}$$

which reflect the multiplicative structure of the integers. If a_n is a multiplicative function (so that $a_{mn} = a_m a_n$ for all relatively prime positive integers m and n) then the function (6.23)

has an Euler product representation

$$f(z) = \prod_p (1 + a_p p^{-z} + a_{p^2} p^{-2z} + \cdots) \ , \tag{6.24}$$

where p runs over the primes. This allows new tools to be used to study $f(z)$ and through it a_n. Additive problems in combinatories and number theory often are handled using functions such as functions such as

$$f(z) = \sum_{n=1}^{\infty} z^{a_k} \ , \tag{6.25}$$

where $0 \le a_1 < a_2 < \cdots$ is a sequence of integers. Addition of two such sequences then corresponds to a multiplication of the generating functions of the form (6.25).

We next mention the "snake oil method." This is the name given by Wilf [377] to the use of generating functions for proving identities, and comes from the surprising power of this technique. The typical application is to evaluation of sequences given by sums of the type

$$a_n = \sum_k b_{n,k} \ . \tag{6.26}$$

The standard procedure is to form a generating function of the a_n and manipulate it through interchanges of summation and other tricks to obtain the final answer. The generating function can be ordinary, exponential, or (less commonly) of another type, depending on what gives the best results. We show a simple application of this principle that exhibits the main features of the method.

Example 6.2. *A binomial coefficient sum* [377]. Let

$$a_n = \sum_{k=0}^{n} \binom{n+k}{2k} 2^{n-k} \ , \quad n \ge 0 \ . \tag{6.27}$$

We define $A(z)$ to be the ordinary generating function of a_n. We find that

$$\begin{aligned} A(z) &= \sum_{n=0}^{\infty} a_n z^n = \sum_{n=0}^{\infty} z^n \sum_{k=0}^{n} \binom{n+k}{2k} 2^{n-k} \\ &= \sum_{k=0}^{\infty} 2^{-k} \sum_{n=k}^{\infty} 2^n z^n \binom{n+k}{2k} = \sum_{k=0}^{\infty} 2^{-k} (2z)^{-k} \sum_{n=0}^{\infty} \binom{n+k}{2k} (2z)^{n+k} \\ &= \sum_{k=0}^{\infty} 2^{-k} (2z)^{-k} \frac{(2z)^{2k}}{(1-2z)^{2k+1}} = \frac{1}{1-2z} \sum_{k=0}^{\infty} \left(\frac{z}{1-2z} \right)^k \\ &= \frac{1-2z}{(1-4z)(1-z)} = \frac{2}{3(1-4z)} + \frac{1}{3(1-z)} \ . \end{aligned} \tag{6.28}$$

Therefore we immediately find the explicit form

$$a_n = (2^{2n+1} + 1)/3 \quad \text{for} \quad n \geq 0 \ . \tag{6.29}$$

■

We next present some additional examples of how generating functions are derived. We start by considering linear recurrences with constant coefficients.

The first step in solving a linear recurrence is to obtain its generating function. Suppose that a sequence $a_0, a_1, a_2, \ldots$ satisfies the recurrence

$$a_n = \sum_{i=1}^{d} c_i a_{n-i}, \quad n \geq d \ . \tag{6.30}$$

Then

$$\begin{aligned} f(z) &= \sum_{n=0}^{\infty} a_n z^n = \sum_{n=0}^{d-1} a_n z^n + \sum_{n=d}^{\infty} z^n \sum_{i=1}^{d} c_i a_{n-i} \\ &= \sum_{n=0}^{d-1} a_n z^n + \sum_{i=1}^{d} c_i z^i \sum_{n=d}^{\infty} a_{n-i} z^{n-i} \\ &= \sum_{n=0}^{d-1} a_n z^n + \sum_{i=1}^{d} c_i z^i \left(f(z) - \sum_{n=0}^{d-i-1} a_n z^n \right) \ , \end{aligned} \tag{6.31}$$

and so

$$f(z) = \frac{g(z)}{1 - \sum_{i=1}^{d} c_i z^i} \ , \tag{6.32}$$

where

$$g(z) = \sum_{n=0}^{d-1} a_n z^n - \sum_{i=1}^{d} c_i z^i \sum_{n=0}^{d-i-1} a_n z^n \tag{6.33}$$

is a polynomial of degree $\leq d-1$. Eq. (6.32) is the fundamental relation in the study of linear recurrences, and $1 - \sum c_i z^i$ is called the *characteristic polynomial* of the recursion.

Example 6.3. *Fibonacci numbers.* We let $F_0 = 0$, $F_1 = 1$, $F_n = F_{n-1} + F_{n-2}$ for $n \geq 2$, and

$$F(z) = \sum_{n=0}^{\infty} F_n z^n \ .$$

Then by (6.32) and (6.33),

$$F(z) = \frac{z}{1 - z - z^2} \ . \qquad \blacksquare \tag{6.34}$$

Often there is no obvious recurrence for the sequence a_n being studied, but there is one involving some other auxiliary function. Usually if one can obtain at least as many recurrences as there are sequences, one can obtain their generating functions by methods similar to those used for a single sequence. The main additional complexity comes from the need to solve a system of linear equations with polynomial coefficients. We illustrate this with the following example.

Example 6.4. *Sequences with forbidden subwords.* Let $A = a_1 a_2 \cdots a_k$ be a binary string of length k. Define $f_A(n)$ to be the number of binary strings of length n that do not contain A as a subword of k adjacent characters. (Subsequences do not count, so that if $A = 1110$, then A is contained in 1101110010, but not in 101101.) We introduce the correlation polynomial $C_A(z)$ of A:

$$C_A(z) = \sum_{j=0}^{k-1} c_A(j) z^j \ , \tag{6.35}$$

where $c_A(0) = 1$ and for $1 \leq j \leq k-1$,

$$c_A(j) = \begin{cases} 1 & \text{if } \ a_1 a_2 \cdots a_{k-j} = a_{j+1} a_{j+2} \cdots a_k \ , \\ 0 & \text{otherwise .} \end{cases} \tag{6.36}$$

As examples, we note that if $A = 1000$, then $C_A(z) = 1$, whereas $C_A(z) = 1 + z + z^2 + z^3$ if $A = 1111$. The generating function

$$F_A(z) = \sum_{n=0}^{\infty} f_A(n) z^n \tag{6.37}$$

then satisfies

$$F_A(z) = \frac{C_A(z)}{z^k + (1-2z) C_A(z)} \ . \tag{6.38}$$

To prove this, define $g_A(n)$ to be the number of binary sequences $b_1 b_2 \cdots b_n$ of length n such that $b_1 b_2 \cdots b_k = A$, but such that $b_j b_{j+1} \cdots b_{j+k-1} \neq A$ for any j with $2 \leq j \leq n-k+1$; i.e., sequences that start with A but do not contain it any place else. We then have $g_A(n) = 0$ for $n < k$, and $g_A(k) = 1$. We also define

$$G_A(z) = \sum_{n=0}^{\infty} g_A(n) z^n \ . \tag{6.39}$$

We next obtain a relation between $G_A(z)$ and $F_A(z)$ that will enable us to determine both.

If $b_1 b_2 \cdots b_n$ is counted by $f_A(n)$, then for x either 0 or 1, the string $x b_1 b_2 \cdots b_n$ either does not contain A at all, or if it does contain it, then $A = x b_1 b_2 \cdots b_{k-1}$. Therefore for $n \geq 0$,

$$2 f_A(n) = f_A(n+1) + g_A(n+1) \tag{6.40}$$

and multiplying both sides of Eq. (6.40) by z^n and summing on $n \geq 0$ yields

$$2F_A(z) = z^{-1}(F_A(z) - 1) + z^{-1}G_A(z) \ . \tag{6.41}$$

We need one more relation, and to obtain it we consider any string $B = b_1 b_2 \cdots b_n$ that does not contain A any place inside. If we let C be the concatenation of A and B, so that $C = a_1 a_2 \cdots a_k b_1 b_2 \cdots b_n$, then C starts with A, and may contain other occurrences of A, but only at positions that overlap with the initial A. Therefore we obtain,

$$f_A(n) = \sum_{\substack{j=1 \\ c_A(k-j)=1}}^{k} g_A(n+j) \quad \text{for} \quad n \geq 0 \ , \tag{6.42}$$

and this gives the relation

$$F_A(z) = z^{-k} C_A(z) G_A(z) \ . \tag{6.43}$$

Solving the two equations (6.41) and (6.43), we find that $F_A(z)$ satisfies (6.38), while

$$G_A(z) = \frac{z^k}{z^k + (1-2z)C_A(z)} \ . \tag{6.44}$$

The proof above follows that in [182], except that [182] uses generating functions in z^{-1}, so the formulas look different. Applications of the formulas (6.38) and (6.44) will be found later in this chapter, as well as in [182, 130]. Other approaches to string enumeration problems are referenced there as well. Other approaches and applications of string enumerations are given in the references to [182] and in papers such as [18]. ■

The above example can be generalized to provide generating functions that enumerate sequences in which any of a given set of patterns are forbidden [182].

Whenever one has a finite system of linear recurrences with constant coefficients that involve several sequences, say $a_n^{(i)}$, $1 \leq i \leq k$, $n \geq 0$, one can translate these recurrences into linear equations with polynomial coefficients in the generating functions $A^{(i)}(z) = \sum a_n^{(i)} z^n$ for these sequences. To obtain the $A^{(i)}(z)$, one then needs to solve the resulting system. Such solutions will exist if the matrix of polynomial coefficients is nonsingular over the field of rational functions in z. In particular, one needs at least as many equations (i.e., recurrence relations) as k, the number of sequences, and if there are exactly as many equations as sequences, then the determinant of the matrix of the coefficients has to be a nonzero polynomial.

One interesting observation is that when a system of recurrences involving several sequences is solved by the above method, each of the generating functions $A^{(i)}(z)$ is a rational function

in z. What this means is that each of the sequences $a_n^{(i)}$, $1 \le i \le k$, satisfies a linear recurrence with constant coefficients that does not involve any of the other $a_n^{(j)}$ sequences! In principle, therefore, that recurrence could have been found right at the beginning by combinatorial methods. However, usually the degree of the recurrence for an isolated $a_n^{(j)}$ sequence is high, typically about k times as large as the average degree of the k recurrences involving all the $a_n^{(j)}$. Thus the use of several sequences $a_n^{(j)}$ leads to much simpler and combinatorially more appealing relations.

That generating functions can significantly simplify combinatorial problems is shown by the following example. It is taken from [349], and is a modification of a result of Klarner [229] and Pólya [321]. This example also shows a more complicated derivation of explicit generating functions than the simple ones presented so far.

Example 6.5. *Polyomino enumeration* [349]. Let a_n be the number of n-square polyominoes P that are inequivalent under translation, but not necessarily under rotation or reflection, and such that each row of P is an unbroken line of squares. Then $a_1 = 1$, $a_2 = 2$, $a_3 = 6$. We define $a_0 = 0$. It is easily seen that

$$a_n = \sum (m_1 + m_2 - 1)(m_2 + m_3 - 1) \cdots (m_{s-1} + m_s - 1) \ , \tag{6.45}$$

where the sum is over all ordered partitions $m_1 + \cdots + m_s = n$ of n into positive integers m_i. Let $a_{r,n}$ be the sum of terms in (6.45) with $m_1 = r$, where we set $a_{n,n} = 1$, and $a_{r,n} = 0$ if $r > n$ or $n < 0$. Then

$$a_n = \sum_{r=1}^{\infty} a_{r,n} \ , \tag{6.46}$$

$$a_{r,n} = \sum_{i=1}^{\infty} (r + i - 1) a_{i,n-r} \ , \quad r < n \ . \tag{6.47}$$

Define

$$A(x, y) = \sum_{n=1}^{\infty} \sum_{r=1}^{\infty} a_{r,n} x^r y^n \ , \tag{6.48}$$

so that

$$A(1, y) = \sum_{n=1}^{\infty} a_n y^n \tag{6.49}$$

is the generating function of the a_n, which are what we need to estimate.

By (6.47), we find that

$$A(x, y) = \sum_{n=1}^{\infty} x^n y^n + \sum_{n=1}^{\infty} \sum_{r=1}^{\infty} \sum_{i=1}^{\infty} (r + i - 1) a_i (n - r) x^r y^n$$

$$= \frac{xy}{1-xy} + \frac{x^2y^2}{(1-xy)^2}A(1,y) + \frac{xy}{1-xy}G(x,y) \ , \tag{6.51}$$

where

$$G(y) = \sum_{n=1}^{\infty}\sum_{i=1}^{\infty} i a_{i,n} y^n = \frac{\partial}{\partial x}A(x.y)\Big|_{x=1} \ , \tag{6.52}$$

We now set $x = 1$ in (6.50) and obtain an equation involving $A(1,y)$ and $G(y)$, namely

$$A(1,y) = \frac{y}{1-y} + \frac{y^2}{(1-y)^2}A(1,y) + \frac{y}{1-y}G(y) \ . \tag{6.53}$$

We next differentiate (6.50) with respect to x, and set $x = 1$. This gives us a second equation,

$$G(y) = \frac{y}{(1-y)^2} + \frac{2y^2}{(1-y)^3}A(1,y) + \frac{y}{(1-y)^2}G(y) \ . \tag{6.54}$$

We now eliminate $G(y)$ from (6.53) and (6.54) to obtain

$$A(1,y) = \frac{y(1-y)^3}{1-5y+7y^2-4y^3} \ . \tag{6.55}$$

This formula shows that

$$a_{n+3} = a_{n+2} - 7a_{n+1} + 4a_n \quad \text{for} \quad n \geq 2 \ . \tag{6.56}$$

Using the results of Section 10 we can easily obtain from (6.55) an asymptotic estimate

$$a_n \sim c\alpha^n \quad \text{as} \quad n \to \infty \ , \tag{6.57}$$

where c is a certain constant and $\alpha = 3.205569\ldots$ is the inverse of the smallest zero of $1 - 5y + 7y^2 - 4y^3$. ■

For other methods and results related to polyomino enumeration, see [326, 327].

6.2. Composition and inversion of power series

So far we have only discussed simple operations on generating functions, such as multiplication. What happens when we do something more complicated? There are several frequently occurring operations on generating functions whose results can be described explicitly.

Faà di Bruno's formula [81]. Suppose that

$$A(z) = \sum_{m=0}^{\infty} a_m \frac{z^m}{m!} \ , \quad B(z) = \sum_{n=0}^{\infty} b_n \frac{z^n}{n!} \ , \tag{6.58}$$

are two exponential generating functions with $b_0 = 0$. Then the formal composition $C(z) = A(B(z))$ is well-defined, and

$$C(z) = \sum_{n=0}^{\infty} c_n \frac{z^n}{n!} \tag{6.59}$$

with

$$c_0 = 0, \quad c_n = \sum_{k=1}^{n} a_k B_{n,k}(b_1, b_2, \ldots, b_{n-k+1}) \ , \tag{6.60}$$

where the $B_{n,k}$ are the exponential Bell polynomials defined by

$$\sum_{n,k=0}^{\infty} B_{n,k}(x_1, \ldots, x_{n-k+1}) \frac{t^n u^k}{n!} = \exp\left(u \sum_{m=1}^{\infty} x_m \frac{t^m}{m!} \right) \ , \tag{6.61}$$

with the x_j independent variables.

Faà di Bruno's formula makes it possible to compute successive derivatives of functions such as $\log A(z)$ in terms of the derivatives of $A(z)$. For further examples, see [81, 335, 336]. Faà di Bruno's formula is derivable in a straightforward way from the multinomial theorem.

Composition of generating functions occurs frequently in combinatorics and analysis of algorithms. When it yields the desired generating function as a composition of several known generating functions, the basic problem is solved, and one can work on the asymptotics of the coefficients using Faà di Bruno's formula or other methods. A more frequent event is that the composition yields a functional equation for the generating function, as in Example 6.1, where the exponential generating function $t(z)$ for labeled rooted trees was shown to satisfy $t(z) = z \exp(t(z))$. General functional equations are hard to deal with. (Many examples will be presented later.) However, there is a class of them for which an old technique, the Lagrange-Bürmann inversion formula, works well. We start by noting that if

$$f(z) = \sum_{n=0}^{\infty} f_n z^n \tag{6.62}$$

is a formal power series with $f_0 = 0$, $f_1 \neq 0$, then there is an inverse formal power series $f^{\langle -1 \rangle}(z)$ such that

$$f(f^{\langle -1 \rangle}(z)) = f^{\langle -1 \rangle}(f(z)) = z \ . \tag{6.63}$$

The coefficients of $f^{\langle -1 \rangle}(z)$ can be expressed explicitly in terms of the coefficients of $f(z)$. More generally, we have the following result.

Lagrange-Bürmann inversion formula. Suppose that $f(z)$ is a formal power series with $[z^0]f(z) = 0$, $[z^1]f(z) \neq 0$, and that $g(z)$ is any formal power series. Then for $n \geq 1$,

$$[z^n]\{g(f^{\langle -1 \rangle})(z)\} = n^{-1}[z^{n-1}]\{g'(z)(f(z)/z)^{-n}\} \ . \tag{6.64}$$

In particular, for $g(z) = z$, we have

$$[z^n] f^{\langle -1 \rangle}(z) = n^{-1}[z^{n-1}](f(z)/z)^{-n} \ . \tag{6.65}$$

Example 6.6. *Rooted labeled trees.* As was shown in Example 6.1, the exponential generating function of rooted labeled trees satisfies $t(z) = z\exp(t(z))$. If we rewrite it as $z = t(z)\exp(-t(z))$, we see that $t(z) = f^{\langle -1 \rangle}(z)$, where $f(z) = z\exp(-z)$. Therefore Eq. (6.65) yields

$$\begin{aligned} [z^n]t(z) &= n^{-1}[z^{n-1}]\exp(-nz) \\ &= n^{-1}n^{n-1}/(n-1)! \ = \ n^{n-1}/n! \ , \end{aligned} \tag{6.66}$$

which shows that t_n, the number of rooted labeled trees on n nodes, is n^{n-1}. ■

Proof of a form of the Lagrange-Bürmann theorem is given in Chapter ?. Extensive discussion, proofs, and references are contained in [81, 173, 205, 375]. Some additional recent references are [159, 208]. There exist generalizations of the Lagrange-Bürmann formula to several variables [173, 169, 208].

The Lagrange-Bürmann formula, as stated above, is valid for general formal power series. If $f(z)$ is analytic in a neighborhood of the origin, then so are $f^{\langle -1 \rangle}(z)$ and $g(f^{\langle -1 \rangle})(z)$, provided $g(z)$ is also analytic near 0 and $f'(0) \neq 0$, $f(0) = 0$. Most of the presentations of this inversion formula in the literature assume analyticity. However, that is not a real restriction. To prove (6.65), say, in full generality, it suffices to prove it for any n. Given n, if we let

$$F(z) = \sum_{k=0}^{n} f_k z^k \ , \quad G(z) = \sum_{k=0}^{n} g_k z^k \ ,$$

then we see that

$$[z^n]\{g(f^{\langle -1 \rangle})(z)\} = [z^n]G(F^{\langle -1 \rangle})(z) \ , \tag{6.67}$$

and $F(z)$ and $G(z)$ are analytic, so the formula (6.65) can be applied. Thus combinatorial proofs of the Lagrange-Bürmann formula do not offer greater generality than analytic ones.

While the analytic vs. combinatorial distinction in the proofs of the Lagrange-Bürmann formula does not matter, it is possible to use analyticity of the functions $f(z)$ and $g(z)$ to obtain useful information. Example 6.6 above was atypical in that a simple explicit formula

was derived. Often the quantity on the right-hand side of (6.64) is not explicit enough to make clear its asymptotic behavior. When that happens, and $g(z)$ and $f(z)$ are analytic, one can use the contour integral representation

$$[z^{n-1}]\{g'(z)(f(z)/z)^{-n}\} = \frac{1}{2\pi i}\int_\Gamma g'(z)f(z)^{-n}dz \ , \tag{6.68}$$

where Γ is a positively oriented simple closed contour enclosing the origin that lies inside the region of analyticity of both $g(z)$ and $f(z)$. This representation, which is discussed in Section 10, can often be used to obtain asymptotic information about coefficients $[z^n]g(f^{\langle -1\rangle})(z)$ (cf. [273]).

The Lagrange-Bürmann formula can provide numerical approximations to roots of equations and even convergent infinite series representations for such roots. An important case is the trinomial equation $y = z(1 + y^r)$, and there are many others.

Example 6.7. *Dominant zero for forbidden subword generating functions.* The generating functions $F_A(z)$ and $G_A(z)$ of Example 6.4 both have denominators

$$h(z) = z^k + (1 - 2z)C(z) \ , \tag{6.69}$$

where $C(z)$ is a polynomial of degree $\le k$, with coefficients 0 and 1, and with $C(0) = 1$. It will be shown later that $h(z)$ has only one zero ρ of small absolute value, and that this zero is the dominant influence on the asymptotic behavior of the coefficients of $F_A(z)$ and $G_A(z)$. Right now we obtain accurate estimates for ρ.

For simplicity, we will consider only large k. Since $C(z)$ has nonnegative coefficients and $C(0) = 1$, $h(3/4) \le (3/4)^k - 1/2 < 0$ for $k \ge 3$. On the other hand, $h(1/2) = 2^{-k}$. Therefore $h(z)$ has a real zero ρ with $1/2 < \rho < 3/4$. As $k \to \infty$, $\rho \to 1/2$, since

$$\rho^k = (2\rho - 1)C(\rho) \ , \tag{6.70}$$

and $\rho^k \to 0$ as $k \to \infty$ for $1/2 < \rho < 3/4$, while $2\rho - 1$ and $C(\rho)$ are bounded. We can deduce from (6.69) that

$$2\rho - 1 \sim 2^{-k}C(1/2)^{-1} \quad \text{as} \quad k \to \infty \ , \tag{6.71}$$

uniformly for all polynomials $C(z)$ of the prescribed type. By applying the bootstrapping technique (see Section 5.4) we can find even better approximations. By (6.71),

$$C(\rho) \ = \ C(1/2) + O(|\rho - 1/2|) \ = \ C(1/2) + O(2^{-k}) \ , \tag{6.72}$$

$$\rho^k \ = \ 2^{-k}(1 + O(2^{-k}))^k \ = \ 2^{-k}(1 + O(k2^{-k})) \ , \tag{6.73}$$

so (6.70) now yields

$$\rho = 1/2 + 2^{-k-1}C(1/2)^{-1} + O(k2^{-2k}) \ . \tag{6.74}$$

Even better approximations can be obtained by repeating the process using (6.74). At the next stage we would apply the expansion

$$\begin{aligned} C(\rho) &= C(1/2) + (\rho - 1/2)C'(1/2) + O((\rho - 1/2)^2) \\ &= C(1/2) + 2^{-k-1}C'(1/2) + O(k2^{-2k}) \end{aligned} \tag{6.75}$$

and a similar one for ρ^k.

A more systematic way to obtain a rapidly convergent series for ρ is to use the inversion formula. If we set $u = \rho - 1/2$, then (6.70) can be rewritten as $w(u) = 1$, where

$$w(u) = 2uC(1/2+u)(1/2+u)^{-k} = \sum_{j=1}^{\infty} a_j u^j \ , \tag{6.76}$$

with

$$a_1 = 2^{k+1}C(1/2) \neq 0 \ . \tag{6.77}$$

Hence $u = w^{\langle -1 \rangle}(1)$, and the Lagrange-Bürmann inversion formula (6.65) yields the coefficients of $w^{\langle -1 \rangle}(z)$. In particular, we find that

$$\rho = 1/2+u \approx 1/2+2^{-k-1}C(1/2)^{-1}+k2^{-2k-1}C(1/2)^{-2}-2^{-2k-2}C'(1/2)C(1/2)^{-3}+\cdots \tag{6.78}$$

as a Poincaré asymptotic series. With additional work one can show that the series (6.78) converges, and that

$$\begin{aligned} \rho = 1/2 &+ 2^{-k-1}C(1/2)^{-1} + k2^{-2k-1}C(1/2)^{-2} \\ &- 2^{-2k-2}C'(1/2)C(1/2)^{-3} + O(k^2 2^{-3k}) \ , \end{aligned} \tag{6.79}$$

for example. The same estimate can be obtained by the bootstrapping technique. ■

6.3. Differentiably finite power series

Homogeneous recurrences with constant coefficients are the nicest large set of sequences one can imagine, with rational generating functions, and well-understood asymptotic behavior. The next class in complexity consists of the polynomially-recursive or, *P-recursive sequences*, $a_0, a_1, \ldots$, which satisfy recurrences of the form

$$p_d(n)a_{n+d} + p_{d-1}(n)a_{n+d-1} + \cdots + p_0(n)a_n = 0, \quad n \geq 0 \ , \tag{6.80}$$

where d is fixed and $p_0(n), \ldots, p_d(n)$ are polynomials in n. Such sequences are common in combinatorics, with $a_n = n!$ a simple example. Normally P-recursive sequences do not have explicit forms for their generating functions. In this section we briefly summarize some of their main properties. Asymptotic properties of P-recursive sequences will be discussed in Section 9.2. The main references for the results quoted here are [254, 350].

A formal power series

$$f(z) = \sum_{k=0}^{\infty} a_k z^k \tag{6.81}$$

is called differentiably finite, or *D-finite*, if the derivatives $f^{(n)}(z) = \frac{d^n f(z)}{dz^n}$, $n \geq 0$, span a finite-dimensional vector space over the field of rational functions with complex coefficients. The following three conditions are equivalent for a formal power series $f(z)$:

i) $f(z)$ is D-finite.

ii) There exist finitely many polynomials $q_0(z), \ldots, q_k(z)$ and a polynomial $q(z)$, not all 0, such that

$$q_k(z) f^{(k)}(z) + \cdots + q_0(z) f(z) = q(z) \ . \tag{6.82}$$

iii) There exist finitely many polynomials $p_0(z), \ldots, p_m(z)$, not all 0, such that

$$p_m(z) f^{(m)}(z) + \cdots + p_0(z) f(z) = 0 \ . \tag{6.83}$$

The most important result for combinatorial enumeration is that a sequence $a_0, a_1, \ldots$, is P-recursive if and only if its ordinary generating function $f(z)$, defined by (6.81), is D-finite. This makes it possible to apply results that are more easily proved for D-finite power series.

If $f(z)$ is D-finite, then so is the power series obtained by changing a finite number of the coefficients of $f(z)$. If $f(z)$ is algebraic (i.e., there exist polynomials $q_0(z), \ldots, q_d(z)$, not all 0, such that $q_d(z) f(z)^d + \cdots + q_0(z) f(z) + q_0(z) = 0$), then $f(z)$ is D-finite. The product of two D-finite power series is also D-finite, as is any linear combination with polynomial coefficients. Finally, the Hadamard product of two D-finite series is D-finite. The proofs rely on elementary linear algebra constructions. An important feature of the theory is that identity between D-finite series is decidable.

The concept of a D-finite power series can be extended to several variables [254, 405], and there are generalizations of P-recursiveness [254, 405]. (See also [161].) Zeilberger [405] has used the word *holonomic* to describe corresponding sequences and generating functions.

When we investigate a sequence $\{a_n\}$, sometimes the combinatorial context yields only relations for more complicated object with several indices. While we might like to obtain the generating function $f(z) = \sum a_n z^n$, we might instead find a formula for a generating function

$$F(z_1, z_2, \ldots, z_k) = \sum_{n_1,\ldots,n_k} b_{n_1}, \ldots, n_k z_1^{n_1}, \ldots, z_k^{n_k} \ , \tag{6.84}$$

where $a_n = b_{n,n,\ldots,n}$, say. When this happens, we say that $f(z)$ is a *diagonal* of $F(z_1, \ldots, z_k)$. (There are more general definitions of diagonals in [90, 253, 254, 255], which are recent references for this topic.) Diagonals of D-finite power series in any number of variables are D-finite. Diagonals of two-variable rational functions are algebraic, but there are three-variable rational functions whose diagonals are not algebraic [151].

6.4. Unimodality and log-concavity

A finite sequence $a_0, a_1, \ldots, a_n$ of real numbers is called *unimodal* if for some index k, $a_0 \le a_1 \le \cdots \le a_k$ and $a_k \ge a_{k+1} \ge \cdots \ge a_n$. A sequence $a_0, \ldots, a_n$ of nonnegative elements is called *log-concave* (short for logarithmically concave) if $a_j^2 \ge a_{j-1}a_{j+1}$ holds for $1 \le j \le n-1$. Unimodal and log-concave sequences occur frequently in combinatorics and are objects of intensive study. We present a brief review of some of their properties because asymptotic methods are often used to prove unimodality and log-concavity. Furthermore, knowledge that a sequence is log-concave or unimodal is often helpful in obtaining asymptotic information. For example, some methods provide only asymptotic estimates for summatory functions of sequences, and unimodality helps in obtaining from those estimates bounds on individual coefficients. This approach will be presented in Section 13, in the discussion of central and local limit theorems.

The basic references for unimodality and log-concavity are [222, 352]. For recent results, see also [56] and the references given there. All the results listed below can be found in those sources and the references they list.

In the rest of this subsection we will consider only sequences of nonnegative elements. A sequence $a_0, \ldots, a_n$ will be said to *have no internal zeros* if there is no triple of integers $0 \le i < j < k \le n$ such that $a_j = 0$, $a_i a_k \ne 0$. It is easy to see that a log-concave sequence with no internal zeros is unimodal, but there are sequences of positive elements that are unimodal but not concave. The convolution of two unimodal sequences does not have to be unimodal. However, it is unimodal if each of the two unimodal sequences is also symmetric.

Convolution of two log-concave sequences is log-concave. The convolution of a log-concave and a unimodal sequence is unimodal. A log-concave sequence is even characterized by the property that its convolution with any unimodal sequence is unimodal. This last property is related to the variation-diminishing character of log-concave sequences (see [222]), which we will not discuss at greater length here except to note that there are more restrictive sets of sequences (the Pólya frequency classes, see [56, 222]) which have stronger convolution properties.

The binomial coefficients $\binom{n}{k}$, $0 \le k \le n$, are log-concave, and therefore unimodal. The q-binomial coefficients $\begin{bmatrix} n \\ k \end{bmatrix}_q$ are log-concave for any $q \ge 1$. On the other hand, if we write a single coefficient $\begin{bmatrix} n \\ k \end{bmatrix}_q$ for fixed n and k as a polynomial in q, the sequence of coefficients is unimodal, but does not have to be log-concave.

The most frequently used method for showing that a sequence $a_0, \ldots, a_n$ is log-concave is to show that all the zeros of the polynomial

$$A(z) = \sum_{k=0}^{n} a_k z^k \tag{6.85}$$

are real and ≤ 0. In that case not only are the a_k log-concave, but so are $a_k \binom{n}{k}^{-1}$. Absolute values of the Stirling numbers of both kinds were first shown to be log-concave by this method [195]. There are many unsolved conjectures about log-concavity of combinatorial sequences, such as the Read-Hoggar conjecture that coefficients of chromatic polynomials are log-concave (cf. [57]).

A variety of combinatorial, algebraic, and geometric methods have been used to prove unimodality of sequences, and we refer the reader to [352] for a comprehensive and insightful survey. In Section 12.3 we will discuss briefly some proofs of unimodality and log-concavity that use asymptotic methods. The basic philosophy is that since the Gaussian distribution is log-concave and unimodal (when we extend the definition of these concepts to continuous distributions), these properties should also hold for sequences that by the central limit theorem or its variants are asymptotic to the Gaussian. Therefore one can expect high-order convolutions of sequences to be log-concave at least in their central region, and there are theorems that prove this under certain conditions.

6.5. Moments and distributions

The second moment method is a frequently used technique in probabilistic arguments, as is shown in Chapter ? and [55, 108, 348]. It is based on *Chebyshev's inequality*, which says

that if X is a real-valued random variable with finite second moment $E(X^2)$, then

$$\text{Prob}\left(|X - E(X)| \geq \alpha |E(X)|\right) \leq \frac{E(X^2) - E(X)^2}{\alpha^2 E(X)^2} \ . \tag{6.86}$$

An easy corollary of inequality (6.86) that is often used is

$$\text{Prob}\left(X = 0\right) \leq \frac{E(X^2) - E(X)^2}{E(X)^2} \ . \tag{6.87}$$

(There is a slightly stronger version of the inequality (6.87), in which $E(X)^2$ in the denominator is replaced by $E(X^2)$.) The inequalities (6.86) and (6.87) are usually applied for $X = Y_1 + \cdots + Y_n$, where the Y_j are other random variables. The helpful feature of the inequalities is that they require only knowledge of the pairwise dependencies among the Y_j, which is easier to study than the full joint distribution of the Y_j. For other bounds on distributions that can be obtained from partial information about moments, see [343].

The reason moment bounds are mentioned at all in this chapter is that asymptotic methods are often used to derive them. Generating functions are a common and convenient method for doing this.

Example 6.8. *Waiting times for subwords.* In a continuation and application of Example 6.4, let A be a binary string of length k. How many tosses of a fair coin (with sides labeled 0 and 1) are needed on average before A appears as a block of k consecutive outcomes? By a general observation of probability theory, this is just the sum over $n \geq 0$ of the probability that A does not appear in the first n coin tosses, and thus equals

$$\sum_{n=0}^{\infty} f_A(n) 2^{-n} = F_A(1/2) = 2^k C_A(1/2) \ , \tag{6.88}$$

where the last equality follows from Eq. (6.38). Another, more general, way to derive this is to use $G_A(z)$. Note that $g_A(n)2^{-n}$ is the probability that A appears in the first n coin tosses, but not in the first $n-1$. Hence the r-th moment of the time until A appears is

$$\sum_{n=0}^{\infty} n^r g_A(n) 2^{-n} = \left(z \frac{d}{dz}\right)^r G_A(z)\Big|_{z=1/2} \ . \tag{6.89}$$

If we take $r = 1$, we again obtain the expected waiting time given by (6.88). When we take $r = 2$, we find that the second moment of the time until the appearance of A is

$$\sum_{n=0}^{\infty} n^2 g_A(n) 2^{-n} = 2^{2k+1} C_A(1/2)^2 - (2k-1) 2^k C_A(1/2) + 2^k C_A'(1/2) \ , \tag{6.90}$$

and therefore the variance is

$$\begin{aligned} & 2^{2k}C_A(1/2)^2 - (2k-1)2^k C_A(1/2) + 2^k C'_A(1/2) \\ & \quad = \; 2^{2k}C_A(1/2)^2 + O(k2^k) \; , \end{aligned} \tag{6.91}$$

since $1 \leq C_A(1/2) \leq 2$. Higher moments can be used to obtain more detailed information. A better approach is to use the method of Example 9.2, which gives precise estimates for the tails as well as the mean of the distribution. ■

Information about moments of distribution functions can often be used to obtain the limiting distribution. If $F_n(x)$ is a sequence of distribution functions such that for every integer $k \geq 0$, the k-th moment

$$\mu_n(k) = \int x^k dF_n(x) \tag{6.92}$$

converges to $\mu(k)$ as $n \to \infty$, then there is a limiting measure with distribution function $F(x)$ whose k-th moment is $\mu(k)$. If the moments $\mu(k)$ do not grow too rapidly, then they determine the distribution function $F(x)$ uniquely, and the $F_n(x)$ converge to $F(x)$ (in the weak star sense [50]). A sufficient condition for the $\mu(k)$ to determine $F(x)$ uniquely is that the generating function

$$U(x) = \sum_{k=0}^{\infty} \frac{\mu(2k)x^k}{(2k)!} \tag{6.93}$$

should converge for some $x > 0$. In particular, the standard normal distribution with

$$F(x) = (2\pi)^{-1/2} \int_{-\infty}^{x} \exp(-u^2/2)du \tag{6.94}$$

has $\mu(2k) = 1 \cdot 3 \cdot 5 \cdot 7 \cdot \ldots \cdot (2k-1)$ (and $\mu(2k+1) = 0$), so it is determined uniquely by its moments. On the other hand, there are some frequently encountered distributions, such as the log-normal one, which do not have this property.

7. Formal power series

This section discusses generating functions $f(z)$ that might not converge in any interval around the origin. Sequences that grow rapidly are common in combinatorics, with $a_n = n!$ the most obvious example for which

$$f(z) = \sum_{n=0}^{\infty} a_n z^n \tag{7.1}$$

does not converge for any $z \neq 0$. The usual way to deal with the problem of a rapidly growing sequence a_n is to study the generating function of a_n/b_n, where b_n is some sequence with

known asymptotic behavior. When $b_n = n!$, the ordinary generating function of a_n/b_n is then the exponential generating function of a_n. For derangements (Eqs. (1.1) and (6.7)) this works well, as the exponential generating function of d_n converges in $|z| < 1$ and has a nice form. Unfortunately, while we can always find a sequence b_n that will make the ordinary generating function $f(z)$ of a_n/b_n converge (even for all z), usually we cannot do it in a way that will yield any useful information about $f(z)$. The combinatorial structure of a problem almost always severely restricts what forms of generating function can be used to take advantage of the special properties of the problem. This difficulty is common, for example, in enumeration of labeled graphs. In such cases one often resorts to formal power series that do not converge in any neighborhood of the origin. For example, if $c(n,k)$ is the number of connected labeled graphs on n vertices with k edges, then it is well known (cf. [349]) that

$$\sum_{n=0}^{\infty}\sum_{k=0}^{\infty} c(n,k)\frac{x^k y^n}{n!} = \log\left(\sum_{m=0}^{\infty}\frac{(1+x)^{\binom{m}{2}}y^m}{m!}\right) . \tag{7.2}$$

While the series inside the log in (7.2) does converge for $-2 \le x \le 0$, and any y, it diverges for any $x > 0$ as long as $y \neq 0$, and so this is a relation of formal power series.

There are few methods for dealing with asymptotics of formal power series, at least when compared to the wealth of techniques available for studying analytic generating functions. Fortunately, combinatorial enumeration problems that do require the use of formal power series often involve rapidly growing sequences of positive terms, for which some simple techniques apply. We start with an easy general result that is applicable both to convergent and purely formal power series.

Theorem 7.1. ([33]) *Suppose that* $a(z) = \sum a_n z^n$ *and* $b(z) = \sum b_n z^n$ *are power series with radii of convergence* $\alpha > \beta \ge 0$, *respectively. Suppose that* $b_{n-1}/b_n \to \beta$ *as* $n \to \infty$. *If* $a(\beta) \neq 0$, *and* $\sum c_n z^n = a(z)b(z)$, *then*

$$c_n \sim a(\beta)b_n \quad as \quad n \to \infty . \tag{7.3}$$

The proof of Theorem 7.1, which can be found in [33], is simple. The condition $\alpha > \beta$ is important, and cannot be replaced by $\alpha = \beta$. We can have $\beta = 0$, and that is indeed the only possibility if the series for $b(z)$ does not converge in a neighborhood of $z = 0$.

Example 7.1. *Double set coverings* [33, 80]. Let v_n be the number of choices of subsets $S_1, \ldots, S_r$ of an n-element set T such that each $t \in T$ is in exactly two of the S_i. There is

no restriction on r, the number of subsets, and some of the S_i can be repeated. Let c_n be the corresponding number when the S_i are required to be distinct. We let $C(z) = \sum c_n z^n/n!$, $V(z) = \sum v_n z^n/n!$ be the exponential generating functions. Then it can be shown that

$$C(z) = \exp(-1 - (e^z - 1)/2)A(z) \ , \tag{7.4}$$

$$V(z) = \exp(-1 + (e^z - 1)/2)A(z) \ , \tag{7.5}$$

where

$$A(z) = \sum_{k=0}^{\infty} \exp(k(k-1)z/2)/k! \ . \tag{7.6}$$

We see immediately that $A(z)$ does not converge in any neighborhood of the origin. We have

$$a_n = [z^n]A(z) = 2^{-n} \sum_{k=2}^{\infty} \frac{k^n (k-1)^n}{k!} \ . \tag{7.7}$$

By considering the ratio of consecutive terms in the sum in (7.7), we find that the largest term occurs for $k = k_0$ with $k_0 \log k_0 \sim 2n$, and by the methods of Section 5.1 we find that

$$a_n \sim \frac{\pi^{1/2} k_0^n (k_0 - 1)^n}{n^{1/2} 2^n (k_0 - 1)!} \quad \text{as} \quad n \to \infty \ . \tag{7.8}$$

Therefore $a_{n-1}/a_n \to 0$ as $n \to \infty$, and Theorem 7.1 tells us that

$$c_n \sim v_n \sim e^{-1} n! a_n \quad \text{as} \quad n \to \infty \ . \tag{7.9}$$

■

Usually formal power series occur in more complicated relations than those covered by Theorem 7.1. For example, if f_n is the number of connected graphs on n labeled vertices which have some property, and F_n is the number of graphs on n labeled vertices each of whose connected components has that property, then (cf. [394])

$$1 + \sum_{n=1}^{\infty} F_n \frac{x^n}{n!} = \exp\left(\sum_{n=1}^{\infty} f_n \frac{x^n}{n!} \right) \ . \tag{7.10}$$

Theorem 7.2. ([34]) *Suppose that*

$$\begin{aligned} a(x) &= \sum_{n=1}^{\infty} a_n x^n \ , \quad F(x,y) = \sum_{h,k \geq 0} f_{hk} x^h y^k \ , \\ b(x) &= \sum_{n=0}^{\infty} b_n x^n = F(x, a(x)) \ , \quad D(x) = F_y(x, a(x)) \ , \end{aligned} \tag{7.11}$$

where $F_y(x,y)$ is the partial derivative of $F(x,y)$ with respect to y. Assume that $a_n \neq 0$ and

(i)

$$a_{n-1} = o(a_n) \quad as \quad n \to \infty \ , \tag{7.12}$$

(ii)

$$\sum_{k=r}^{n-r} |a_k a_{n-k}| = O(a_{n-r}) \quad for\ some \quad r > 0 \ , \tag{7.13}$$

(iii) for every $\delta > 0$ there are $M(\delta)$ and $K(\delta)$ such that for $n \geq M(\delta)$ and $h + k > r + 1$,

$$|f_{hk} a_{n-h-k+1}| \leq K(\delta)\delta^{h+k} |a_{n-r}| \ . \tag{7.14}$$

Then

$$b_n = \sum_{k=0}^{r-1} d_k a_{n-k} + O(a_{n-r}) \ . \tag{7.15}$$

Condition (iii) of Theorem 7.2 is often hard to verify. Theorem 2 of [34] shows that this condition holds under certain simpler hypotheses. It follows from that result that (iii) is valid if $F(x, y)$ is analytic in x and y in a neighborhood of $(0, 0)$. Hence, if $F(x, y) = \exp(y)$ or $F(x, y) = 1+y$, then Theorem 7.2 becomes easy to apply. One can also deduce from Theorem 2 of [34] that Theorem 7.2 applies when (i) and (ii) hold, $b_0 = 0$, $b_n \geq 0$, and

$$1 + a(z) = \exp\left(\sum_{k=1}^{\infty} b(z^k)/k \right) \ , \tag{7.16}$$

another relation that is common in graph enumeration (cf. Example 15.1). There are also some results weaker than Theorem 7.2 that are easier to apply [393].

Example 7.2. *Indecomposable permutations* [81]. For every permutation σ of $\{1, \ldots, n)$, let $\{1, \ldots, n\} = \cup I_h$, where the I_h are the smallest intervals such that $\sigma(I_h) = I_h$ for all h. For example, $\sigma = (134)(2)(56)$ corresponds to $I_1 = \{1, 2, 3, 4\}$, $I_2 = \{5, 6\}$, and the identity permutation has n components. A permutation is said to be indecomposable if it has one component. For example, if σ has the 2-cycle $(1n)$, it is indecomposable. Let c_n be the number of indecomposable permutations of $\{1, \ldots, n\}$. Then [81]

$$\sum_{n=1}^{\infty} c_n z^n = 1 - \frac{1}{1 + \sum_{n=1}^{\infty} n! z^n} \ . \tag{7.17}$$

We apply Theorem 7.2 with $a_n = n!$ for $n \geq 1$ and $F(x, y) = 1 - (1 + y)^{-1}$. We easily obtain

$$c_n \sim n! \quad \text{as} \quad n \to \infty \ , \tag{7.18}$$

so that almost all permutations are indecomposable. ■

Some further useful expansions for functional inverses and computations of formal power series have been obtained by Bender and Richmond [40].

8. Elementary estimates for convergent generating functions

The word "elementary" in the title of this section is a technical term that means the proofs do not use complex variables. It does not necessarily imply that the proofs are simple. While some, such as those of Section 8.1, are easy, others are more complicated. The main advantage of elementary methods is that they are much easier to use, and since they impose much weaker requirements on the generating functions, they are more widely applicable. Usually they only impose conditions on the generating function $f(z)$ for $z \in \mathbb{R}^+$.

The main disadvantage of elementary methods is that the estimates they give tend to be much weaker than those derived using analytic function approaches. It is easy to explain why that is so by considering the two generating functions

$$f_1(z) = \sum_{n=0}^{\infty} z^n = (1-z)^{-1} \tag{8.1}$$

and

$$f_2(z) = 3/2 + \sum_{n=1}^{\infty} 2z^{2n} = 3/2 + 2z^2(1-z^2)^{-1} \ . \tag{8.2}$$

Both series converge for $|z| < 1$ and diverge for $|z| > 1$, and both blow up as $z \to 1$. However,

$$f_1(z) - f_2(z) = -\frac{1-z}{2(1+z)} \to 0 \quad \text{as} \quad z \to 1 \ . \tag{8.3}$$

Thus these two functions behave almost identically near $z = 1$. Since $f_1(z)$ and $f_2(z)$ are both $\sim (1-z)^{-1}$ as $z \to 1^-$, $z \in \mathbb{R}^+$, and their difference is $O(|z-1|)$ for $z \in \mathbb{R}^+$, it would require exceptionally delicate methods to detect the differences in the coefficients of the $f_j(z)$ just from their behavior for $z \in \mathbb{R}^+$. There is a substantial difference in the behavior of $f_1(z)$ and $f_2(z)$ for real z if we let $z \to -1$, so our argument does not completely exclude the possibility of obtaining detailed information about the coefficients of these functions using methods of real variables only. However, if we consider the function

$$f_3(z) = 2 + \sum_{n=1}^{\infty} 3z^{3n} = 2 + 3z^3(1-z^3)^{-1} \ , \tag{8.4}$$

then $f_1(z)$ and $f_3(z)$ are both $\sim (1-z)^{-1}$ as $z \to 1^-$, $z \in \mathbb{R}^+$, yet now

$$|f_1(z) - f_3(z)| = O(|z-1|) \quad \text{for all} \quad z \in \mathbb{R} \ .$$

This difference is comparable to what would be obtained by modifying a single coefficient of one generating function. To determine how such slight changes in the behavior of the generating functions affect the behavior of the coefficients we would need to know much more about the functions if we were to use real variable methods. On the other hand, analytic methods, discussed in Section 10 and later, are good at dealing with such problems. They require less precise knowledge of the behavior of a function on the real line. Instead, they impose weak conditions on the function in a wider domain, namely that of the complex numbers.

For reasons discussed above, elementary methods cannot be expected to produce precise estimates of individual coefficients. They often do produce good estimates of summatory functions of the coefficients, though. In the examples above, we note that

$$\sum_{n=1}^{N} [z^n] f_j(z) \sim N \quad \text{as} \quad N \to \infty \tag{8.5}$$

for $1 \le j \le 3$. This holds because the $f_j(z)$ have the same behavior as $z \to 1^-$, and is part of a more general phenomenon. Good knowledge of the behavior of the generating function on the real axis combined with weak restrictions on the coefficients often leads to estimates for the summatory function of the coefficients.

There are cases where elementary methods give precise bounds for individual coefficients. Typically when we wish to estimate f_n, with ordinary generating function $f(z) = \sum f_n z^n$ that converges for $|z| < 1$ but not for $|z| > 1$, we apply the methods of this section to

$$g_n = f_n - f_{n-1} \quad \text{for} \quad n \ge 1, \quad g_0 = f_0 \tag{8.6}$$

with generating function

$$g(z) = \sum_{n=0}^{\infty} g_n z^n = (1-z) f(z) \ . \tag{8.7}$$

Then

$$\sum_{k=0}^{n} g_k = f_n \ , \tag{8.8}$$

and so estimates of the summatory function of the g_k yield estimates for f_n. The difficulty with this approach is that now $g(z)$ and not $f(z)$ has to satisfy the hypotheses of the theorems, which requires more knowledge of the f_n. For example, most of the Tauberian theorems apply only to power series with nonnegative coefficients. Hence to use the differencing trick above to obtain estimates for f_n we need to know that $f_{n-1} \le f_n$ for all n. In some cases (such as that of $f_n = p_n$, the number of ordinary partitions of n) this is easily seen to hold

through combinatorial arguments. In other situations where one might like to apply elementary methods, though, $f_{n-1} \le f_n$ is either false or else is hard to prove. When that happens, other methods are required to estimate f_n.

8.1. Simple upper and lower bounds

A trivial upper bound method turns out to be widely applicable in asymptotic enumeration, and is surprisingly powerful. It relies on nothing more than the nonnegativity of the coefficients of a generating function.

Lemma 8.1. *Suppose that $f(z)$ is analytic in $|z| < R$, and that $[z^n]f(z) \ge 0$ for all $n \ge 0$. Then for any x, $0 < x < R$, and any $n \ge 0$,*

$$[z^n]f(z) \le x^{-n} f(x) \ . \tag{8.9}$$

Example 8.1. *Lower bound for factorials.* Let $f(z) = \exp(z)$. Then Lemma 8.1 yields

$$\frac{1}{n!} = [z^n]e^z \le x^{-n} e^x \tag{8.10}$$

for every $x > 0$. The logarithm of $x^{-n}e^x$ is $x - n \log x$, and differentiating and setting it equal to 0 shows that the minimum value is attained at $x = n$. Therefore

$$\frac{1}{n!} = [z^n]e^z \le n^{-n} e^n \ , \tag{8.11}$$

and so $n! \ge n^n e^{-n}$. This lower bound holds uniformly for all n, and is off only by an asymptotic factor of $(2\pi n)^{1/2}$ from Stirling's formula (4.1). ■

Suppose that $f(z) = \sum f_n z^n$. Lemma 8.1 is proved by noting that for $0 < x < R$, the n-th term, $f_n x^n$, in the power series expansion of $f(x)$, is $\le f(x)$. As we will see in Section 10, it is often possible to derive a similar bound on the coefficients f_n even without assuming that they are nonnegative. However, the proof of Lemma 8.1 shows something more, namely that

$$f_0 x^{-n} + f_1 x^{-n+1} + \cdots + f_{n-1} x^{-1} + f_n \le x^{-n} f(x) \tag{8.12}$$

for $0 < x < R$. When $x \le 1$, this yields an upper bound for the summatory function of the coefficients. Because (8.12) holds, we see that the bound of Lemma 8.1 cannot be sharp in general. What is remarkable is that the estimates obtainable from that lemma are often not far from best possible.

Example 8.2. *Upper bound for the partition function.* Let $p(n)$ denote the partition function. It has the ordinary generating function

$$f(z) = \sum_{n=0}^{\infty} p(n) z^n = \prod_{k=1}^{\infty} (1 - z^k)^{-1} \ . \tag{8.13}$$

Let $g(s) = \log f(e^{-s})$, and consider $s > 0$, $s \to 0$. There are extremely accurate estimates of $g(s)$. It is known [13, 23], for example, that

$$g(s) = \pi^2/(6s) + (\log s)/2 - (\log 2\pi)/2 - s/24 + O(\exp(-4\pi^2/s)) \ . \tag{8.14}$$

If we use (8.14), we find that $x^{-n} f(x)$ is minimized at $x = \exp(-s)$ with

$$s = \pi/(6n)^{1/2} - 1/(4n) + O(n^{-3/2}) \ , \tag{8.15}$$

which yields

$$p(1) + p(2) + \cdots + p(n) \le 2^{-3/4} e^{-1/4} n^{-1/4} (1 + o(1)) \exp(2\pi 6^{-1/2} n^{1/2}) \ . \tag{8.16}$$

Comparing this to the asymptotic formula for the sum that is obtainable from (1.6) (see Example 5.2), we see that the bound of (8.16) is too high by a factor of $n^{1/4}$. If we use (8.16) to bound $p(n)$ alone, we obtain a bound that is too large by a factor of $n^{3/4}$.

The application of Lemma 8.1 outlined above depended on the expansion (8.14), which is complicated to derive, involving modular transformation properties of $p(n)$ that are beyond the scope of this survey. (See [13, 23] for derivations.) Weaker estimates that are still useful are much easier to derive. We obtain one such bound here, since the arguments illustrate some of the methods from the preceding sections.

Consider

$$g(s) = \sum_{k=1}^{\infty} -\log(1 - e^{-ks}) \ . \tag{8.17}$$

If we replace the sum by the integral

$$I(s) = \int_1^{\infty} -\log(1 - e^{-us}) du \ , \tag{8.18}$$

we find on expanding the logarithm that

$$I(s) = \int_1^{\infty} \left(\sum_{m=1}^{\infty} m^{-1} e^{-mus} \right) du = s^{-1} \sum_{m=1}^{\infty} m^{-2} e^{-ms} \ , \tag{8.19}$$

since the interchange of summation and integration is easy to justify, as all the terms are positive. Therefore as $s \to 0^+$,

$$sI(s) \to \sum_{m=1}^{\infty} m^{-2} = \pi^2/6 \ , \tag{8.20}$$

so that $I(s) \sim \pi^2/(6s)$ as $s \to 0^+$. It remains to show that I is indeed a good approximation to $g(s)$. This follows easily from the bound (5.32), since it shows that

$$g(s) = I(s) + O\left(\int_1^{\infty} \frac{se^{-vs}}{1-e^{-vs}} dv \right) \ . \tag{8.21}$$

We could estimate the integral in (8.21) carefully, but we only need rough upper bounds for it, so we write it as

$$\begin{aligned} \int_1^{\infty} \frac{se^{-vs}}{1-e^{-vs}} dv &= \int_s^{\infty} \frac{e^{-u}}{1-e^{-u}} du \\ &= \int_s^1 \frac{e^{-u}}{1-e^{-u}} du + \int_1^{\infty} \frac{e^{-u}}{1-e^{-u}} du \\ &= \int_s^1 \frac{du}{e^u - 1} + c \le \int_s^1 \frac{du}{u} + c = c - \log s \end{aligned} \tag{8.22}$$

for some constant c. Thus we find that

$$g(s) = I(s) + O(\log(s^{-1})) \quad \text{as} \quad s \to 0^+ \ . \tag{8.23}$$

Combining (8.23) with (8.20) we see that

$$g(s) \sim \pi^2/(6s) \quad \text{as} \quad s \to 0^+ \ . \tag{8.24}$$

Therefore, choosing $s = \pi/(6n)^{1/2}$, $x = \exp(-s)$ in Lemma 8.1, we obtain a bound of the form

$$p(n) \le \exp((1+o(1))\pi(2/3)^{1/2} n^{1/2}) \quad \text{as} \quad n \to \infty \ . \quad \blacksquare \tag{8.25}$$

Lemma 8.1 yields a lower bound for $n!$ that is only a factor of about $n^{1/2}$ away from optimal. That is common. Usually, when the function $f(z)$ is reasonably smooth, the best bound obtainable from Lemma 8.1 will only be off from the correct value by a polynomial factor of n, and often only by a factor of $n^{1/2}$.

The estimate of Lemma 8.1 can often be improved with some additional knowledge about the f_n. For example, if $f_{n+1} \ge f_n$ for all $n \ge 0$, then we have

$$x^{-n} f(x) \ge f_n + f_{n+1}x + f_{n+2}x^2 + \cdots \ge f_n (1-x)^{-1} \ . \tag{8.26}$$

For $f_n = p(n)$, the partition function, then yields an upper bound for $p(n)$ that is too large by a factor of $n^{1/4}$.

To optimize the bound of Lemma 8.1, one should choose $x \in (0, R)$ carefully. Usually there is a single best choice. In some pathological cases the optimal choice is obtained by letting $x \to 0^+$ or $x \to R^-$. However, usually we have $\lim_{x\to R^-} f(x) = \infty$, and $[z^m]f(z) > 0$ for some m with $0 \le m < n$ as well as for some $m > n$. Under these conditions it is easy to see that

$$\lim_{x\to 0^+} x^{-n} f(x) = \lim_{x\to R^-} x^{-n} f(x) = \infty \ . \tag{8.27}$$

Thus it does not pay to make x too small or too large. Let us now consider

$$g(x) = \log(x^{-n} f(x)) = \log f(x) - n \log x \ . \tag{8.28}$$

Then

$$g'(x) = \frac{f'}{f}(x) - \frac{n}{x} \ , \tag{8.29}$$

and the optimal choice must be at a point where $g'(x) = 0$. For most commonly encountered functions $f(x)$, there exists a constant $x_0 > 0$ such that

$$\left(\frac{f'}{f}\right)'(x) > 0 \tag{8.30}$$

for $x_0 < x < R$, and so $g''(x) > 0$ for all $x \in (0, R)$ if n is large enough. For such n there is then a unique choice of x that minimizes the bound of Lemma 8.1. However, one major advantage of Lemma 8.1 is that its bound holds for all x. To apply this lemma, one can use any x that is convenient to work with. Usually if this choice is not too far from the optimal one, the resulting bound is fairly good.

We have already remarked above that the bound of Lemma 8.1 is usually close to best possible. It is possible to prove general lower bounds that show this for a wide class of functions. The method, originated in [277] and developed in [305], relies on simple elementary arguments. However, the lower bounds it produces are substantially weaker than the upper bounds of Lemma 8.1. Furthermore, to apply them it is necessary to estimate accurately the minimum of $x^{-n} f(x)$, instead of selecting any convenient values of x. A more general version of the bound below is given in [305].

Theorem 8.1. *Suppose that $f(x) = \sum f_n x^n$ converges for $|x| < 1$, $f_n \ge 0$ for all n, $f_{m_0} > 0$ for some m_0, and $\sum f_n = \infty$. Then for $n \ge m_0$, there is a unique $x_0 = x_0(n) \in (0, 1)$ that*

minimizes $x^{-n}f(x)$. *Let* $s_0 = -\log x_0$, *and*

$$A = \frac{\partial^2}{\partial s^2} \log f(e^{-s})\Big|_{s=s_0} . \tag{8.31}$$

If $A \geq 10^6$ *and for all* t *with*

$$s_0 \leq t \leq s_0 + 20A^{-1/2} \tag{8.32}$$

we have

$$\left| \frac{\partial^3}{\partial s^3} \log f(e^{-s})\Big|_{s=t} \right| \leq 10^{-3} A^{3/2} , \tag{8.33}$$

then

$$\sum_{k=0}^{n} f_k \geq x_0^{-n} f(x_0) \exp(-30 s_0 A^{1/2} - 100) . \tag{8.34}$$

As is usual for Tauberian theorems, Theorem 8.1 only provides bounds on the sum of coefficients of $f(z)$. As we mentioned before, this is unavoidable when one relies only on information about the behavior of $f(z)$ for z a positive real number. The conditions that Theorem 8.1 imposes on the derivatives are usually satisfied in combinatorial enumeration applications and are easy to verify.

Example 8.3. *Lower bound for the partition function.* Let $f(z)$ and $g(s)$ be as in Example 8.2. We showed there that $g(s)$ satisfies (8.24) and similar rough estimates show that $g'(s) \sim -\pi^2/(6s^2)$, $g''(s) \sim \pi^2/(3s^3)$, and $g'''(s) \sim -\pi^2/s^4$ as $s \to 0^+$. Therefore the hypotheses of Theorem 8.1 are satisfied, and we obtain a lower bound for $p(0) + p(1) + \cdots + p(n)$. If we only use the estimate (8.24) for $g(s)$, then we can only conclude that for $x = e^{-s}$,

$$\log(x^{-n} f(x)) = ns + g(s) \sim ns + \pi^2/(6s) \quad \text{as} \quad s \to 0 , \tag{8.35}$$

and so the minimum value occurs at $s \sim \pi/(6n)^{1/2}$ as $n \to \infty$. This only allows us to conclude that for every $\epsilon > 0$ and n large enough,

$$\log(p(0) + \cdots + p(n)) \geq (1 - \epsilon)\pi(2/3)^{1/2} n^{1/2} . \tag{8.36}$$

However, we can also conclude even without further computations that this lower bound will be within a multiplicative factor of $\exp(cn^{1/4})$ of the best upper bound that can be obtained from Lemma 8.1 for some $c > 0$ (and therefore within a multiplicative factor of $\exp(cn^{1/4})$ of the correct value). In particular, if we use the estimate (8.14) for $g(s)$, we find that for some $c' > 0$,

$$p(0) + \cdots + p(n) \geq \exp(\pi(2/3)^{1/2} n^{1/2} - c' n^{1/4}) . \tag{8.37}$$

Since $p(k) \le p(k+1)$, the quantity on the right-hand side of (8.37) is also a lower bound for $p(n)$ if we increase c', since $(n+1)p(n) \ge p(0) + \cdots + p(n)$. ∎

The differencing trick described at the introduction to Section 8 could also be used to estimate $p(n)$, since Theorem 8.1 can be applied to the generating function of $p(n+1) - p(n)$. However, since the error term is a multiplicative factor of $\exp(cn^{1/4})$, it is simpler to use the approach above, which bounds $p(n)$ below by $(p(0) + \cdots + p(n))/(n+1)$.

Brigham [58] has proved a general theorem about asymptotics of partition functions that can be derived from Theorem 8.1. (For other results and references for partition asymptotics, see [13, 23, 150].)

Theorem 8.2. *Suppose that*

$$f(z) = \prod_{k=1}^{\infty} (1 - z^k)^{-b(k)} = \sum_{n=0}^{\infty} a(n) z^n \ , \tag{8.38}$$

where the $b(k) \in \mathbf{Z}$, $b(k) \ge 0$ *for all* k, *and that for some* $C > 0$, $u > 0$, *we have*

$$\sum_{k \le x} b(k) \sim C x^u (\log x)^v \quad \textit{as} \quad x \to \infty \ . \tag{8.39}$$

Then

$$\begin{aligned} \log \left(\textstyle\sum_{n \le m} a(n) \right) \sim u^{-1} \{ C u \Gamma(u+2) \zeta(u+1) \}^{1/(u+1)} \\ \cdot (u+1)^{(u-v)/(u+1)} m^{u/(u+1)} (\log m)^{v/(u+1)} \end{aligned} \tag{8.40}$$

as $m \to \infty$.

If $b(k) = 1$ for all k, $a(n)$ is p_n, the ordinary partition function. If $b(k) = k$ for all k, $a(n)$ is the number of plane partitions of n. Thus Brigham's theorem covers a wide class of interesting partition functions. The cost of this generality is that we obtain only the asymptotics of the logarithm of the summatory function of the partitions being enumerated. (For better estimates of the number of plane partitions, for example, see [9, 170, 387]. For ordinary partitions, we have the expansion (1.3).)

Brigham's proof of Theorem 8.2 first shows that

$$f(e^{-w}) \sim C w^{-u} (-\log w)^v \Gamma(u+1) \zeta(u+1) \quad \text{as} \quad w \to 0^+ \tag{8.41}$$

and then invokes the Hardy-Ramanujan Tauberian theorem [328]. Instead, one can obtain a proof from Theorem 8.1. The advantage of using Theorem 8.1 is that it is much easier to generalize. Hardy and Ramanujan proved their Tauberian theorem only for functions whose

growth rates are of the form given by (8.41). Their approach can be extended to other functions, but this is complicated to do. In contrast, Theorem 8.1 is easy to apply. The conditions of Theorem 8.1 on the derivatives are not restrictive. For a function $f(z)$ defined by (8.38) we have $B \to \infty$ if $\sum b(k) = \infty$, and the condition (8.33) can be shown to hold whenever there are constants c_1 and c_2 such that for all $w > 1$, and all sufficiently large m,

$$\sum_{k \le mw} b(k) \le c_1 w^{c_2} \sum_{k \le m} b(k) \ , \tag{8.42}$$

say. The main difficulty in applying Theorem 8.1 to generalizations of Brigham's theorem is in accurately estimating the minimal value in Lemma 8.1.

There are many other applications of Lemma 8.1 and Theorem 8.1. For example, they can be used to prove the results of [158] on volumes of spheres in the Lee metric.

Lemma 8.1 can be generalized in a straightforward way to multivariate generating functions. If

$$f(x,y) = \sum_{m,n \ge 0} a_{m,n} x^m y^n \tag{8.43}$$

and $a_{m,n} \ge 0$ for all m and n, then for any $x, y > 0$ for which the sum in (8.43) converges we have

$$a_{m,n} \le x^{-m} y^{-n} f(x,y) \ . \tag{8.44}$$

Generalizations of the lower bound of Theorem 8.1 to multivariate functions can also be derived, but are again harder than the upper bound [289].

8.2. Tauberian theorems

The Brigham Tauberian theorem for partitions [58], based on the Hardy-Ramanujan Tauberian theorem [328], was quoted already in Section 8.1. It applies to certain generating functions that have (in notation to be introduced in Section 10) a large singularity and gives estimates only for the logarithm of the summatory function of the coefficients. Another theorem that is often more precise, but is again designed to deal with rapidly growing partition functions, is that of Ingham [212], and will be discussed at the end of this section. Most of the Tauberian theorems in the literature apply to functions with small singularities (i.e., ones that do not grow rapidly as the argument approaches the circle of convergence) and give asymptotic relations for the sum of coefficients. References for Tauberian theorems are [117, 154, 190, 212, 325]. Their main advantage is generality and ease of use, as is shown

by the applications made to 0-1 laws in [77, 78, 79]. They can often be applied when the information about generating functions is insufficient to use the methods of Sections 11 and 12. This is especially true when the circle inside which the generating function converges is a natural boundary beyond which the function cannot be continued.

One Tauberian theorem that is often used in combinatorial enumeration is that of Hardy, Littlewood, and Karamata. We say a function $L(t)$ varies slowly at infinity if, for every $u > 0$, $L(ut) \sim L(t)$ as $t \to \infty$.

Theorem 8.3. *Suppose that $a_k \geq 0$ for all k, and that*

$$f(x) = \sum_{k=0}^{\infty} a_k x^k$$

converges for $0 \leq x < r$. If there is a $\rho \geq 0$ and a function $L(t)$ that varies slowly at infinity such that

$$f(x) \sim (r-x)^{-\rho} L\left(\frac{1}{r-x}\right) \quad \text{as} \quad x \to r- \ , \tag{8.45}$$

then

$$\sum_{k=0}^{n} a_k r^k \sim (n/r)^{\rho} L(n)/\Gamma(\rho+1) \quad \text{as} \quad n \to \infty \ . \tag{8.46}$$

Example 8.4. *Cycles of permutations* ([33]). If S is a set of positive integers, and f_n the probability that a random permutation on n letters will have all cycle lengths in S (i.e., $f_n = a_n/n!$, where a_n is the number of permutations with cycle length in S), then

$$f(z) = \sum_{n=0}^{\infty} f_n z^n = \prod_{k \in S} \exp(z^k/k) = (1-z)^{-1} \prod_{k \notin S} \exp(-z^k/k) \ . \tag{8.47}$$

If $|\mathbb{Z}^+ \setminus S| < \infty$, then the methods of Sections 10.2 and 11 apply easily, and one finds that

$$f_n \sim \exp\left(-\sum_{k \notin S} 1/k\right) \quad \text{as} \quad n \to \infty \ . \tag{8.48}$$

This estimate can also be proved to apply for $|\mathbb{Z}^+ \setminus S| = \infty$, provided $|\{1, \ldots, m\} \setminus S|$ does not grow too rapidly when $m \to \infty$. If $|S| < \infty$ (or when $|\{1, \ldots, m\} \cap S|$ does not grow rapidly), the methods of Section 12 apply. When $S = \{1, 2\}$, one obtains, for example, the result of Moser and Wyman [292] that the number of permutations of order 2 is

$$\sim (n/e)^{n/2} 2^{-1/2} \exp(n^{1/2} - 1/4) \quad \text{as} \quad n \to \infty \ . \tag{8.49}$$

(For sharper and more general results, see [292, 376].) The methods used in these cases are different from the ones we are considering in this section.

We now consider an intermediate case, with

$$|\{1,\dots,m\}\cap S| \sim \rho m \quad \text{as} \quad m\to\infty\ . \tag{8.50}$$

for some fixed ρ, $0\le\rho\le 1$. This case can be handled by Tauberian techniques. To apply Theorem 8.3, we need to show that $L(t)=f(1-t^{-1})t^{-\rho}$ varies slowly at infinity. This is equivalent to showing that for any $u\in(0,1)$,

$$f(1-t^{-1}) \sim f(1-t^{-1}u)u^{\rho} \quad \text{as} \quad t\to\infty\ . \tag{8.51}$$

Because of (8.47), it suffices to prove that

$$\sum_{k\in S} k^{-1}\{(1-t^{-1})^k-(1-t^{-1}u)^k\} = \rho\log u + o(1) \quad \text{as} \quad t\to\infty\ , \tag{8.52}$$

but this is easy to deduce from (8.50) using summation by parts (Section 5). Therefore we find from Theorem 8.3 that

$$\sum_{n=0}^{m} f_n \sim f(1-1/n)\Gamma(\rho+1)^{-1} \quad \text{as} \quad n\to\infty\ . \tag{8.53}$$

(For additional results and references on this problem see [317].) ■

As the above example shows, Tauberian theorems yield estimates under weak assumptions. These theorems do have some disadvantages. Not only do they usually estimate only the summatory function of the coefficients, but they normally give no bounds for the error term. (See [154] for some Tauberian theorems with remainder terms.) Furthermore, they usually apply only to functions with nonnegative coefficients. Sometimes, as in the following theorem of Hardy and Littlewood, one can relax the nonnegativity condition slightly.

Theorem 8.4. *Suppose that $a_k\ge -c/k$ for some $c>0$,*

$$f(z)=\sum_{k=1}^{\infty} a_k x^k\ , \tag{8.54}$$

and that $f(x)$ converges for $0<x<1$, and that

$$\lim_{x\to 1-} f(x) = A\ . \tag{8.55}$$

Then

$$\lim_{n\to\infty}\sum_{k=1}^{n} a_k = A\ . \tag{8.56}$$

Some condition such as $a_k \geq -c/k$ on the a_k is necessary, or otherwise the theorem would not hold. For example, the function

$$f(x) = \frac{1-x}{1+x} = 1 - 2x + 2x^2 \cdots \tag{8.57}$$

satisfies (8.55) with $A = 0$, but (8.56) fails.

We next present an example that shows an application of the above results in combination with other asymptotic methods that were presented before.

Example 8.5. *Permutations with distinct cycle lengths.* The probability that a random permutation on n letters will have cycles of distinct lengths is $[z^n]f(z)$, where

$$f(z) = \prod_{k=1}^{\infty} \left(1 + \frac{z^k}{k}\right) \ . \tag{8.58}$$

Greene and Knuth [177] note that this is also the limit as $p \to \infty$ of the probability that a polynomial of degree n factors into irreducible polynomials of distinct degrees modulo a prime p. It is shown in [177] that

$$[z^n]f(z) = e^{-\gamma}(1 + n^{-1}) + O(n^{-2}\log n) \quad \text{as} \quad n \to \infty \ , \tag{8.59}$$

where $\gamma = 0.577\ldots$ is Euler's constant. A simplified version of the argument of [177] will be presented that shows that

$$[z^n]f(z) \sim e^{-\gamma} \quad \text{as} \quad n \to \infty \ . \tag{8.60}$$

Methods for obtaining better expansions, even more precise than that of (8.59), are discussed in Section 11.2. For related results obtained by probabilistic methods, see [20].

We have, for $|z| < 1$,

$$\begin{aligned} f(z) &= (1+z)\exp\left(\sum_{k=2}^{\infty} \log(1 + z^k/k)\right) \\ &= (1+z)\exp\left(\sum_{k=2}^{\infty} z^k/k + g(z)\right) \\ &= (1+z)(1-z)^{-1}\exp(g(z)) \ , \end{aligned} \tag{8.61}$$

where

$$g(z) = -z + \sum_{m=2}^{\infty} \frac{(-1)^{m-1}}{m} \sum_{k=2}^{\infty} \frac{z^{mk}}{k^m} \ . \tag{8.62}$$

Since the coefficients of $g(z)$ are small, the double sum in (8.62) converges for $z = 1$, and we have

$$\begin{aligned} g(1) &= \lim_{z\to 1-} g(z) = -1 + \sum_{k=2}^{\infty}\sum_{m=2}^{\infty} \frac{(-1)^{m-1}}{m} k^{-m} \\ &= -1 + \sum_{k=2}^{\infty} \{\log(1+k^{-1}) - k^{-1}\} \\ &= -\log 2 + \lim_{n\to\infty} (\log(n+1) - H_n) = -\log 2 - \gamma \ , \end{aligned} \tag{8.63}$$

where $H_n = 1 + 1/2 + 1/3 + \cdots + 1/n$ is the n-th *harmonic number*. Therefore, by (8.61), we find from Theorem 8.4 that if $f_n = [z^n]f(z)$, then

$$f_0 + f_1 + \cdots + f_n \sim ne^{-\gamma} \quad \text{as} \quad n \to \infty \ . \tag{8.64}$$

To obtain asymptotics of f_n, we note that if $h_n = [z^n]\exp(g(z))$, then by (8.61),

$$f_n = 2h_0 + 2h_1 + \cdots + 2h_{n-1} + h_n \ . \tag{8.65}$$

We next obtain an upper bound for $|h_n|$. There are several ways to proceed. The method used below gives the best possible result $|h_n| = O(n^{-2})$.

Since $g(z)$ has the power series expansion (8.62), and $h_n = [z^n]\exp(g(z))$, comparison of terms in the full expansion of $\exp(g(z))$ and $\exp(v(z))$ shows that $|h_n| \le [z^n]\exp(v(z))$, where $v(z)$ is any power series such that $|[z^n]g(z)| \le [z^n]v(z)$. For $n \ge 2$,

$$[z^n]g(z) = \sum_{\substack{m|n \\ m\ge 2 \\ m<n}} \frac{(-1)^{m-1}}{m} \left(\frac{m}{n}\right)^m \ . \tag{8.66}$$

The term $(m/n)^m$ is monotone decreasing for $1 \le m \le n/e$, since its derivative with respect to m is ≤ 0 in that range. Therefore

$$|[z^n]g(z)| \le \frac{1}{2}\left(\frac{2}{n}\right)^2 + \sum_{3\le m\le n/3} \frac{1}{m}\left(\frac{3}{n}\right)^3 + \frac{2}{n}2^{-n/2} \le 10n^{-2} \ , \tag{8.67}$$

say. Hence we can take

$$v(z) = 10\sum_{n=1}^{\infty} n^{-2}z^n \ , \tag{8.68}$$

and then we need to estimate

$$w_n = [z^n]\exp(v(z)) \ . \tag{8.69}$$

We let $w(z) = \exp(v(z))$, and note that

$$w'(z) = v'(z)w(z) \ , \tag{8.70}$$

so for $n \geq 1$,

$$nw_n = 10 \sum_{k=0}^{n-1} w_k (n-k)^{-1} \ . \tag{8.71}$$

Further, since $v(1) < \infty$, and $w_n \geq 0$ for all n, we have $w_n \leq A = w(1) = \exp(v(1))$ for all n. Let $B = 10^6 A$ and note that $w_n \leq Bn^{-2}$ for $1 \leq n \leq 10^3$. Suppose now that $w_m \leq Bm^{-2}$ for $1 \leq m < n$ for some $n \geq 10^3$. We will prove that $w_n \leq Bn^{-2}$, and then by induction this inequality will hold for all $n \geq 1$. We apply Eq. (8.70). For $0 \leq k \leq 100$, we use $w_k \leq A$, $(n-k)^{-1} \leq 2n^{-1}$. For $100 < k \leq n/2$,

$$w_k (n-k)^{-1} \leq Bk^{-2}(n-k)^{-1} \leq 2Bk^{-2}n^{-1} \ , \tag{8.72}$$

and so

$$\sum_{100 \leq k \leq n/2} w_k (n-k)^{-1} \leq B(40n)^{-1} \ . \tag{8.73}$$

Finally,

$$\sum_{n/2 < k \leq n-1} w_k (n-k)^{-1} \leq 4Bn^{-2} \sum_{n/2 < k \leq n-1} (n-k)^{-1} \leq 4Bn^{-2} H_n \ . \tag{8.74}$$

Therefore, by (8.71),

$$nw_n \leq 2000An^{-1} + B(4n)^{-1} + 4BH_n n^{-2} \leq Bn^{-1} \ , \tag{8.75}$$

which completes the induction step and proves that $w_n \leq Bn^{-2}$ for all $n \geq 1$. ∎

There are Tauberian theorems that apply to generating functions with rapidly growing coefficients but are more precise than Brigham's theorem or the estimates obtainable with the methods of Section 8.1. One of the most useful is Ingham's Tauberian theorem for partitions [212]. The following result is a corollary of the more general Theorem 2 of [212].

Theorem 8.5. *Let $1 \leq u_1 < u_2 < \ldots$ be positive integers such that*

$$|\{u_j : u_j \leq x\}| = Bx^\beta + R(x) \ , \tag{8.76}$$

where $B > 0$, $\beta > 0$, and

$$\int_1^y x^{-1} R(x) dx = b \log y + c + o(1) \quad \textit{as} \quad y \to \infty \ . \tag{8.77}$$

Let

$$a(z) = \sum_{n=1}^{\infty} a_n z^n = \prod_{j=1}^{\infty} (1 - z^{u_j})^{-1} , \tag{8.78}$$

$$a^*(z) = \sum_{n=1}^{\infty} a_n^* z^n = \prod_{j=1}^{\infty} (1 + z^{u_j}) . \tag{8.79}$$

Then, as $m \to \infty$,

$$\sum_{n=1}^{m} a_n \sim (2\pi)^{-1/2} (1-\alpha)^{1/2} e^c V^{-\alpha(b+1/2)} m^{(b+1/2)(1-\alpha)-1/2} \exp(\alpha^{-1}(Vm)^{\alpha}) , \tag{8.80}$$

$$\sum_{n=1}^{m} a_n^* \sim (2\pi)^{-1/2} (1-\alpha)^{1/2} 2^b (V^* m)^{-\alpha/2} \exp(\alpha^{-1}(V^* m)^{\alpha}) , \tag{8.81}$$

where

$$\alpha = \beta(\beta+1)^{-1}, \quad V = \{B\beta\Gamma(\beta+1)\zeta(\beta+1)\}^{1/\beta} , \quad V^* = (1-2^{-\beta})^{1/\beta} V . \tag{8.82}$$

If $u_1 = 1$, *then as* $n \to \infty$

$$a_n \sim (2\pi)^{-1/2} (1-\alpha)^{1/2} e^c V^{-\alpha(b-1/2)} n^{(b-1/2)(1-\alpha)-1/2} \exp(\alpha^{-1}(Vn)^{\alpha}) , \tag{8.83}$$

and if $1, 2, 4, 8, \ldots$ *all belong to* $\{u_j\}$, *then*

$$a_n^* \sim (2\pi)^{-1/2} (1-\alpha)^{1/2} 2^b (V^*)^{\alpha/2} n^{\alpha/2-1} \exp(\alpha^{-1}(V^* n)^{\alpha}) . \tag{8.84}$$

Theorem 8.5 provides more precise information than Brigham's Theorem 8.2, but under more restrictive conditions. It is derived from Ingham's main result, Theorem 1 of [212], which can be applied to wider classes of functions. However, that theorem cannot be used to derive Theorem 8.2. The disadvantage of Ingham's main theorem is that it requires knowledge of the behavior of the generating function in the complex plane, not just on the real axis. On the other hand, the region where this behavior has to be known is much smaller than it is for the analytic methods that give more accurate answers, and which are presented in Sections 10–12. Only behavior of the generating functions $\Pi(1 - z^{\lambda_j})^{-1}$ or $\Pi(1 + z^{\lambda_j})$ in an angle $|\mathrm{Arg}|(1-z)| \le \pi/2 - \delta$ for some $\delta > 0$ needs to be controlled.

Ingham's paper [212] contains an extended discussion of the relations between different Tauberian theorems and of the necessity for various conditions.

9. Recurrences

This section presents some basic methods for handling recurrences. The title is slightly misleading, since almost all of this chapter is devoted to methods that are useful in this area. Almost all asymptotic estimation problems concern quantities that are defined through implicit or explicit recurrences. Furthermore, the most common and most effective method of solving recurrences is often to determine its generating function and then apply the methods presented in the other sections. However, there are many recurrences, and those discussed in Sections 9.4 and 9.5 require special methods that do not fit into other sections. These methods deserve to be included, so it seems preferable to explain them after treating some of the more common types of recurrences, even though those could have been covered elsewhere in this chapter.

Since generating functions are the most powerful tool for handling combinatorial recurrences, all the books listed in Section 18 that help in dealing with combinatorial identities and generating functions are also useful in handling recurrences. Methods for recurrences that are not amenable to generating function methods are presented in [175, 177]. Lueker [264] is an introductory survey to some recurrence methods.

Wimp's book [382] is concerned primarily with numerical stability problems in computing with recurrences. Such problems are important in computing values of orthogonal polynomials, for example, but seldom arise in combinatorial enumeration. However, there are sections of [382] that are relevant to our topic, for example to the discussion of differential equations in Section 9.2.

9.1. Linear recurrences with constant coefficients

The most famous sequence that satisfies a linear recurrence with constant coefficients is that of the Fibonacci numbers, defined by $F_0 = F_1 = 1$, $F_n = F_{n-1} + F_{n-2}$ for $n \geq 2$. There are many others that are only slightly less well known. Fortunately, the theory of such sequences is well developed, and from the standpoint of asymptotic enumeration their behavior is well understood. (For a survey of number theoretic results, together with a list of many unsolved problems about such sequences that arise in that area, see [73].) There are even several different approaches to solving linear recurrences with constant coefficients. The one we emphasize here is that of generating functions, since it fits in best with the rest of this chapter. For other approaches, see [287, 298], for example.

Suppose that we have a linear recurrence or a system of recurrences and have found that

the generating function $f(z)$ we are interested in has the form

$$f(z) = \frac{G(z)}{h(z)} \ , \tag{9.1}$$

where $G(z)$ and $h(z)$ are polynomials. The basic tool for obtaining asymptotic information about $[z^n]f(z)$ is the partial fraction expansion of a rational function [205]. Dividing $G(z)$ by $h(z)$ we obtain

$$f(z) = p(z) + \frac{g(z)}{h(z)} \ , \tag{9.2}$$

where $p(z)$, $g(z)$, and $h(z)$ are all polynomials in z and $\deg g(z) < \deg h(z)$. We can assume that $h(0) \neq 0$, since if that were not the case, we would have $g(0) = 0$ (as in the opposite case $f(z)$ would not be a power series in z, but would have terms such as z^{-1} or z^{-2}) and we could cancel a common factor of z from $g(z)$ and $h(z)$. Therefore, if $d = \deg h(z)$, we can write

$$h(z) = h(0) \prod_{j=1}^{d'} \left(1 - \frac{z}{z_j}\right)^{m_j} \ , \tag{9.3}$$

where z_j, $1 \leq j \leq d'$ are the distinct roots of $h(z) = 0$, z_j has multiplicity $m_j \geq 1$, and $\sum m_j = d$. Hence we find [175, 205] that for certain constants $c_{j,k}$,

$$\begin{aligned} f(z) &= p(z) + \sum_{j=1}^{d'} \sum_{k=1}^{m_j} \frac{c_{j,k}}{(1 - z/z_j)^k} \\ &= p(z) + \sum_{j=1}^{d'} \sum_{k=1}^{m_j} c_{j,k} \sum_{h=0}^{\infty} \binom{h+k-1}{k-1} z^h z_j^{-h} \ . \end{aligned} \tag{9.4}$$

Thus

$$a_n = [z^n]p(z) + \sum_{j=1}^{d'} \sum_{k=1}^{m_j} c_{j,k} \binom{h+k-1}{k-1} z_j^{-n} \ . \tag{9.5}$$

When $m_j = 1$,

$$c_{j,1} = \frac{-g(z_j)}{z_j h'(z_j)} \ , \tag{9.6}$$

and explicit formulas for the $c_{j,k}$ when $m_j > 1$ can also be derived [175], but are unwieldy and seldom used.

Example 9.1. *Fibonacci numbers.* As was noted in Example 6.3,

$$F(z) = \sum_{n=0}^{\infty} F_n z^n = \frac{z}{1 - z - z^2} \ .$$

Now

$$h(z) = 1 - z - z^2 = (1 + \phi^{-1} z)(1 - \phi z) \ , \tag{9.7}$$

where $\phi = (1 + 5^{1/2})/2$ is the golden ratio. Therefore

$$F(z) = \frac{1}{\sqrt{5}} \left(\frac{1}{1 - \phi z} - \frac{1}{1 + \phi^{-1} z} \right) \tag{9.8}$$

and for $n \geq 0$,

$$F_n = [z^n] F(z) = 5^{-1/2} (\phi^n - (-\phi)^{-n}) \ . \tag{9.9}$$

■

The partial fraction expansion (9.4) shows that the first-order asymptotics of sequence a_n satisfying a linear recurrence of the form (6.30) are determined by the smallest zeros of the characteristic polynomial $h(z)$. The full asymptotic expansion is given by (9.5), and involves all the zeros. In practice, using (9.5) presents some difficulties, in that multiplicities of zeros are not always easy to determine, and the coefficients $c_{j,k}$ are often even harder to deal with. Eventually, for large n, their influence becomes negligible, but when uniform estimates are required they present a problem. In such cases the following theorem is often useful.

Theorem 9.1. *Suppose that $f(z) = g(z)/h(z)$, where $g(z)$ and $h(z)$ are polynomials, $h(0) \neq 0$, $\deg g(z) < \deg h(z)$, and that the only zeros of $h(z)$ in $|z| < R$ are $\rho_1, \ldots, \rho_k$, each of multiplicity 1. Suppose further that*

$$\max_{|z|=R} |f(z)| \leq W \ , \tag{9.10}$$

and that $R - |\rho_j| \geq \delta$ for some $\delta > 0$ and $1 \leq j \leq k$. Then

$$\left| [z^n] f(z) + \sum_{j=1}^{k} \frac{g(\rho_j)}{h'(\rho_j)} \rho_j^{-n-1} \right| \leq W R^{-n} + \delta^{-1} R^{-n} \sum_{j=1}^{k} |g(\rho_j)/h'(\rho_j)| \ . \tag{9.11}$$

Theorem 9.1 is derived using methods of complex variables, and a proof is sketched in Section 10. That section also discusses how to locate all the zeros $\rho_1, \ldots, \rho_k$ of a polynomial $h(z)$ in a disk $|z| < R$. In general, the zero location problem is not a serious one in enumeration problems. Usually there is a single positive real zero that is closer to the origin than any other, it can be located accurately by simple methods, and R is chosen so that $|z| < R$ encloses only that zero.

Example 9.2. *Sequences with forbidden subblocks.* We continue with the problem presented in Examples 6.4 and 6.8. Both $F_A(z)$ and $G_A(z)$ have as denominators

$$h(z) = z^k + (1 - 2z) C_A(z) \ , \tag{9.12}$$

which is a polynomial of degree exactly k. Later, in Example 10.6, we will show that for $k \geq 9$, $h(z)$ has exactly one zero ρ in $|z| \leq 0.6$, and that for $|z| = 0.55$, $|h(z)| \geq 1/100$. Furthermore, by Example 6.7, $\rho \to 1/2$ as $k \to \infty$. On $|z| = 0.55$,

$$|F_A(z)| \leq 100 \cdot (0.55)^k \ . \tag{9.13}$$

Theorem 9.1 then shows, for example, that for $n > k \geq k_0$,

$$\begin{aligned} \left| [z^n] F_A(z) + \frac{C_A(\rho)\rho^{-n-1}}{h'(\rho)} \right| &\leq 100(0.55)^{k-n} + 40(0.55)^{-n}|h'(\rho)|^{-1} \\ &\leq 50(0.55)^{-n} \ , \end{aligned} \tag{9.14}$$

since by Example 6.7, as $k \to \infty$,

$$h'(\rho) = k\rho^{k-1} - 2C_A(\rho) + (1-2\rho)C_A'(\rho) \sim -2C_A(\rho) \sim -\rho^{-1} \ . \tag{9.15}$$

The estimate (9.14), when combined with the expansions of Example 6.7, gives accurate approximations for p_n, the probability that A does not appear as a block among the first n coin tosses. We have

$$\begin{aligned} p_n &= 2^{-n}[z^n]F_z(z) \\ &= -2^{-n}C_A(\rho)\rho^{-n-1}(h'(\rho))^{-1} + O(\exp(-0.09n)) \ . \end{aligned} \tag{9.16}$$

We now estimate $h'(\rho)$ as before, in (9.15), but more carefully, putting in the approximation for ρ from Example 6.7. We find that

$$h'(\rho) = -\rho^{-1} + O(k2^{-k}) \ , \tag{9.17}$$

and

$$\rho^{-n} = 2^n \exp(-n(2^k C_A(1/2))^{-1} + O(nk2^{-2k})) \ . \tag{9.18}$$

Therefore

$$p_n = \exp(-n(2^k C_A(1/2))^{-1} + O(nk2^{-2k})) + O(\exp(-n/12)) \ . \tag{9.19}$$

This shows that p_n has a sharp transition. It is close to 1 for $n = o(2^k)$, and then, as n increases through 2^k, drops rapidly to 0. (The behavior on the two sides of 2^k is not symmetric, as the drop towards 0 beyond 2^k is much faster than the increases towards 1 on the other side.) For further results and applications of such estimates, see [180, 181]. Estimates such as (9.19) yield results sharper than those of Example 6.8. They also prove (see

Example 14.1) that the expected lengths of the longest run of 0's in a random sequence of length n is $\log_2 n + u(\log_2 n) + o(1)$ as $n \to \infty$, where $u(x)$ is a continuous function that is not constant and satisfies $u(x+1) = u(x)$. (See also the discussion of carry propagation in [236].) For other methods and results in this area, see [18]. ■

Inhomogeneous recurrences with constant coefficients, say,

$$a_n = \sum_{i=1}^{d} c_i a_{n-i} + b_n, \quad n \geq d \ , \tag{9.20}$$

are not covered by the techniques discussed above. One can still use the basic generating function approach to derive the ordinary generating function of a_n, but this time it is in terms of the ordinary generating function of b_n. If b_n does not grow too rapidly, the "subtraction of singularities" method of Section 10.2 can be used to derive the asymptotics of a_n in a form similar to that given by (9.26).

9.2. Linear recurrences with varying coefficients

Linear recurrences with constant coefficients have a nice and complete theory. That is no longer the case when one allows coefficients that vary with the index. This is not a fault of mathematicians in not working hard enough to derive elegant results, but reflects the much more complicated behavior that can occur. The simplest case is when the recurrence has a finite number of terms, and the coefficients are polynomials in n.

Example 9.3. *Two-sided generalized Fibonacci sequences.* Let t_n be the number of integer sequences $(b_j, \ldots, b_2, b_1, 1, 1, a_1, a_2, \ldots, a_k)$ with $j + k + 2 = n$ in which each b_i is the sum of one or more contiguous terms immediately to its right, and each a_i is likewise the sum of one or more contiguous terms immediately to its left. It was shown in [120] that $t_1 = t_2 = 1$ and that

$$t_{n+1} = 2nt_n - (n-1)^2 t_{n-1} \quad \text{for} \quad n \geq 2 \ . \tag{9.21}$$

If we let

$$t(z) = \sum_{n=1}^{\infty} \frac{t_n z^{n-1}}{(n-1)!} \tag{9.22}$$

be a modified exponential generating function, then the recurrence (9.21) shows that

$$t'(z)(1-z)^2 - t(z)(2-z) = 1 \ . \tag{9.23}$$

Standard methods for solving ordinary differential equations, together with the initial conditions $t_1 = t_2 = 1$, then yield the explicit solution

$$t(z) = (1-z)^{-1} \exp((1-z)^{-1}) \left[C + \int_z^1 (1-w)^{-1} \exp(-(1-w)^{-1}) dw \right] , \tag{9.24}$$

where

$$C = e^{-1} - \int_0^1 (1-w)^{-1} \exp(-(1-w)^{-1}) dw = 0.148495\ldots . \tag{9.25}$$

Once the explicit formula (9.24) for $t(z)$ is obtained, the methods of Section 12 give the estimate

$$t_n \sim C(n-1)!(e/\pi)^{1/2} \exp(2n^{1/2})(2n^{1/4})^{-1} \quad \text{as} \quad n \to \infty . \tag{9.26}$$

It is easy to show that the absolute value of

$$(1-z)^{-1} \exp((1-z)^{-1}) \int_z^1 (1-w)^{-1} \exp(-(1-w)^{-1}) dw \tag{9.27}$$

is small for $|z| < 1$. Therefore the asymptotics of the t_n are determined by the behavior of coefficients of

$$C(1-z)^{-1} \exp((1-z)^{-1}) , \tag{9.28}$$

and that can be obtained easily. The estimate (9.26) then follows. ■

To see just how different the behavior of linear recurrences with polynomial coefficients can be from those with constant coefficients, compare the behavior of the sequences in Example 9.3 above and Example 9.4 (given below). The existence of such differences should not be too surprising, since after all even the first order recurrence $a_n = na_{n-1}$ for $n \geq 2$, $a_1 = 1$, has the obvious solution $a_n = n!$, which is not at all like the solutions to constant coefficient recurrences. However, when $a_n = na_{n-1}$, a simple change of variables, namely $a_n = b_n n!$, transforms this recurrence into the trivial one of $b_n = b_{n-1} = \cdots = b_1 = 1$ for all n. Such rescaling is among the most fruitful methods for dealing with nonlinear recurrences, even though it is seldom as simple as for $a_n = n!$.

Example 9.3 is typical in that a sequence satisfying a linear recurrence of the form

$$a_n = \sum_{j=1}^{r} c_j(n) a_{n-j} , \qquad n \geq r , \tag{9.29}$$

where r is fixed and the $c_j(n)$ are rational functions (a P-recursive sequence in the notation of Section 6.3) can always be transformed into a differential equation for a generating function. Whether anything can be done with that generating function depends strongly on the

recurrence and the form of the generating function. Example 9.3 is atypical in that there is an explicit solution to the differential equation. Further, this explicit solution is a nice analytic function. This is due to the special choice of the form of the generating function. An exponential generating function seems natural to use in that example, since the recurrence (9.21) shows immediately that $t_n \le (2n-2)(2n-4)\dots 2 = 2^{n-1}(n-1)!$, and a slightly more involved induction proves that t_n grows at least as fast as a factorial. If we tried to use an ordinary generating function

$$u(z) = \sum_{n=1}^{\infty} t_n z^n \ , \tag{9.30}$$

then the recurrence (9.21) would yield the differential equation

$$z^4 u''(z) + z^3 u'(z) + (1-2z^2)u(z) = z - z^2 \ , \tag{9.31}$$

which is not as tractable. (This was to be expected, since $u(z)$ is only a formal power series.) Even when a good choice of generating function does yield an analytic function, the differential equation that results may be hard to solve. (One can always find a generating function that is analytic, but the structure of the problem may not be reflected in the resulting differential equation, and there may not be anything nice about it.)

There is an extensive literature on analytic solutions of differential equations (cf. [205, 206, 207, 272, 368, 372]), but it is not easy to apply in general. Singularities of analytic functions that satisfy linear differential equations with analytic coefficients are usually of only a few basic forms, and so the methods of Sections 11 and 12 suffice to determine the asymptotic behavior of the coefficients. The difficulty is in locating the singularities and determining their nature. We refer to [206, 207, 272, 368, 372] for methods for dealing with this difficulty, since they are involved and so far have been seldom used in combinatorial enumeration. There will be some further discussion of differential equations in Section 15.3.

Some aspects of the theory of linear recurrences with constant coefficients do carry over to the case of varying coefficients, even when the coefficients are not rational functions. For example, there will in general be r linearly independent solutions to the recurrence (9.29) (corresponding to the different starting conditions). Also, if a solution a_n has the property that a_{n+1}/a_n tends to a limit α as $n \to \infty$, then $1/\alpha$ is a limit of zeros of

$$1 - \sum_{j=1}^{r} c_j(n) z^j \ , \tag{9.32}$$

and therefore is often a root of

$$1 - \sum_{j=1}^{r} \left(\lim_{n\to\infty} c_j(n) \right) z^j \ . \tag{9.33}$$

Whether there are exactly r linearly independent solutions is a difficult problem. Extensive research was done on this topic 1920's and 1930's [2, 29], culminating in the work of Birkhoff and Trjitzinsky [51, 52, 53, 366, 367]. This work applies to recurrences of the form (9.29) where the $c_j(n)$ have Poincaré asymptotic expansions

$$c_j(n) \sim n^{k_j/k}\{c_{j,0} + c_{j,1}n^{-1/k} + c_{j,2}n^{-2/k} + \cdots\} \quad \text{as} \quad n \to \infty \ , \tag{9.34}$$

where the k_j and k are integers and $c_{j,0} \neq 0$ if $c_j(n)$ is not identically 0 for all n. It follows from this work that solutions to the recurrence are expressible as linear combinations of elements of the form

$$(n!)^{p/q} \exp(P(n^{1/m}))n^{\alpha}(\log n)^h \ , \tag{9.35}$$

where h, m, p, and q are integers, $P(z)$ a polynomial, and α a complex number. An exposition of this theory and how it applies to enumeration has been given by Wimp and Zeilberger [384]. (There is a slight complication in that most of the literature cited above is concerned with recurrences for functions of a real argument, not sequences, but this is not a major difficulty.) There is still a problem in identifying which linear combination provides the derived solution. Wimp and Zeilberger point out that it is usually easy to show that the largest of the terms of the form (9.35) does show up with a nonzero coefficient, and so determines the asymptotics of a_n up to a multiplicative constant. However, the Birkhoff-Trjitzinsky method does not in general provide any techniques for determining that constant.

The major objection to the use of the Birkhoff-Trjitzinsky results is that they may not be rigorous, since gaps are alleged to exist in the complicated proofs [211, 383]. Furthermore, in almost all combinatorial enumeration applications the coefficients are rational, and so one can use the theory of analytic differential equations.

When there is no way to avoid linear recurrences with coefficients that vary but are not rational, one can sometimes use the work of Kooman [243, 244], which develops the theory of second order linear recurrences with almost-constant coefficients.

Example 9.4. *An oscillating sequence.* Let

$$a_n = \sum_{k=0}^{n} \binom{n}{k} \frac{(-1)^k}{k!} \ , \qquad n = 0, 1, \ldots \ . \tag{9.36}$$

Then a_n satisfies the linear recurrence

$$a_{n+2} - \left(2 - \frac{2}{n}\right) a_{n+1} + \left(1 - \frac{1}{n}\right) a_n = 0, \quad n \geq 0 \ . \tag{9.37}$$

The methods of [244] can be used to show that for some constants c and ϕ

$$a_n = cn^{-1/4} \sin(2n^{1/2} + \phi) + o(n^{-1/4}) \quad \text{as} \quad n \to \infty \ , \tag{9.38}$$

which is a much more precise estimate than the crude one mentioned in Example 10.1.

Another, in some ways preferable method for obtaining asymptotic expansions for a_n is mentioned in Example 12.8. It is based on an explicit form for the generating function of a_n, $f(z) = \sum a_n z^n$. An interchange of orders of summation (easily justified for $|z|$ small, say $|z| < 1/2$) shows that

$$\begin{aligned} f(z) &= \sum_{k=0}^{\infty} \frac{(-1)^k}{k!} \sum_{n=k}^{\infty} \binom{n}{k} z^n \\ &= \sum_{k=0}^{\infty} \frac{(-1)^k}{k!} \frac{z^k}{(1-z)^{k+1}} = \frac{1}{1-z} \exp\left(-\frac{z}{1-z}\right) \ . \end{aligned} \tag{9.39}$$

The saddle point method can then be applied to obtain asymptotic expansions for a_n. ■

9.3. Linear recurrences in several variables

Linear recurrences in several variables that have constant coefficients can be attacked by methods similar to those used in a single variable. If we have

$$a_{m,n} = \sum_{\substack{i=0 \\ i+j>0}}^{d} \sum_{i=0}^{d} c_{i,j} a_{m-i,n-j} \tag{9.40}$$

for $m, n \geq d$, say, then the generating function

$$f(x,y) = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} a_{m,n} x^m y^n \tag{9.41}$$

satisfies the relation

$$f(x,y)\left(1-\sum_{\substack{i=0\\ i+j>0}}^{d}\sum_{i=0}^{d}c_{i,j}x^iy^j\right) = \sum_{\substack{m=0\\ m>d \text{ or } n>d}}^{\infty}\sum_{n=0}^{\infty}a_{m,n}x^my^n - \sum_{\substack{i=0\\ i+j>0}}^{d}\sum_{i=0}^{d}c_{ij}x^iy^j\sum_{\substack{m,n\\ m\le d-i\\ \text{or } n\le d-i}}a_{m,n}x^my^n\ . \tag{9.42}$$

If $a_{m,n}=0$ for $0\le m<d$ and $n\ge d$ as well as for $0\le n<d$ and $m\ge d$ (so that all the $a_{m,n}$ are fully determined by $a_{m,n}$ for $0\le m<d$, $0\le n<d$), then $f(x,y)$ is a rational function. If this condition does not hold, $f(x,y)$ can be complicated.

The paragraph above shows that under common conditions, constant coefficient recurrences lead to generating functions that are rational even in several variables. However, even when the rational function is determined, there is no equivalent of partial fraction decomposition to yield elegant asymptotics of the coefficients. Coefficients of multivariate generating functions are much harder to handle than those of univariate functions. There are tools (discussed in Section 13), that are usually adequate to handle rational generating functions, but they are not simple.

When the coefficients of the multivariate recurrences vary, available knowledge is extremely limited. Even if the coefficients are polynomials, we obtain a partial differential equation for the generating function. Sometimes there are tricks that lead to a simple solution (cf. Example 15.6), but this is not common.

9.4. Nonlinear recurrences

Nonlinear recurrences come in a great variety of shapes, and the methods that are used to solve them are diverse, depending on the nature of the problem. This section presents a sample of the most useful techniques that have been developed.

Sometimes a nonlinear recurrence has a simple solution because of a nice algebraic factorization. For example, suppose that z_0 is any given complex number, and

$$z_{n+1}=z_n^2-2 \quad \text{for} \quad n\ge 0\ . \tag{9.43}$$

If we set

$$w=(z_0+(z_0^2-4)^{1/2})/2\ , \tag{9.44}$$

we have $z_0 = w + w^{-1}$, and more generally

$$z_n = w^{2^n} + w^{-2^n} \quad \text{for} \quad n \geq 0 \; . \tag{9.45}$$

Eq. (9.45) is easily established through induction. However, this is an exceptional instance, and already recurrences of the type $z_{n+1} = z_n^2 + c$ for c a complex constant lead to deep questions about the Mandelbrot set and chaotic behavior [91].

Since linear recurrences are well understood, the best that one can hope for when confronted with a nonlinear recurrence is that it might be reducible to a linear one. This works in many situations.

Example 9.5. *Planted plane trees.* Let $a_{n,h}$ be the number of planted plane trees with n nodes and height $\leq h$ [64, 177], and let

$$A_h(z) = \sum_{n=0}^{\infty} a_{n,h} z^n \; . \tag{9.46}$$

Since a tree of height $\leq h+1$ has a root and any number of subtrees, each of height $\leq h$,

$$\begin{aligned} A_{h+1}(z) &= z(1 + A_h(z) + A_h(z)^2 + \cdots) \\ &= z(1 - A_h(z))^{-1} \; . \end{aligned} \tag{9.47}$$

Iterating this recurrence, we obtain a finite continued fraction that looks like

$$A_{h+1}(z) = \cfrac{z}{1 - \cfrac{z}{1 - \cfrac{z}{1 - \cdots}}} \; . \tag{9.48}$$

The general theory of continued functions represents a convergent as a quotient of two sequences satisfying recurrences involving the partial quotients. (For references, see [218, 319].) After playing with this idea, one finds that the substitution

$$A_h(z) = \frac{z P_h(z)}{P_{h+1}(z)} \tag{9.49}$$

gives

$$P_{h+1}(z) = P_h(z) - z P_{h-1}(z) \; , \qquad h \geq 2 \; ,$$

where $P_0(z) = 0$, $P_1(z) = 1$. This is a linear recurrence when we regard z as fixed, and so the theory presented before leads to the explicit representation

$$P_h(z) = (1 - 4z)^{-1/2} \left\{ \left(\frac{1 + (1-4z)^{1/2}}{2} \right)^h - \left(\frac{1 - (1-4z)^{1/2}}{2} \right)^h \right\} \; . \tag{9.50}$$

De Bruijn, Knuth, and Rice [64] use this representation to determine the average height of plane trees. ■

Greene and Knuth (p. 30 of [177]) note that the continued fraction method of replacing a convergent by a quotient of elements of two sequences in general leads not to a single sequence of polynomials like the $P_h(z)$ of Example 9.5, but to two sequences. This is only slightly harder to handle, and allows one to linearize more complicated recurrences.

There are many additional ways to linearize a recurrence. (A small list is given on p. 31 of [177].) For example, a purely multiplicative relation $a_n = a_{n-1}^2/a_{n-2}$ is transformed into the linear $\log a_n = 2\log a_{n-1} - \log a_{n-2}$ by taking logarithms. One of the most fruitful tricks of this type is taking inverses. Thus $a_n = a_{n-1}/(1 + a_{n-1})$ is equivalent to

$$\frac{1}{a_n} = \frac{1}{a_{n-1}} + 1 \ , \tag{9.51}$$

which has the obvious solution $a_n^{-1} = a_0^{-1} + n$. (This assumes $a_0 \neq -1/k$ for any $k \in \mathbb{Z}^+$.)

Linearization works well, but is limited in applicability. More widely applicable, but producing answers that are not as clear, is approximate linearization, where a given nonlinear recurrence is close to a linear one. The following example combines approximate linearization with bootstrapping.

Example 9.6. *A quadratic recurrence.* The study of the average height of binary trees in [132] involves the recurrence

$$a_n = a_{n-1}(1 - a_{n-1}) \quad \text{for} \quad n \geq 1 \ , \tag{9.52}$$

with $a_0 = 1/2$. The a_n are monotone decreasing, so we try the inverse trick. We find

$$\frac{1}{a_n} = \frac{1}{a_{n-1}(1 - a_{n-1})} = \frac{1}{a_{n-1}} + 1 + \frac{a_{n-1}}{1 - a_{n-1}} \ . \tag{9.53}$$

Iterating this recurrence (but applying it only to the first term on the right-hand side of Eq. (9.53)) we obtain

$$\begin{aligned} \frac{1}{a_n} &= \frac{1}{a_{n-2}} + 2 + \frac{a_{n-2}}{1 - a_{n-2}} + \frac{a_{n-1}}{1 - a_{n-1}} \\ &= \cdots \\ &= \frac{1}{a_0} + n + \sum_{j=0}^{n-1} \frac{a_j}{1 - a_j} \\ &= n + 2 + \sum_{j=0}^{n-1} \frac{a_j}{1 - a_j} \ . \end{aligned} \tag{9.54}$$

Equation (9.54) shows that $a_n^{-1} > n$, so $a_n < 1/n$. Applying this bound to a_j for $2 \le j \le n-1$ in the sum on the right-hand side of Eq. (9.54), we find that

$$n \le a_n^{-1} \le n + O(\log n) \ . \tag{9.55}$$

When we substitute this into (9.54), we find that $a_n^{-1} = n + \log n + o(\log n)$, and further iterations produce even more accurate estimates. ■

Approximate linearization also works well for some rapidly growing sequences.

Example 9.7. *Doubly exponential sequences.* Many recurrences are of the form

$$a_{n+1} = a_n^2 + b_n \ , \tag{9.56}$$

where b_n is much smaller than a_n^2 (and may even depend on the a_n for $k \le n$, as in $b_n = a_n$ or $b_n = a_{n-1}$). Aho and Sloane [3] found that surprisingly simple solutions to such recurrences can often be found. The basic idea is to reduce to approximate linearization by taking logarithms. We find that if a_0 is the given initial value, and $a_n > 0$ for all n, then the transformation

$$u_n = \log a_n \ , \tag{9.57}$$

$$\delta_n = \log(1 + b_n a_n^{-2}) \ , \tag{9.58}$$

reduces (9.56) to

$$u_{n+1} = 2u_n + \delta_n \ , \quad n \ge 0 \ . \tag{9.59}$$

Therefore

$$\begin{aligned} u_n &= \delta_{n-1} + 2u_{n-1} = \delta_{n-1} + 2\delta_{n-2} + 4u_{n-2} \\ &= \dots \\ &= \sum_{j=1}^{n} 2^{j-1}\delta_{n-j} + 2^n u_0 \\ &= 2^n(u_0 + \delta_0/2 + \delta_1/4 + \cdots + \delta_{n-1}/2^n) \ . \end{aligned} \tag{9.60}$$

If we assume that the δ_k are small, then

$$\alpha = u_0 + \sum_{k=0}^{\infty} \delta_k 2^{-k-1} \tag{9.61}$$

exists, and

$$r_n = u_n - 2^n\alpha = 2^n \sum_{k=n}^{\infty} \delta_k 2^{-k-1} \ . \tag{9.62}$$

If the δ_k are sufficiently small, the difference r_n in (9.62) will be small, and

$$a_n = \exp(u_n) = \exp(2^n\alpha - r_n) \ . \tag{9.63}$$

The expression (9.63) might not seem satisfactory, since both a_n and r_n are expressed in terms of all the a_k, for $k < n$ and for $k \geq n$. The point of (9.63) is that for many recurrences, r_n is negligibly small, while α is given by the rapidly convergent series (9.61), so that only the first few a_n are needed to obtain a good estimate for the asymptotic behavior of a_n. We next discuss a particularly elegant case.

Suppose that $a_n \geq 1$ and $|b_n| < a_n/4$ for all $n \geq 0$. Then $a_{n+1} \geq a_n$ and $|\delta_{n+1}| \leq |\delta_n|$ for $n \geq 0$, and so $|r_n| \leq |\delta_n|$. Hence

$$a_n \exp(-|\delta_n|) \leq \exp(2^n\alpha) \leq a_n \exp(|\delta_n|) \tag{9.64}$$

and since

$$\begin{aligned} \exp(|\delta_n|) &\leq 1 + |b_n|a_n^{-2} < 1 + (4a_n)^{-1} \ , \\ \exp(-|\delta_n|) &\geq (1 + (4a_n)^{-1})^{-1} \geq 1 - (3a_n)^{-1} \ , \end{aligned} \tag{9.65}$$

we find that

$$|a_n - \exp(2^n\alpha)| < (2a_n)^{-1} \leq 1/2 \ . \tag{9.66}$$

If a_n is an integer, then we can assert that it is the closest integer to $\exp(2^n\alpha)$.

The restriction $|b_n| < a_n/4$ is severe. The basic method applies even without it, and the expansion (9.63) is valid, for example, if we only require that $|\delta_{n+1}| \leq |\delta_n|$ for $n \geq n_0$. However, we will not in general obtain results as nice as (9.66) if we only impose these weak conditions.

The method outlined above can be applied to recurrences that appear to be of a slightly different form. Sometimes only a trivial transformation is required. For example, Golomb's nonlinear recurrence,

$$a_{n+1} = a_0 a_1 \cdots a_n + b, \quad a_0 = 1 \ , \tag{9.67}$$

for b a constant, is easily seen to be equivalent to

$$a_{n+1} = (a_n - b)a_n + b, \quad a_0 = 1, \quad a_1 = b + 1 \ . \tag{9.68}$$

The substitution

$$x_n = a_n - b/2 \tag{9.69}$$

transforms (9.68) into

$$x_{n+1} = x_n^2 + (2 - b)b/4 \ , \tag{9.70}$$

which is of the form treated above. (If the x_n are integers, the inequality (9.66) with x_n replacing a_n might not apply to the x_n because the condition $|(2-b)b/4| < |x_k|/4$ might fail for some k. The trick to use here is to start the recurrence with some x_k, say x_{k_0}, so that the condition $|(2-b)b/4| < |x_k|/4$ applies for $k \geq k_0$. The new α for which (9.66) holds will then be defined in terms of $x_{k_0}, x_{k_0+1}, \ldots$.)

In some situations the results presented above cannot be applied, but the basic method can still be extended. That is the case for the recurrence

$$a_{n+1} = a_n a_{n-1} + 1, \quad a_0,\ a_1 \geq 1 \tag{9.71}$$

of [3]. The result is that a_n is the nearest integer to

$$\alpha^{F_n} \beta^{F_{n-1}} \ , \tag{9.72}$$

where α and β are positive constants, and the F_k are the Fibonacci numbers. What matters is that the recurrence leads to doubly exponential (and regular) growth of a_n. Example 15.3 shows how this principle can be applied even when the a_n are not numbers, but polynomials whose coefficients need to be estimated. ■

9.5. Quasi-linear recurrences

This section mentions some methods and results for studying recurrences that have linearity properties, but are not linear. The most important of them are recurrences involving minimization or maximization. They arise frequently in problems that use dynamic programming approaches and in divide and conquer methods. An important example, treated in [147], is that of a sequence f_n, given by $f_0 = 1$ and

$$f_{n+1} = g_{n+1} + \min_{0 \leq k \leq n} (\alpha f_k + \beta f_{n-k}) \quad \text{for} \quad n \geq 0 \ , \tag{9.73}$$

where $\alpha, \beta > 0$, and g_n is some given sequence. Fredman and Knuth showed that if $g_n = 0$ for $n \geq 1$ and $\alpha + \beta < 1$, then

$$f_n \geq c n^{1+1/\gamma} \quad \text{for some} \quad c = c(\alpha, \beta) > 0 \ , \tag{9.74}$$

where γ is the solution to

$$\alpha^{-\gamma} + \beta^{-\gamma} = 1 \ . \tag{9.75}$$

They proved that $\lim_{n\to\infty} f_n n^{-1-1/\gamma}$ exists if and only if $(\log\alpha)/(\log\beta)$ is irrational. They also presented analyses of this recurrence for $\alpha+\beta\geq 1$, as well as of several recurrences that have different g_n.

The value of the Fredman-Knuth paper is less in the precise results they obtain for several recurrences of the type (9.73) than in the methods they develop, which allow one to analyze related problems. A crucial role in their approach is played by the observation that for the g_n they consider, the minimum in (9.73) can be located rather precisely. The conditions for such localization are applicable to many other sequences as well.

Further work on the recurrence (9.73) was done by Kapoor and Reingold [220], who obtained a complete solution under certain conditions. Their solution is complicated, expressed in terms of the weighted external path length of a binary tree. It is sufficiently explicit, though, to give a complete picture of the continuity, convexity, and oscillation properties of f_n. In some cases their solution simplifies dramatically.

Another class of quasi-linear recurrences involves the greatest integer function. Following [104], consider recurrences of the form

$$a(0)=1,\quad a(n)=\sum_{i=1}^{s} r_i a(\lfloor n/m_i\rfloor),\quad n\geq 1, \tag{9.76}$$

where $r_i>0$ for all i, and the m_i are integers, $m_i\geq 2$ for all i. Let $\tau>0$ be the (unique) solution to

$$\sum_{i=1}^{s} r_i m_i^{-\tau}=1\ . \tag{9.77}$$

If there is an integer d and integers u_i such that $m_i=d^{u_i}$ for $1\leq i\leq s$, then $\lim\ a(n)n^{-\tau}$ as $n\to\infty$ does not exist, but the limit of $a(d^k)d^{-k\tau}$ as $k\to\infty$ does exist. If there is no such d, then the limit of $a(n)n^{-\tau}$ as $n\to\infty$ does exist, and can readily be computed. For example, when

$$a(n)=a(\lfloor n/2\rfloor)+a(\lfloor n/3\rfloor)+a(\lfloor n/6\rfloor)\quad\text{for}\quad n\geq 1\ ,$$

this limit is $12(\log 432)^{-1}$. Convergence to the limit is extremely slow, as is shown in [104]. The method of proof used in [104] is based on renewal theory. Several other methods for dealing with recurrences of the type (9.76) are mentioned in [104] and the references listed in that paper. There are connections to other recurrences that are linear in two variables, such as

$$b(m,n)=b(m,n-1)+b(m-1,n)+b(m-1,n-1),\quad m,n\geq 1\ . \tag{9.78}$$

Consider an infinite sequence of integers $2 \le a_1 < a_2 < \dots$ such that

$$\sum_{j=1}^{\infty} a_j^{-1} \log a_j < \infty \ ,$$

and define $c(0) = 0$,

$$c(n) = \sum_{j=1}^{\infty} c(\lfloor n/a_j \rfloor) + 1, \qquad n \ge 1 \ . \tag{9.79}$$

If ρ is the (unique) positive solution to

$$\sum_{j=1}^{\infty} a_j^{-\rho} = 1 \ ,$$

then Erdös [103] showed that

$$c(n) \sim cn^{\rho} \quad \text{as} \quad n \to \infty \tag{9.80}$$

for a positive constant c. Although the recurrence (9.79) is similar to that of Eq. (9.76), the results are different (no oscillations can occur for a recurrence given by Eq. (9.79)) and the methods are dissimilar.

Karp [221] considers recurrences of the type $T(x) = a(x)+T(h(x))$, where x is a nonnegative real variable, $a(x) \ge 0$, and $h(x)$ is a random variable, $0 \le h(x) \le x$, with $m(x)$ being the expectation of $h(x)$. Such recurrences arise frequently in the analysis of algorithms, and Karp proves several theorems that bound the probability that $T(x)$ is large. For example, he obtains the following result.

Theorem 9.2. *Suppose that $a(x)$ is a nondecreasing continuous function that is strictly increasing on $\{x : \ a(x) > 0\}$, and $m(x)$ is a continuous function. Then for all $x \in \mathbb{R}^+$ and $k \in \mathbb{Z}^+$,*

$$\text{Prob}\left(T(x) \ge u(x) + ka(x)\right) \le \left(m(x)/x\right)^k \ ,$$

where $u(x)$ is the unique least nonnegative solution to the equation $u(x) = a(x) + u(m(x))$.

Another result, proved in [176], is the following estimate.

Theorem 9.3. *Suppose that $r, a_1, \dots, a_N \in \mathbb{R}^+$ and that $b \ge 0$. For $n > N$, define*

$$a_n = 1 + \max_{1 \le k \le n-1} \frac{b + a_{n-1} + a_{n-2} + \cdots + a_{n-k}}{k + r} \ . \tag{9.81}$$

Then

$$a_n \sim (n/r)^{1/2} \qquad \text{as} \qquad n \to \infty \ . \tag{9.82}$$

Theorem 9.3 is proved by an involved induction on the behavior of the a_n.

10. Analytic generating functions

Combinatorialists use recurrence, generating functions, and such transformations as the Vandermonde convolution; others, to my horror, use contour integrals, differential equations, and other resources of mathematical analysis.

J. Riordan [336]

The use of analytic methods in combinatorics did horrify Riordan. They are widespread, though, because of their utility, which even Riordan could not deny. About half of this chapter is devoted to such methods, as they are extremely flexible and give very precise estimates.

10.1. Introduction and general estimates

This section serves as an introduction to most of the remaining sections of the paper, which are concerned largely with the use of methods of complex variables in asymptotics. Many of the results to be presented later can be used with little or no knowledge of analytic functions. However, even some slight knowledge of complex analysis is helpful in getting an understanding of the scope and limitations of the methods to be discussed. There are many textbooks on analytic functions, such as [205, 364]. This chapter assumes that the reader has some knowledge of this field, but not a deep one. It reviews the concepts that are most relevant in asymptotic enumeration, and how they affect the estimates that can be obtained. It is not a general introduction to the subject of complex analysis, and the choices of topics, their ordering, and the decision of when to include proofs were all made with the goal of illustrating how to use complex analysis in asymptotics.

There are several definitions of analytic functions, all equivalent. For our purposes, it will be most convenient to call a function $f(z)$ of one complex variable *analytic* in a connected open set $S \subseteq \mathbb{C}$ if in a small neighborhood of every point $w \in S$, $f(z)$ has an expansion as a power series

$$f(z) = \sum_{n=0}^{\infty} a_n (z-w)^n, \quad a_n = a_n(w), \tag{10.1}$$

that converges. Practically all the functions encountered in asymptotic enumeration that are analytic are analytic in a disk about the origin. A necessary and sufficient condition for $f(z)$, defined by a power series (6.1), to be analytic in a neighborhood of the origin is that $|a_n| \le C^n$ for some constant $C > 0$. Therefore there is an effective dichotomy, with common generating functions either not converging near 0 and being only formal power series, or else converging

and being analytic.

A function $f(z)$ is called *meromorphic* in S if it is analytic in S except at a (countable isolated) subset $S' \subseteq S$, and in a small neighborhood of every $w \in S'$, $f(z)$ has an expansion of the form

$$f(z) = \sum_{n=-N(w)}^{\infty} a_n (z-w)^n \ , \qquad a_n = a_n(w) \ . \tag{10.2}$$

Thus meromorphic functions can have poles, but nothing more. Alternatively, a function is meromorphic in S if and only if it is the quotient of two functions analytic in S. In particular, z^{-5} is meromorphic throughout the complex plane, but $\sin(1/z)$ is not. In general, functions given by nice expressions are analytic away from obvious pathological points, since addition, multiplication, division, and composition of analytic functions usually yield analytic or meromorphic functions in the proper domains. Thus $\sin(1/z)$ is analytic throughout $\mathbb{C} \setminus \{0\}$, and so is z^{-5}, while $\exp(1/(1-z))$ is analytic throughout $\mathbb{C} \setminus \{1\}$, but is not meromorphic because of the essential singularity at $z = 1$. Not all functions that might seem smooth are analytic, though, as neither $f(z) = \bar{z}$ ($\bar{z}$ denoting the complex conjugate of z) nor $f(z) = |z|$ is analytic anywhere. The smoothness condition imposed by (10.1) is very stringent.

Analytic continuation is an important concept. A function $f(z)$ may be defined and analytic in S, but there may be another function $g(z)$ that is analytic in $S' \supset S$ and such that $g(z) = f(z)$ for $z \in S$. In that case we say that $g(z)$ provides an analytic continuation of $f(z)$ to S', and it is a theorem that this extension is unique. A simple example is provided by

$$\sum_{n=0}^{\infty} z^n = \frac{1}{1-z} \ . \tag{10.3}$$

The power series on the left side converges only for $|z| < 1$, and defines an analytic function there. On the other hand, $(1-z)^{-1}$ is analytic throughout $\mathbb{C} \setminus \{1\}$, and so provides an analytic continuation for the power series. This is a common phenomenon in asymptotic enumeration. Typically a generating function will converge in a disk $|z| < r$, will have a singularity at r, but will be continuable to a region of the form

$$\{z : |z| < r + \delta, \ |\mathrm{Arg}(z-r)| > \pi/2 - \epsilon\} \tag{10.4}$$

for $\delta, \ \epsilon > 0$. When this happens, it can be exploited to provide better or easier estimates of the coefficients, as is shown in Section 11.1. That section explains the reasons why continuation to a region of the form (10.4) is so useful.

If $f(z)$ is analytic in S, z is on the boundary of S, but $f(z)$ cannot be analytically continued to a neighborhood of z, we say that z is a *singularity* of $f(z)$. Isolated singularities that are not poles are called essential, so that $z = 1$ is an essential singularity of $\exp(1/(1-z))$, but not of $1/(1-z)$. (Note that $z = 1$ is an essential singularity of $f(z) = (1-z)^{1/2}$ even though $f(1) = 0$.) Throughout the rest of this chapter we will often refer to *large singularities* and *small singularities*. These are not precise concepts, and are meant only to indicate how fast the function $f(z)$ grows as $z \to z_0$, where z_0 is a singularity. If $z_0 = 1$, we say that $(1-z)^{1/2}$, $\log(1-z)$, $(1-z)^{-10}$ have small singularities, since $|f(z)|$ either decreases or grows at most like a negative power of $|1-z|$ as $z \to 1$. On the other hand, $\exp(1/(1-z))$ or $\exp((1-z)^{-1/5})$ will be said to have large singularities. Note that for $z = 1+iy$, $y \in \mathbb{R}$, $\exp(1/(1-z))$ is bounded, so the choice of path along which the singularity is approached is important. In determining the size of a singularity z_0, we will usually be concerned with real z_0 and generating functions $f(z)$ with nonnegative coefficients, and then usually will need to look only at z real, $z \to z_0^-$. When the function $f(z)$ is *entire* (that is, analytic throughout $\mathbb{C}$), we will say that ∞ is a singularity of $f(z)$ (unless $f(z)$ is a constant), and will use the large vs. small singularity classification depending on how fast $f(z)$ grows as $|z| \to \infty$. The distinction between small and large singularities is important in asymptotics because different methods are used in the two cases.

A simple closed contour Γ in the complex plane is given by a continuous mapping $\gamma : [0,1] \to \mathbb{C}$ with the properties that $\gamma(0) = \gamma(1)$, and that $\gamma(s) \neq \gamma(t)$ whenever $0 \leq s < t \leq 1$ and either $s \neq 0$ or $t \neq 1$. Intuitively, Γ is a closed path in the complex plane that does not intersect itself. For most applications that will be made in this chapter, simple closed contours Γ will consist of line segments and sections of circles. For such contours it is easy to prove that the complex plane is divided by the contour into two connected components, the inside and the outside of the curve. This result is true for all simple closed curves by the Jordan curve theorem, but this result is surprisingly hard to prove.

In asymptotic enumeration, the basic result about analytic functions is the Cauchy integral formula for their coefficients.

Theorem 10.1. *If $f(z)$ is analytic in an open set S containing 0, and*

$$f(z) = \sum_{n=0}^{\infty} a_n z^n \tag{10.5}$$

in a neighborhood of 0, *then for any* $n \geq 0$,

$$a_n = [z^n]f(z) = (2\pi i)^{-1} \int_\Gamma f(z) z^{-n-1} dz \ , \tag{10.6}$$

where Γ *is any simple closed contour in* S *that contains the origin inside it and is positively oriented (i.e., traversed in counterclockwise direction).*

An obvious question is why should one use the integral formula (10.6) to determine the coefficient a_n of $f(z)$. After all, the series (10.5) shows that

$$n!\, a_n = \frac{d^n}{dz^n} f(z)\Big|_{z=0} \ . \tag{10.7}$$

Unfortunately the differentiation involved in (10.7) is hard to control. Derivatives involve taking limits, and so even small changes in a function can produce huge changes in derivatives, especially high order ones. The special properties of analytic functions are not reflected in the formula (10.7), and for nonanalytic functions there is little that can be done. On the other hand, Cauchy's integral formula (10.6) does use special properties of analytic functions, which allow the determination of the coefficients of $f(z)$ from the values of $f(z)$ along any closed path. This determination involves integration, so that even coarse information about the size of $f(z)$ can be used with it. The analytic methods that will be outlined exploit the freedom of choice of the contour of integration to relate the behavior of the coefficients to the behavior of the function near just one or sometimes a few points.

If the power series (10.5) converges for $|z| < R$, and for the contour Γ we choose a circle $z = r\exp(i\theta)$, $0 \leq \theta \leq 2\pi$, $0 < r < R$, then the validity of (10.6) is easily checked by direct computation, since the power series converges absolutely and uniformly so one can interchange integration and summation. The strength of Cauchy's formula is in the freedom to choose the contour Γ in different ways. This freedom yields most of the powerful results to be discussed in the following sections, and later in this section we will outline how this is achieved. First we discuss some simple applications of Theorem 10.1 obtained by choosing Γ to be a circle centered at the origin.

Theorem 10.2. *If* $f(z)$ *is analytic in* $|z| < R$, *then for any* r *with* $0 < r < R$ *and any* $n \in Z$, $n \geq 0$,

$$|[z^n]f(z)| \leq r^{-n} \max_{|z|=r} |f(z)| \ . \tag{10.8}$$

The choice of Γ in Theorem 10.1 to be the circle of radius r gives Theorem 10.2. If $f(z)$, defined by (10.5), has $a_n \geq 0$ for all n, then

$$|f(z)| \leq \sum_{n=0}^{\infty} a_n |z|^n = f(|z|)$$

and therefore we obtain Lemma 8.1 as an easy corollary to Theorem 10.2. The advantage of Theorem 10.2 over Lemma 8.1 is that there is no requirement that $a_n \geq 0$. The bound of Theorem 10.2 is usually weaker than the correct value by a small multiplicative factor such as $n^{1/2}$.

If $f(z)$ is analytic in $|z| < R$, then for any $\delta > 0$, $f(z)$ is bounded in $|z| < R - \delta$, and so Theorem 10.2 shows that $a_n = [z^n]f(z)$ satisfies $|a_n| = O((R-\delta)^{-n})$. On the other hand, if $|a_n| = O(S^{-n})$, then the power series (10.5) converges for $|z| < S$ and defines an analytic function in that disk. Thus we obtain the easy result that if $f(z)$ is analytic in a disk $|z| < R$ but in no larger disk, then

$$\limsup |a_n|^{1/n} = R^{-1} \ . \tag{10.9}$$

Example 10.1. *Oscillating sequence.* Consider the sequence, discussed already in Example 9.4, given by

$$a_n = \sum_{k=0}^{n} \binom{n}{k} \frac{(-1)^k}{k!} \ , \qquad n = 0, 1, \ldots \ . \tag{10.10}$$

The maximal term in the sum (10.10) is of order roughly $\exp(cn^{1/2})$, so a_n cannot be much larger. However, the sum (10.10) does not show that a_n cannot be extremely small. Could we have $|a_n| \leq \exp(-n)$ for all n, say? That this is impossible is obvious from (9.39), though, by the argument above. The generating function $f(z)$, given by Eq. (9.39), is analytic in $|z| < 1$, but has an essential singularity at $z = 1$, so we immediately see that for any $\epsilon > 0$, $|a_n| < (1+\epsilon)^n$ for all sufficiently large n, and that $|a_n| > (1-\epsilon)^n$ for infinitely many n. (More powerful methods for dealing with analytic generating functions, such as the saddle point method to be discussed in Section 12, can be used to obtain the asymptotic relation for a_n given in Example 9.4.) ■

There is substantial literature dealing with the growth rate of coefficients of analytic functions. The book of Evgrafov [110] is a good reference for these results. However, the estimates presented there are not too useful for us, since they apply to wide classes of often pathological

functions. In combinatorial enumeration we usually encounter much tamer generating functions for which the crude bounds of [110] are obvious or easy to derive. Instead, we need to use the tractable nature of the functions we encounter to obtain much more delicate estimates.

The basic result, derived earlier, is that the power series coefficients a_n of a generating function $f(z)$, defined by (10.5), grow in absolute value roughly like R^{-n}, if $f(z)$ is analytic in $|z| < R$. A basic result about analytic functions says that if the Taylor series (10.5) of $f(z)$ converges for $|z| < R$ but for every $\epsilon > 0$ there is a z with $|z| = R + \epsilon$ such that the series (10.5) diverges at z, then $f(z)$ has a singularity z with $|z| = R$. Thus the exponential growth rate of the a_n is determined by the distance from the origin of the nearest singularity of $f(z)$, with close singularities giving large coefficients. Sometimes it is not obvious what R is. When the coefficients of $f(z)$ are positive, as is common in combinatorial enumeration and analysis of algorithms, there is a useful theorem of Pringsheim [364]:

Theorem 10.3. *Suppose that $f(z)$ is defined by Eq. (10.5) with $a_n \geq 0$ for all $n \geq n_0$, and that the series (10.5) for $f(z)$ converges for $|z| < R$ but not for any $|z| > R$. Then $z = R$ is a singularity of $f(z)$.*

As we remarked above, the exponential growth rate of the a_n is determined by the distance from the origin of the nearest singularity. Theorem 10.3 says that if the coefficients a_n are nonnegative, it suffices to look along the positive real axis to determine the radius of convergence R, which is also the desired distance to the singularity. There can be other singularities at the same distance from the origin (for example, $f(z) = (1 - z^2)^{-1}$ has singularities at $z = \pm 1$), but Theorem 10.3 guarantees that none are closer to 0 than the positive real one.

Since the singularities of smallest absolute value of a generating function exert the dominant influence on the asymptotics of the corresponding sequence, they are called the *dominant singularities*. In the most common case there is just one dominant singularity, and it is almost always real. However, we will sometimes speak of a large set of singularities (such as the k first order poles in Theorem 9.1, which are at different distances from the origin) as dominant ones. This allows some dominant singularities to be more influential than others.

Many techniques, including the elementary methods of Section 8, obtain bounds for summatory functions of coefficients even when they cannot estimate the individual coefficients. These methods succeed largely because they create a dominant singularity. If $f(z) = \sum f_n z^n$ converges for $|z| < 1$, diverges for $|z| > 1$, and has $f_n \geq 0$, then the singularity at $z = 1$ is at

least as large as any other. However, there could be other singularities on $|z| = 1$ that are just as large. (This holds for the functions $f_2(z)$ and $f_3(z)$ defined by (8.2) and (8.4).) When we consider the generating function of $\sum_{k \le n} f_k$, though, we find that

$$h(z) = \sum_{n=0}^{\infty} \left(\sum_{k=0}^{n} f_k \right) z^n = (1-z)^{-1} f(z) \ , \tag{10.11}$$

so that $h(z)$ has a singularity at $z = 1$ that is much larger than any other one. That often provides enough of an extra boost to push through the necessary technical details of the estimates.

Most generating functions $f(z)$ have their coefficients $a_n = [z^n]f(z)$ real. If $f(z)$ is analytic at 0, and has real coefficients, then $f(z)$ satisfies the reflection principle,

$$f(z) = \overline{f(\overline{z})} \ . \tag{10.12}$$

This implies that zeros and singularities of $f(z)$ come in complex conjugate pairs.

The success of analytic methods in asymptotics comes largely from the use of Cauchy's formula (10.6) to estimate accurately the coefficients a_n. At a more basic level, this success comes because the behavior of an analytic function $f(z)$ reflects precisely the behavior of the coefficients a_n. In the discussion of elementary methods in Section 8, we pointed out that the behavior of a generating function for real arguments does not distinguish between functions with different coefficients. For example, the functions $f_1(z)$ and $f_3(z)$ defined by (8.1) and (8.4) are almost indistinguishable for $z \in \mathbb{R}$. However, they differ substantially in their behavior for complex z. The function $f_1(z)$ has only a first order pole at $z = 1$ and no other singularities, while $f_3(z)$ has poles at $z = 1$, $\exp(2\pi i/3)$, and $\exp(4\pi i/3)$. The three poles at the three cubic roots of unity reflect the modulo 3 periodicity of the coefficients of $f_3(z)$. This is a general phenomenon, and in the next section we sketch the general principle that underlies it. (The degree to which coefficients of an analytic function determine the behavior at the singularities is the subject of Abelian theorems. We will not need to delve into this subject to its full depth. For references, see [190, 364].)

Analytic methods are extremely powerful, and when they apply, they often yield estimates of unparalleled precision. However, there are tricky situations where analytic methods seem as if they ought to apply, but don't (at least not easily), whereas simpler approaches work.

Example 10.2. *Set partitions with distinct block sizes.* Let a_n be the number of partitions of a set of n elements into blocks of distinct sizes. Then $a_n = b_n \cdot n!$, where $b_n = [z^n]f(z)$, with

$$f(z) = \prod_{k=1}^{\infty} \left(1 + \frac{z^k}{k!}\right) . \tag{10.13}$$

The function $f(z)$ is entire and has nonnegative coefficients, so it might appear as an ideal candidate for an application of some of the methods for dealing with large singularities (such as the saddle point technique) that will be presented later. However, on circles $|z| = (n+1/2)/e$, $n \in \mathbb{Z}^+$, $f(z)$ does not vary much, so there are technical problems in applying these analytic methods. On the other hand, combinatorial estimates can be used to show [233] that the b_n behave in a "regularly irregular" way, so that, for example,

$$b_{m(m+1)/2-1} \sim b_{m(m+1)/2} \quad \text{as} \quad m \to \infty , \tag{10.14}$$

$$b_{m(m+1)/2} \sim m b_{m(m+1)/2+1} \quad \text{as} \quad m \to \infty . \tag{10.15}$$

These estimates are obtained by expanding the product in Eq. (10.13) and noting that

$$b_n = \sum_{\substack{1 \le k_1 < \cdots < k_r \\ \sum k_i = n}} \frac{1}{\prod_{i=1}^{r} k_i!} . \tag{10.16}$$

Since factorials grow rapidly, the only terms in the sum in (10.16) that are significant are those with small k_i. The term $b_n z^n$ for $n = m(m+1)/2$ for example, comes almost entirely from the product of $z^k/k!$, $1 \le k \le m$, all other products contributing an asymptotically negligible amount. ■

10.2. Subtraction of singularities

An important basic tool in asymptotics of coefficients of analytic functions is that of subtraction of singularities. If we wish to estimate $[z^n]f(z)$, and we know $[z^n]g(z)$, and the singularities of $f(z) - g(z)$ are smaller than those of $f(z)$, then we can usually conclude that $[z^n]f(z) \sim [z^n]g(z)$ as $n \to \infty$. In practice, given a function $f(z)$, we find the dominant singularities of $f(z)$ (usually poles), and construct a simple function $g(z)$ with those singularities. We illustrate this approach with several examples. The basic theme will recur in other sections.

Example 10.3. *Bernoulli numbers.* The Euler-Maclaurin summation formula, introduced in Section 5.3, involves the Bernoulli numbers B_n with exponential generating function

$$f(z) = \sum_{n=0}^{\infty} B_n \frac{z^n}{n!} = \frac{z}{e^z - 1} . \tag{10.17}$$

The denominator $\exp(z) - 1$ has zeros at 0, $\pm 2\pi i$, $\pm 4\pi i, \ldots$. The zero at 0 is canceled by the zero of z, so $f(z)$ is analytic for $|z| < 2\pi$, but has first order poles at $z = \pm 2\pi i$, $\pm 4\pi i, \ldots$. Consider

$$g(z) = 2\pi i \left(\frac{1}{z - 2\pi i} - \frac{1}{z + 2\pi i} \right) . \tag{10.18}$$

Then $f(z) - g(z)$ is analytic for $|z| < 4\pi$, so

$$|[z^n](f(z) - g(z))| = O((4\pi - \epsilon)^{-n}) \quad \text{as} \quad n \to \infty \tag{10.19}$$

for every $\epsilon > 0$. On the other hand,

$$[z^n]g(z) = \begin{cases} 0 & n \text{ odd} , \\ 2(2\pi)^{-n} & n \text{ even} . \end{cases} \tag{10.20}$$

This gives the leading term asymptotics of B_n. By taking more complicated $g(z)$, we can subtract more of the singularities of $f(z)$ and obtain more accurate expansions for B_n. It is even possible to obtain an exponentially rapidly convergent series for B_n. ■

Example 10.4. *Rational function asymptotics.* As another example of the subtraction of singularities principle, we sketch a proof of Theorem 9.1. Suppose that the hypotheses of that theorem are satisfied. Let

$$u(z) = \sum_{j=1}^{k} \frac{-g(\rho_j)}{\rho_j h'(\rho_j)(1 - z/\rho_j)} . \tag{10.21}$$

Then $f(z) - u(z)$ has no singularities in $|z| \le R$, and for $|z| = R$,

$$|f(z) - u(z)| \le |f(z)| + |u(z)| \le W + \delta^{-1} \sum_{j=1}^{k} |g(\rho_j)/h'(\rho_j)| . \tag{10.22}$$

Hence, by Theorem 10.2,

$$\left| [z^n](f(z) - u(z)) \right| \le W R^{-n} + \delta^{-1} R^{-n} \sum_{j=1}^{k} |g(\rho_j)/h'(\rho_j)| . \tag{10.23}$$

On the other hand,

$$[z^n]u(z) = -\sum_{j=1}^{k} \rho_j^{-n-1} g(\rho_j)/h'(\rho_j) . \tag{10.24}$$

The last two estimates yield Theorem 9.1. ■

The reader may have noticed that the proof of Theorem 9.1 presented above does not depend on $f(z)$ being rational. We have proved the following more general result.

Theorem 10.4. *Suppose that $f(z)$ is meromorphic in an open set containing $|z| \le R$, that it is analytic at $z = 0$ and on $|z| = R$, and that the only poles of $f(z)$ in $|z| < R$ are at $\rho_1, \dots, \rho_k$, each of multiplicity 1. Suppose further that*

$$\max_{|z|=R} |f(z)| \le W \tag{10.25}$$

and that $R - |\rho_j| \ge \delta$ for some $\delta > 0$ and $1 \le j \le k$. Then

$$\left| [z^n] f(z) + \sum_{j=1}^{k} r_j \rho_j^{-n-1} \right| \le W R^{-n} + \delta^{-1} R^{-n} \sum_{j=1}^{k} |r_j| \ , \tag{10.26}$$

where r_j is the residue of $f(z)$ at ρ_j.

In the examples above, the dominant singularities were separated from other ones, so their contributions were larger than those of lower order terms by an exponential factor. Sometimes the singularity that remains after subtraction of the dominant one is on the same circle, and only slightly smaller. Section 11 presents methods that deal with some cases of this type, at least when the singularity is not large. What makes those methods work is the subtraction of singularities principle. Next we illustrate another application of this principle where the singularity is large. (The generating function is entire, and so the singularity is at infinity.)

Example 10.5. *Permutations without long increasing subsequences.* Let $u_k(n)$ be the number of permutations of $\{1, 2, \dots, n\}$ that have no increasing subsequence of length $> k$. Logan and Shepp [257] and Vershik and Kerov [370] established by calculus of variations and combinatorics that the average value of the longest increasing subsequence in a random permutation is asymptotic to $2n^{1/2}$. Frieze [149] has proved recently, using probabilistic methods, a stronger result, namely that almost all permutations have longest increasing subsequences of length close to $2n^{1/2}$. Here we consider asymptotics of $u_k(n)$ for k fixed and $n \to \infty$. The Schensted correspondence and the hook formula express $u_k(n)$ in terms of Young diagrams with $\le k$ columns. For k fixed, there are few diagrams and their influence can be estimated explicitly using Stirling's formula, although Selberg-type integrals are involved and the analysis is complicated. This analysis was done by Regev [329], who proved more general results. Here we sketch another approach to the asymptotics of $u_k(n)$ for k fixed. It is based on a result of Gessel [161]. If

$$U_k(z) = \sum_{n=0}^{\infty} \frac{u_k(n) z^{2n}}{(n!)^2} \ , \tag{10.27}$$

then

$$U_k(z) = \det(I_{|i-j|}(2z))_{1\le i,j\le k} \ , \tag{10.28}$$

where the $I_m(x)$ are Bessel functions (Chapter 9 of [297]). H. Wilf and the author have noted that one can obtain the asymptotics of the $u_k(n)$ by using known asymptotic results about the $I_m(x)$. Eq. (9.7.1) of [297] states that for every $H \in \mathbb{Z}^+$,

$$I_m(z) = (2\pi z)^{-1/2} e^z \left(\sum_{h=0}^{H-1} c(m,h) z^{-h} + O(|z|^{-H}) \right) \ , \tag{10.29}$$

where this expansion is valid for $|z| \to \infty$ with $|\mathrm{Arg}(z)| \le 3\pi/8$, say. The $c(m,h)$ are explicit constants with $c(m,0) = 1$. Let us consider $k = 4$ to be concrete. Then, taking $H = 7$ in (10.29) (higher values of H are needed for larger k) we find from (10.28) that

$$U_4(z) = e^{8z}(3(256\pi^2 z^8)^{-1} + O(|z|^{-9})) \quad \text{for} \quad |z| \ge 1 \ . \tag{10.30}$$

It is also known that $I_m(-z) = (-1)^m I_m(z)$ and $I_m(z)$ is relatively small in the angular region $|\pi/2 - \mathrm{Arg}(z)| < \pi/8$. Therefore $U_4(-z) = U_4(z)$, and one can show that

$$|U_4(z)| = O(|z|^{-1} U_4(|z|)) \tag{10.31}$$

for z away from the real axis.

To apply the subtraction of singularities principle, we need an entire function $f(z)$ that is even, is large only near the real axis, and such that for $x \in \mathbb{R}$, $x \to \infty$,

$$f(x) \sim 3(256\pi^2 x^8)^{-1} \exp(8x) \ . \tag{10.32}$$

The function

$$f^*(z) = 3(128\pi^2 z^8)^{-1} \cosh(8z)$$

is even and has the desired asymptotic growth, but is not entire. We correct this defect by subtracting the contribution of the pole at $z = 0$, and let

$$f(z) = 3(128\pi^2 z^8)^{-1}(\cosh(8z) - 1 - 32z^2 - 512z^4/3 - 16384z^6/45 - 131072z^8/315) \ . \tag{10.33}$$

(It is not necessary to know explicitly the first 8 terms in the Taylor expansion of $\cosh(8z)$ that we wrote down above, as they do not affect the final answer.) With this definition

$$|U_4(z) - f(z)| = O(|z|^{-1} f(|z|)) \tag{10.34}$$

uniformly for all z with $|z| \geq 1$, say, and so if we apply Cauchy's theorem on the circle $|z| = n/4$, say, we find that

$$[z^{2n}](U_4(z) - f(z)) = O(n^{-2n}e^{2n}16^n n^{-9}) \ . \tag{10.35}$$

(The choice of $|z| = n/4$ is made to minimize the resulting estimate.) On the other hand, by Stirling's formula,

$$\begin{aligned} [z^{2n}]f(z) &= 3(128\pi^2)^{-1} \cdot ([z^{2n+8}]\cosh(8z)) \\ &= 3(128\pi^2)^{-1}8^{2n+8}/(2n+8)! \\ &\sim 1536\pi^{-5/2}n^{-2n}16^n e^{2n} n^{-17/2} \quad \text{as} \quad n \to \infty \ . \end{aligned} \tag{10.36}$$

Comparing (10.35) and (10.36), we see that

$$\begin{aligned} u_4(n) = (n!)^2[z^{2n}]U_4(z) &\sim (n!)^2 1536\pi^{-5/2}n^{-2n}16^n e^{2n}n^{-17/2} \\ &\sim 1536\pi^{-3/2}n^{-15/2}16^n \quad \text{as} \quad n \to \infty \ . \end{aligned} \tag{10.37}$$

■

Other methods can be applied to Gessel's generating function to obtain asymptotics of $u_k(n)$ for wider ranges of k ([306]).

The above example obtains a good estimate because the remainder term in (10.30) is smaller than the main term by a factor of $|z|^{-1}$. Had it been smaller only by a factor of $|z|^{-1/2}$, the resulting estimate would have been worthless, and it would have been necessary to obtain a fuller asymptotic expansion of $U_4(z)$ or else use smoothness properties of the remainder term. This is due to the phenomenon, mentioned before, that crude absolute value estimates in either Cauchy's theorem, or the elementary approaches of Section 8, usually lose a factor of $n^{1/2}$ when estimating the n-th coefficient.

The subtraction of singularities principle can be applied even when the generating functions seem to be more complicated than those of Example 10.5. If we consider the problem of that example, but with $k = 5$, then we find that

$$U_5(z) = 3\exp(10z)(5 \cdot 2^{13} \cdot \pi^{5/2}z^{25/2})^{-1}(1 + O(|z|^{-1})) \tag{10.38}$$

as $|z| \to \infty$, with $|\mathrm{Arg}(z)| \leq 3\pi/8$, $U_5(-z) = U_5(z)$, and $U_5(z)$ is entire. We now need an entire function with known coefficients that grows as $\exp(10z)z^{-25/2}$. This is not difficult to obtain, as

$$I_0(10z)z^{-12} - \sum_{j=1}^{12} c_j z^{-j} \tag{10.39}$$

for suitable coefficients c_j has the desired properties.

10.3. The residue theorem and sums as integrals

Sometimes sums that are not easily handled by other methods can be converted to integrals that can be evaluated explicitly or estimated by the residue theorem. If $t(z)$ is a meromorphic function that has first order poles at $z = a,\ a+1, \ldots, b$, with $a \in Z$, each with residue 1, then

$$\sum_{n=a}^{b} f(n) = \frac{1}{2\pi i} \int_\Gamma f(z)t(z)dz \ , \tag{10.40}$$

where Γ is a simple closed contour enclosing $a, a+1, \ldots, b$, provided $f(z)$ is analytic inside Γ and $t(z)$ has no singularities inside Γ aside from the first order poles at $a, a+1, \ldots, b$. If $t(z)$ is chosen to have residue $(-1)^n$ at $z = n$, then we obtain

$$\sum_{n=a}^{b} (-1)^n f(n) = \frac{1}{2\pi i} \int_\Gamma f(z)t(z)dz \ . \tag{10.41}$$

A useful example is given by the formula

$$\sum_{k=0}^{n} \binom{n}{k} (-1)^k f(k) = \frac{(-1)^n n!}{2\pi i} \int_\Gamma \frac{f(z)dz}{z(z-1)\cdots(z-n)} \ . \tag{10.42}$$

The advantage of (10.40) and (10.41) is that the integrals can often be manipulated to give good estimates. This is especially valuable for alternating sums such as (10.41). An analytic function $f(z)$ is extremely regular, so a sum such as that in (10.40) can often be estimated by methods such as the Euler-Maclaurin summation formula (Section 5.3). However, that formula cannot always be applied to alternating sums such as that of (10.41), because the sign change destroys the regularity of $f(n)$. (However, as is noted in Section 5.3, there are generalizations of the Euler-Maclaurin formula that are sometimes useful.) It is hard to write down general rules for applying this method, as most situations require appropriate choice of $t(z)$ and careful handling of the integral. For a detailed discussion of this method, often referred to as Rice's method, see Section 4.9 of [205]. A pair of popular functions to use as $t(z)$ are

$$t_1(z) = \pi/(\sin \pi z), \quad t_2(z) = \pi/(\tan \pi z) \ . \tag{10.43}$$

One can show (Theorem 4.9a of [205]) that if $r(z) = p(z)/q(z)$ with $p(z)$ and $q(z)$ polynomials such that $\deg q(z) \geq \deg p(z) + 2$, and $q(n) \neq 0$ for any $n \in Z$, then

$$\sum_{n=-\infty}^{\infty} r(n) \ = \ -\sum \mathrm{Res}(r(z)t_1(z)) \ , \tag{10.44}$$

$$\sum_{n=-\infty}^{\infty} (-1)^n r(n) \ = \ -\sum \mathrm{Res}(r(z)t_2(z)) \ , \tag{10.45}$$

where the sums on the right-hand sides above are over the zeros of $q(z)$.

Examples of applications of these methods to asymptotics of data structures are given in [141] and [360].

10.4. Location of singularities, Rouché's theorem, and unimodality

A recurrent but only implicit theme throughout the discussion in this section is that of isolation of zeros. For example, to apply Theorem 9.1 we need to know that the polynomial $h(z)$ has only k zeros, each of multiplicity one, in $|z| < R$. Proofs of such results can often be obtained with the help of Rouché's theorem [205, 364].

Theorem 10.5. *Suppose that $f_1(z)$ and $f_2(z)$ are functions that are analytic inside and on the boundary of a simple closed contour Γ. If*

$$|f_2(z)| < |f_1(z)| \quad \textit{for all} \quad z \in \Gamma \ , \tag{10.46}$$

then $f_1(z)$ and $f_1(z) + f_2(z)$ have the same number of zeros (counted with multiplicity) inside Γ.

Example 10.6. *Sequences with forbidden subblocks.* We consider again the topic of Examples 6.4, 6.8, and 9.2, and prove the results that were already used in Example 9.2. We again set

$$h(z) = z^k + (1 - 2z)C_A(z) \ , \tag{10.47}$$

where the only fact about $C_A(z)$ we will use is that it is a polynomial of degree $< k$ and coefficients 0 and 1, and $C_A(0) = 1$. We wish to show that $h(z)$ has only one zero in $|z| \le 0.6$ if k is large. Write

$$C_A(z) = 1 + \frac{1}{2}\sum_{j=1}^{\infty} z^j + \frac{1}{2}\sum_{j=1}^{\infty} \epsilon_j z^j \ , \tag{10.48}$$

where $\epsilon_j = \pm 1$ for each j. Then

$$C_A(z) = \frac{2 - z}{2(1 - z)} + u(z) \ , \tag{10.49}$$

where

$$|u(z)| \le \frac{|z|}{2(1 - |z|)} \ .$$

For $|z| = r < 1$, we have $|u(z)| \le r/(2(1 - r))$. On the other hand, $z \to (2 - z)/(1 - z)$ maps circles to circles, since it is a fractional linear transformation, so it takes the circle $|z| = r$ to

the circle with center on the real axis that goes through the two points $(2-r)/(1-r)$ and $(2+r)/(1+r)$. Therefore for $|z| = r < 1$,

$$|C_A(z)| \geq \frac{2+r}{2(1+r)} - \frac{r}{2(1-r)} = \frac{1-r-r^2}{1-r^2} \ , \tag{10.50}$$

and so $|C_A(z)| \geq 1/16$ for $|z| = r \leq 0.6$. Hence, if $k \geq 9$, then on $|z| = 0.6$,

$$|(1-2z)C_A(z)| \geq 1/80 > (0.6)^k \ , \tag{10.51}$$

and thus $(1-2z)C_A(z)$ and $h(z)$ have the same number of zeros in $|z| \leq 0.6$. On the other hand, $C_A(z)$ has no zeros in $|z| \leq 0.6$ by (10.50), while $1-2z$ has one, so we obtain the desired result, at least for $k \geq 9$. (A more careful analysis shows that $h(z)$ has only one root inside $|z| = 0.6$ even for $4 \leq k < 9$. For $1 \leq k \leq 3$, there are cases where there is no zero inside $|z| \leq 0.6$.) Example 6.7 shows how to obtain precise estimates of the single zero.

We note that (10.50) shows that for $|z| = 0.55$, $k \geq 9$

$$|h(z)| \geq |1-1.1|0.2 - (0.55)^k \geq 0.02 - 0.01 \geq 1/100 \ , \tag{10.52}$$

a result that was used in Example 9.2. ■

Example 10.7. *Coins in a fountain.* An (n,k) fountain is an arrangement of n coins in rows such that there are k coins in the bottom row, and such that each coin in a higher row touches exactly two coins in the next lower row. Let $a_{n,k}$ be the number of (n,k) fountains, and $a_n = \sum_k a_{n,k}$ the total number of fountains of n coins. The values of a_n for $1 \leq n \leq 6$ are $1, 1, 2, 3, 5, 9$. If we let $a_0 = 1$ then it can be shown [313] that

$$f(z) = \sum_{n=0}^{\infty} a_n z^n = \frac{1}{1 - \frac{z}{1 - \frac{z^2}{1 - \frac{z^3}{1 - \cdots}}}} \ . \tag{10.53}$$

This is a famous continued fraction of Ramanujan. (Other combinatorial interpretations of this continued fraction are also known, see the references in [313]. For related results, see [326, 327].) Although one can derive the asymptotics of the a_n from the expansion (10.53), it is more convenient to work with another expansion, known from previous studies of Ramanujan's continued fraction:

$$f(z) = \frac{p(z)}{q(z)} \ , \tag{10.54}$$

where

$$p(z) = \sum_{r\geq 0}(-1)^r \frac{z^{r(r+1)}}{(1-z)(1-z^2)\dots(1-z^r)} , \tag{10.55}$$

$$q(z) = \sum_{r\geq 0}(-1)^r \frac{z^{r^2}}{(1-z)(1-z^2)\dots(1-z^r)} . \tag{10.56}$$

Clearly both $p(z)$ and $q(z)$ are analytic in $|z|<1$, so $f(z)$ is meromorphic there. We will show that $q(z)$ has a simple real zero x_0, $0.57 < x_0 < 0.58$, and no other zeros in $|z| < 0.62$, while $p(x_0) > 0$. It will then follow from Theorem 10.4 that

$$a_n = cx_0^{-n} + O((5/3)^n) \quad \text{as} \quad n\to\infty , \tag{10.57}$$

where $c = -p(x_0)/(x_0 q'(x_0))$. Numerical computation shows that $c = 0.31236\dots$, $x_0 = 0.576148769\dots$.

To establish the claim about x_0, let $p_n(z)$ and $q_n(z)$ denote the n-th partial sums of the series (10.55) and (10.56), respectively. Write $a(z) = q_3(z)(1-z)(1-z^2)/(1-z^3)$, so that

$$a(z) = 1 - 2z - z^2 + z^3 + 3z^4 + z^5 - 2z^6 - z^7 - z^9 , \tag{10.58}$$

and consider

$$b(z) = \prod_{j=1}^{9}(z - z_j) ,$$

where the z_j are 0.57577, $-0.46997 \pm i0.81792$, $0.74833 \pm i0.07523$, $-1.05926 \pm i0.36718$, $0.49301 \pm i1.58185$, in that order. (The z_j are approximations to the zeros of $a(z)$, obtained from numerical library subroutines. How they were derived is not important for the verification of our proof.) An easy hand or machine computation shows that if $a(z) = \sum_k a_k z^k$, $b(z) = \sum b_k z^k$, then

$$\sum_{k=0}^{9} |a_k - b_k| \leq 1.7\times 10^{-4} ,$$

and so $|a(z) - b(z)| \leq 1.7\times 10^{-4}$ for all $|z| \leq 1$. Another computation shows that $|b(z)| \geq 8\times 10^{-4}$ for all $|z| = 0.62$.

On the other hand, for $0 \leq u \leq 0.62$ and $|z| = u$, we have for $k \geq 5$

$$\left|\frac{z^{(k+1)^2-k^2}}{1-z^{k+1}}\right| \leq \frac{u^{2k+1}}{1-u^{k+1}} \leq \frac{u^9}{1-u^5} . \tag{10.59}$$

Therefore

$$\left|\sum_{k=4}^{\infty}(-1)^k \frac{z^{k^2}}{\Pi_{j=4}^{k}(1-z^j)}\right| \leq \frac{u^{16}}{1-u^4}\sum_{m\geq 0}\left(\frac{u^9}{1-u^5}\right)^m \leq 6\times 10^{-4} , \tag{10.60}$$

and so by Rouché's theorem, $q(z)$ and $b(z)$ have the same number of zeros in $|z| \le 0.62$, namely 1. Since $q(z)$ has real coefficients, its zero is real. This establishes the existence of x_0. An easy computation shows that $q(0.57) > 0$, $q(0.58) < 0$, so $0.57 < x_0 < 0.58$.

To show that $p(x_0) > 0$, note that successive summands in (10.55) decrease in absolute magnitude for each fixed real $z > 0$, and $p(z) > 1 - z^2/(1-z) > 0$ for $0 < z < 0.6$. ■

The method used in the above example is widely applicable to generating functions given by continued fractions. Typically they are meromorphic in a disk centered at the origin, with a single dominant pole of order 1. Usually there is no convenient representation of the form (10.54) with explicit $p(z)$ and $q(z)$, and one has to work harder to establish the necessary properties about location of poles.

It was mentioned in Section 6.4 that unimodality of a sequence is often deduced from information about the zeros of the associated polynomial. If the zeros of the polynomial

$$A(z) = \sum_{k=0}^{n} a_k z^k$$

are real and ≤ 0, then the a_k are unimodal, and even the $a_k \binom{n}{k}^{-1}$ are log-concave. However, weaker properties follow from weaker assumptions on the zeros. If all the zeros of $A(z)$ are in the wedge-shaped region centered on the negative real axis $|\mathrm{Arg}(-z)| \le \pi/4$, and the a_k are real, then the a_k are log-concave, but the $a_k \binom{n}{k}^{-1}$ are not necessarily log-concave. (This follows by factoring $A(z)$ into polynomials with real coefficients that are either linear or quadratic, and noting that all have log-concave coefficients, so their product does too.) One can prove other results that allow zeros to lie in larger regions, but then it is necessary to impose restrictions on ratios of their distances from the origin.

10.5. Implicit functions

Section 6.2 presented functions, such as $f^{\langle -1 \rangle}(z)$, that are defined implicitly. In this section we consider related problems that arise when a generating function $f(z)$ satisfies a functional equation $f(z) = G(z, f(z))$. Such equations arise frequently in graphical enumeration, and there is a standard procedure invented by Pólya and developed by Otter that is almost algorithmic [188, 189] and routinely leads to them. Typically $G(z, w)$ is analytic in z and w in a small neighborhood of $(0, 0)$. Zeros of analytic functions in more than one dimension are not isolated, and by the implicit function theorem $G(z, w) = w$ is solvable for w as a function of

z, except for those points where

$$G_w(z,w) = \frac{\partial}{\partial w} G(z,w) = 1 \ . \tag{10.61}$$

Usually for z in a small neighborhood of 0 the solution w of $G(z,w) = w$ will not satisfy (10.61), and so w will be analytic in that neighborhood. As we enlarge the neighborhood under consideration, though, a simultaneous solution to $G(z,w) = w$ and (10.61) will eventually appear, and will usually be the dominant singularity of $f(z) = w(z)$. The following theorem covers many common enumeration problems.

Theorem 10.6. *Suppose that*

$$f(z) = \sum_{n=1}^{\infty} f_n z^n \tag{10.62}$$

is analytic at $z = 0$, that $f_n \geq 0$ for all n, and that $f(z) = G(z, f(z))$, where

$$G(z,w) = \sum_{m,n \geq 0} g_{m,n} z^m w^n \ . \tag{10.63}$$

Suppose that there exist real numbers $\delta, r, s > 0$ such that

(i) $G(z,w)$ is analytic in $|z| < r + \delta$ and $|w| < s + \delta$,

(ii) $G(r,s) = s$, $G_w(r,s) = 1$,

(iii) $G_z(r,s) \neq 0$ and $G_{ww}(r,s) \neq 0$.

Suppose that $g_{m,n} \in \mathbb{R}^+ \cup \{0\}$ for all m and n, $g_{0,0} = 0$, $g_{0,1} = 1$, and $g_{m,n} > 0$ for some m and some $n \geq 2$. Assume further that there exist $h > j > i \geq 1$ such that $f_h f_i f_j \neq 0$ while the greatest common divisor of $j - i$ and $h - i$ is 1. Then $f(z)$ converges at $z = r$, $f(r) = s$, and

$$f_n = [z^n] f(z) \sim (r G_z(r,s)/(2\pi G_{ww}(r,s)))^{1/2} n^{-3/2} r^{-n} \quad \text{as} \quad n \to \infty \ . \tag{10.64}$$

Example 10.8. *Rooted labeled trees.* As was shown in Example 6.1, the exponential generating function $t(z)$ of rooted labeled trees satisfies $t(z) = z \exp(t(z))$. Thus we have $G(z,w) = z \exp(w)$, and Theorem 10.6 is easily seen to apply with $r = e^{-1}$, $s = 1$. Therefore we obtain the asymptotic estimate

$$t_n/n! = [z^n] t(z) \sim (2\pi)^{-1/2} n^{-3/2} e^n \quad \text{as} \quad n \to \infty \ . \tag{10.65}$$

On the other hand, from Example 6.6 we know that $t_n = n^{n-1}$, a much more satisfactory answer, so that the estimate (10.65) only provides us with another proof of Stirling's formula. ■

The example above involves an extremely simple application of Theorem 10.6. More complicated cases will be presented in Section 15.1.

The statement of Theorem 10.6 is long, and the hypotheses stringent. All that is really needed for the asymptotic relation (10.64) to hold is that $f(z)$ should be analytic on $\{z : |z| \leq r, z \neq r\}$ and that

$$f(z) = c(r-z)^{1/2} + o(|r-z|^{1/2}) \tag{10.66}$$

for $|z-r| \leq \epsilon$, $|\mathrm{Arg}(r-z)| \geq \pi/2 - \epsilon$ for some $\epsilon > 0$. If these conditions are satisfied, then (10.64) follows immediately from either the transfer theorems of Section 11.1 or (with stronger hypotheses) from Darboux's method of Section 11.2. The purpose of Theorem 10.6 is to present a general theorem that guarantees (10.66) holds, is widely applicable, and is stated to the maximum extent possible in terms of conditions on the coefficients of $f(z)$ and $G(z,w)$.

Theorem 10.6 is based on Theorem 5 of [33] and Theorem 1 of [284]. The hypotheses of Theorem 5 of [33] are simpler than those of Theorem 10.6, but, as was pointed out by Canfield [67], the proof is faulty and there are counterexamples to the claims of that theorem. The difficulty is that Theorem 5 of [33] does not distinguish adequately between the different solutions $w = w(z)$ of $w = G(z,w)$, and the singularity of the combinatorially significant solution may not be the smallest among all singularities of all solutions. The result of Meir and Moon [284] provides conditions that assure such pathological behavior does not occur. (The statement of Theorem 10.6 incorporates some corrections to Theorem 1 of [284] provided by the authors of that paper.) It would be desirable to prove results like (10.64) under a simpler set of conditions.

In many problems the function $G(z,w)$ is of the form

$$G(z,w) = g(z)\phi(w) + h(z) \ , \tag{10.67}$$

where $g(z)$, $\phi(w)$, and $h(z)$ are analytic at 0. For this case Meir and Moon have proved a useful result (Theorem 2 of [284]) that implies an asymptotic estimate of the type (10.64). The hypotheses of that result are often easier to verify than those of Theorem 10.6 above. (As was noted by Meir and Moon, the last part of the conditions (4.12a) of [284] has to be replaced by the condition that $y_i > h_i$, $y_j > h_j$, and $y_k > h_k$ for some $k > j > i \geq 1$ with $\gcd(j-i, k-i) = 1$.)

Whenever Theorem 10.6 applies, $f_n = [z^n]f(z)$ equals the quantity on the right-hand side of (10.64) to within a multiplicative factor of $1 + O(n^{-1})$. One can derive fuller expansions for

the ratio when needed.

11. Small singularities of analytic functions

In most combinatorial enumeration applications, the generating function has a single dominant singularity. The methods used to extract asymptotic information about coefficients split naturally into two main classes, depending on whether this singularity is large or small.

In some situations the same generating function can be said to have either a large or a small singularity, depending on the range of coefficients that we are interested in. This is illustrated by the following example.

Example 11.1. *Partitions with bounded part sizes.* Let $p(n,m)$ be the number of (unordered) partitions of an integer n into integers $\le m$. It is easy to see that

$$P_m(z) = \sum_{n=0}^{\infty} p(n,m) z^n = \prod_{k=1}^{m} (1-z^k)^{-1} \ . \tag{11.1}$$

The function $P_m(z)$ is rational, but has to be treated in different ways depending on the relationship of n and m. If n is large compared to m, it turns out to be appropriate to say that $P_m(z)$ has a small singularity, and use methods designed for this type of problems. However, if n is not too large compared to m, then the singularity of $P_m(z)$ can be said to be large. (Since the largest part in a partition of n is almost always $O(n^{1/2}\log n)$ [105], $p(n,m) \sim p(n)$ if m is much larger than $n^{1/2}\log n$.)

Although $P_m(z)$ has singularities at all the k-th roots of unity for all $k \le m$, $z=1$ is clearly the dominant singularity, as $|P_m(r)|$ grows much faster as $r \to 1^-$ than $|P_m(z)|$ for $z = r\exp(i\theta)$ for any $\theta \in (0, 2\pi)$. If m is fixed, then the partial function decomposition can be used to obtain the asymptotics of $p(n,m)$ as $m \to \infty$. We cannot use Theorem 9.1 directly, since the pole of $P_m(z)$ at $z=1$ has multiplicity 1. However, either by using the generalizations of Theorem 9.1 that are mentioned in Section 9.1, or by the subtraction of singularities principle, we can show that for any fixed m,

$$p(n,m) \sim [z^n] \left(\prod_{k=1}^{m} k! \right)^{-1} (1-z)^{-m} \sim \left(\prod_{k=1}^{m} k! \right)^{-1} ((m-1)!)^{-1} \quad \text{as} \quad n \to \infty \ . \tag{11.2}$$

(See [23] for further details and estimates.) This approach can be extended for m growing slowly with n, and it can be shown without much effort that the estimate (11.2) holds for $n \to \infty$, $m \le \log\log n$, say. However, for larger values of m this approach becomes cumbersome, and other methods, such as those of Section 12, are necessary. ■

11.1. Transfer theorems

This section presents some results, drawn from [135], that allow one to translate an asymptotic expansion of a generating function around its dominant singularity into an asymptotic expansion for the coefficients in a direct way. These results are useful in combinatorial enumeration, since the conditions for validity are frequently satisfied. The proofs, which we do not present here, are based on the subtraction of singularities principle, but are more involved than in the cases treated in Section 10.2.

We start out with an application of the results to be presented later in this section.

Example 11.2. *2-regular graphs.* The generating function for 2-regular graphs is known [81] to be

$$f(z) = (1-z)^{-1/2} \exp\left(-\frac{1}{2}z - \frac{1}{4}z^2\right) \ . \tag{11.3}$$

(A simpler proof can be obtained from the exponential formula, cf. Eq. (3.9.1) of [377].) We see that $f(z)$ is analytic throughout the complex plane except for the slit along the real axis from 1 to ∞, and that near $z = 1$ it has the asymptotic expansion

$$f(z) = e^{-3/4}\left\{(1-z)^{-1/2} + (1-z)^{1/2} + \frac{1}{4}(1-z)^{3/2} + \cdots\right\} \ . \tag{11.4}$$

Theorem 11.1 below then shows that as $n \to \infty$,

$$\begin{aligned}[z^n]f(z) &\sim e^{-3/4}\left\{\binom{n-1/2}{n} + \binom{n-3/2}{n} + \frac{1}{4}\binom{n-5/2}{n} + \cdots\right\} \\ &\sim \frac{e^{-3/4}}{\sqrt{\pi n}}\left\{1 - \frac{5}{8n} - \frac{15}{128n^2} + \cdots\right\} \ . \quad \blacksquare \end{aligned} \tag{11.5}$$

The basic transfer results will be presented for generating functions that have a single dominant singularity, but can be extended substantially beyond their circle of convergence. For r, $\eta > 0$, and $0 < \phi < \pi/2$, we define the closed domain $\Delta = \Delta(r, \phi, \eta)$ by

$$\Delta(r, \phi, \eta) = \{z : \ |z| \le r + \eta, \ |\mathrm{Arg}(z - r)| \ge \phi\} \ . \tag{11.6}$$

In the main result below we will assume that a generating function is analytic throughout $\Delta \setminus \{r\}$. Later in this section we will mention some results that dispense with this requirement. We will also explain why analyticity throughout $\Delta \setminus \{r\}$ is helpful in obtaining results such as those of Theorem 11.1 below.

One advantage to using Cauchy's theorem to recover information about coefficients of generating functions is that it allows one to prove the intuitively obvious result that small smooth

changes in the generating function correspond to small smooth changes in the coefficients. We will use the quantitative notion of a function of slow variation at ∞ to describe those functions for which this notion can be made precise. (With more effort one can prove that the same results hold with a less restrictive definition than that below.)

Definition 11.1. *A function $L(u)$ is of slow variation at ∞ if*

i) There exist real numbers u_0 and ϕ_0 with $u_0 > 0$, $0 < \phi_0 < \pi/2$, such that $L(u)$ is analytic and $\neq 0$ in the domain

$$\{u : \ |\mathrm{Arg}(u - u_0)| \leq \pi - \phi_0\} \ . \tag{11.7}$$

ii) There exists a function $\epsilon(x)$, defined for $x \geq 0$ with $\lim_{x\to\infty} \epsilon(x) = 0$, such that for all $\theta \in [-(\pi - \phi_0), \pi - \phi_0]$ and $u \geq u_0$, we have

$$\left| \frac{L(ue^{i\theta})}{L(u)} - 1 \right| \ < \ \epsilon(u) \tag{11.8}$$

and

$$\left| \frac{L(u \log^2 u)}{L(u)} - 1 \right| \ < \ \epsilon(u) \ . \tag{11.9}$$

Theorem 11.1. *Assume that $f(z)$ is analytic throughout the domain $\Delta \setminus \{r\}$, where $\Delta = \Delta(r, \phi, \eta)$, $r, \eta > 0$, $0 < \phi < \pi/2$, and that $L(u)$ is a function of slow variation at ∞. If α is any real number, then*

A) If

$$f(z) = O\left((z - r)^{\alpha} L\left(\frac{1}{r - z} \right) \right)$$

uniformly for $z \in \Delta \setminus \{r\}$, then

$$[z^n] f(z) = O(r^{-n} n^{-\alpha - 1} L(n)) \quad as \quad n \to \infty \ .$$

B) If

$$f(z) = o\left((z - r)^{\alpha} L\left(\frac{1}{r - z} \right) \right)$$

uniformly as $z \to r$ for $z \in \Delta \setminus \{r\}$, then

$$[z^n] f(z) = o(r^{-n} n^{-\alpha - 1} L(n)) \quad as \quad n \to \infty \ .$$

C) If $\alpha \notin \{0, 1, 2, \ldots\}$ *and*

$$f(z) \sim (r - z)^{\alpha} L\left(\frac{1}{r - z}\right)$$

uniformly as $z \to r$ *for* $z \in \Delta \setminus \{r\}$*, then*

$$[z^n] f(z) \sim \frac{r^{-n} n^{-\alpha - 1}}{\Gamma(-\alpha)} L(n) \ .$$

The restriction that there be only one singularity on the circle of convergence is easy to relax. If there are several (corresponding to oscillatory behavior of the coefficients), their contributions to the coefficients add. The crucial fact is that at each singularity the function $f(z)$ should be continuous except for an angular region similar to that of $\Delta(r, \phi, \eta)$.

The requirement that the generating function $f(z)$ be analytic in the interior of $\Delta(r, \phi, \eta)$ is in general harder to dispense with, at least by the methods of [135]. However, if the singularity at r is sufficiently large, one can obtain the same results with weaker assumptions that only require analyticity inside the disk $|z| < r$. The following result is implicit in [135].

Theorem 11.2. *Assume that* $f(z)$ *is analytic in the domain*$\{z : |z| \le r, z \ne r\}$ *and that* $L(u)$ *is a function of slow variation at* ∞*. If* α *is any fixed real number with* $\alpha < -1$*, then the implications A), B), and C) of Theorem 11.1 are valid.*

Example 11.3. *Longest cycle in a random permutation.* The average length of the longest cycle in a permutation on n letters is $[z^n] f(z)$, where

$$f(z) = (1 - z)^{-1} \sum_{k \ge 0} \left[1 - \exp\left(- \sum_{j \ge k} j^{-1} z^j \right) \right] \ .$$

It is easy to see that $f(z)$ is analytic in $|z| < 1$, and a double application of the Euler-Maclaurin summation formula shows that $f(z) \sim G(1 - z)^{-2}$ as $z \to 1$, uniformly for $|z| \le 1$, $z \ne 1$, where

$$G = \int_0^{\infty} \left[1 - \exp\left(- \int_x^{\infty} t^{-1} e^{-t} dt \right) \right] dx = 0.624 \ldots \ . \tag{11.10}$$

Therefore, by Theorem 11.2 with $L(u) = 1$,

$$[z^n] f(z) \sim Gn \quad \text{as} \quad n \to \infty \ , \tag{11.11}$$

a result first proved by Shepp and Lloyd [342] using Poisson approximations and Tauberian theorems. The derivation sketched above follows [134, 135]. The paper [134] contains many

other applications of transfer theorems to random mapping problems. Additional recent papers on the cycle structure of random permutations are [19, 187]. They use probabilistic methods, not transfer theorems, and contain extensive references to other recent works. ■

In applying transfer theorems, it is useful to have explicit expansions and estimates for the coefficients of some frequently occurring functions. We state several asymptotic series:

$$[z^n](1-z)^\alpha \approx \frac{n^{-\alpha-1}}{\Gamma(-\alpha)}\left(1+\sum_{k\geq 1} e_k^{(\alpha)} n^{-k}\right), \quad \alpha \neq 0,1,2,\ldots, \tag{11.12}$$

where

$$e_k^{(\alpha)} = \sum_{j=k}^{2k} (-1)^j \lambda_{k,j} (\alpha+1)(\alpha+2)\cdots(\alpha+j)\ , \tag{11.13}$$

and the $\lambda_{k,j}$ are determined by

$$e^t(1+vt)^{-1-1/v} = \sum_{k,j\geq 0} \lambda_{k,j} v^k t^j\ . \tag{11.14}$$

In particular,

$$\begin{aligned} e_1^{(\alpha)} &= \alpha(\alpha+1)/2, \\ e_2^{(\alpha)} &= \alpha(\alpha+1)(\alpha+2)(3\alpha+1)/24\ . \end{aligned}$$

Also, for $\alpha, \beta \notin \{0,1,2,\ldots\}$,

$$[z^n](1-z)^\alpha(-z^{-1}\log(1-z))^\beta \approx \frac{n^{-\alpha-1}}{\Gamma(-\alpha)}(\log n)^\beta\left(1+\sum_{k\geq 1} e_k^{(\alpha,\beta)}(\log n)^{-k}\right)\ , \tag{11.15}$$

where

$$e_k^{(\alpha,\beta)} = (-1)^k\binom{\beta}{k}\Gamma(-\alpha)\left(\frac{d^k}{ds^k}\Gamma(-s)^{-1}\Big|_{s=\alpha}\right)\ . \tag{11.16}$$

Further examples of asymptotic expansions are presented in [135].

Why is the analyticity of a function $f(z)$ throughout $\Delta(r,\phi,\eta)\setminus\{r\}$ so important? We explain this using as an example a function $f(z)$ that satisfies

$$f(z) = (1+o(1))(1-z)^{1/2} \tag{11.17}$$

as $z\to 1$ with $z\in\Delta=\Delta(1,\pi/8,1)$. We write

$$f(z) = (1-z)^{1/2} + g(z)\ , \tag{11.18}$$

so that

$$|g(z)| = o(|1-z|^{1/2}) \ . \tag{11.19}$$

Since $[z^n](1-z)^{1/2}$ grows like $n^{-3/2}$, we would like to show that

$$|[z^n]g(z)| = o(n^{-3/2}) \quad \text{as} \quad n \to \infty \ . \tag{11.20}$$

If $g(z)$ were analytic in a disk of radius $1+\delta$ for some $\delta > 0$, then we could conclude that $|[z^n]g(z)| < (1+\delta/2)^{-n}$ for large n, a conclusion much stronger than (11.20). However, if all we know is that $g(z)$ satisfies (11.19) in $|z| \le 1$, then we can only conclude from Cauchy's theorem that $[z^n]g(z) = O(1)$, since (11.19) implies that $|g(z)| \le C$ for all $|z| < 1$ and some $C > 0$. Then Theorem 10.2 gives

$$|[z^n]g(z)| \le Cr^{-n} \tag{11.21}$$

uniformly for all $n \ge 0$ and all $r < 1$, and hence $|[z^n]g(z)| \le C$ for all n, a result that is far from what is required. If we know that $g(z)$ can be continued to $\Delta \setminus \{r\}$ and satisfies (11.19) there, we can do a lot better. We choose the contour $\Gamma = \Gamma_1 \cup \Gamma_2 \cup \Gamma_3 \cup \Gamma_4$, pictured in Fig. 1, with

$$\Gamma_1 = \{z : \ |z-1| = 1/n, \ |\mathrm{Arg}(z-1)| \ge \pi/4\} \ , \tag{11.22}$$

$$\Gamma_2 = \{z : \ z = 1 + r\exp(\pi i/4), \ 1/n \le r \le \delta\} \ , \tag{11.23}$$

$$\Gamma_3 = \{z : \ |z| = |1+\delta\exp(\pi i/4)|, \ |\mathrm{Arg}(z-1)| \ge \pi/4\} \ , \tag{11.24}$$

$$\Gamma_4 = \{z : \ z = 1 + r\exp(-\pi i/4), \ 1/n \le r \le \delta\} \ , \tag{11.25}$$

where $0 < \delta < 1/2$. We will show that the integrals

$$g_j = \frac{1}{2\pi i}\int_{\Gamma_j} g(z) z^{-n-1} dz \tag{11.26}$$

on the Γ_j are small. On Γ_3, $g(z)$ is bounded, so we trivially obtain the exponential upper bound

$$|g_3| = O((1+\delta/2)^{-n}) \ . \tag{11.27}$$

On Γ_1, $|g(z)| = o(n^{-1/2})$, $|z^{-n-1}| \le (1-1/n)^{-n-1} = O(1)$, and the length of Γ_1 is $\le 2\pi/n$, so

$$|g_1| = o(n^{-3/2}) \quad \text{as} \quad n \to \infty \ . \tag{11.28}$$

Next, on Γ_2, for $z = 1 + r\exp(\pi i/4)$,

$$\begin{aligned} |z|^{-n} &= |1 + r2^{-1/2} + ir2^{-1/2}|^{-n} = (1 + r2^{1/2} + r^2)^{-n/2} \\ &\le (1+r)^{-n/2} \le \exp(-nr/10) \end{aligned} \tag{11.29}$$

for $0 \le r < 1$. Since $g(z)$ satisfies (11.19), for any $\epsilon > 0$ we have

$$|g(1 + r\exp(\pi i/4))| \le \epsilon r^{1/2} \tag{11.30}$$

if $0 < r \le \eta$ for some $\eta = \eta(\epsilon) \le \delta$. Therefore

$$\begin{aligned} |g_2| &\le \epsilon \int_0^\eta r^{1/2} \exp(-nr/10) dr + O\left(\int_\eta^\infty \exp(-nr/10) dr \right) \\ &\le \epsilon n^{-3/2} \int_0^\infty r^{1/2} \exp(-r/10) dr + O(\exp(-n\eta/10)) \ , \end{aligned} \tag{11.31}$$

and so

$$|g_2| = o(n^{-3/2}) \ . \tag{11.32}$$

Since $|g_4| = |g_2|$, inequalities (11.27), (11.28), and (11.32) show that (11.20) holds.

The critical factor in the derivation of (11.20) was the bound for (11.29) for $|z|^{-n}$ on the segment $z = 1 + r\exp(\pi i/4)$. Integrating on the circle $|z| = 1$ or even on the line $\mathrm{Re}\,(z) = 1$ does not give a bound for $|z|^{-n}$ that is anywhere as small, and the resulting bounds do not approach (11.20) in strength. The use of the circular arc Γ_1 in the integral is only a minor technical device used to avoid the singularity at $z = 1$.

When one cannot continue a function to a region like $\Delta \setminus \{1\}$, it is sometimes possible to obtain good estimates for coefficients by working with the generating function exclusively in $|z| \le 1$, provided some smoothness properties apply. This method is outlined in the next section.

11.2. Darboux's theorem and other methods

A singularity of $f(z)$ at $z = w$ is called algebraic if $f(z)$ can be written as the sum of a function analytic in a neighborhood of w and a finite number of terms of the form

$$(1 - z/w)^\alpha g(z) \ , \tag{11.33}$$

where $g(z)$ is analytic near w, $g(w) \ne 0$, and $\alpha \notin \{0, 1, 2, \ldots\}$. Darboux's theorem [87] gives asymptotic expansions for functions with algebraic singularities on the circle of convergence. We state one form of Darboux's result, derived from Theorem 8.4 of [354].

Theorem 11.3. *Suppose that $f(z)$ is analytic for $|z| < r$, $r > 0$, and has only algebraic singularities on $|z| = r$. Let a be the minimum of $Re\,(\alpha)$ for the terms of the form (11.33) at*

the singularities of $f(z)$ *on* $|z| = r$*, and let* w_j*,* α_j*, and* $g_j(z)$ *be the* w*,* α*, and* $g(z)$ *for those terms of the form (11.33) for which* $Re(\alpha) = a$*. Then, as* $n \to \infty$*,*

$$[z^n]f(z) - \sum_j \frac{g_j(w_j)n^{-\alpha_j-1}}{\Gamma(-\alpha_j)w_j^n} + o(r^{-n}n^{-a-1}) \ . \tag{11.34}$$

Jungen [219] has extended Darboux's theorem to functions that have a single dominant singularity which is of a mixed algebraic and logarithmic form. His method can be applied also to functions that have several such singularities on their circle of convergence.

We do not devote much attention to Darboux's and Jungen's theorems because they can be obtained from the transfer theorems of Section 11.1. The only reason for stating Theorem 11.3 is that it occurs frequently in the literature.

Some functions, such as

$$f(z) = \prod_{k=1}^{\infty}(1 + z^k/k^2) \ , \tag{11.35}$$

are analytic in $|z| \leq 1$, cannot be continued outside the unit circle, yet are nicely behaved on $|z| = 1$. Therefore there is no dominant singularity that can be studied to determine the asymptotics of $[z^n]f(z)$. To minimize the size of the integrand, it is natural to move the contour of integration in Cauchy's formula to the unit circle. Once that is done, it is possible to exploit smoothness properties of $f(z)$ to bound the coefficients. The Riemann-Lebesgue lemma implies that if $f(z)$ is integrable on the unit circle, then as $n \to \infty$,

$$[z^n]f(z) = (2\pi)^{-1}\int_{-\pi}^{\pi} f(e^{i\theta})\exp(-ni\theta)d\theta = o(1) \ . \tag{11.36}$$

More can be said if the derivative of $f(z)$ exists on the unit circle. When we apply integration by parts to the integral in (11.36), we find

$$[z^n]f(z) = (2\pi n)^{-1}\int_{-\pi}^{\pi} f'(e^{i\theta})\exp(-(n-1)i\theta)d\theta \ , \tag{11.37}$$

and so $|[z^n]f(z)| = o(n^{-1})$ if $f'(z)$ exists and is integrable on the unit circle. Existence of higher derivatives leads to even better estimates. We do not attempt to state a general theorem, but illustrate an application of this method with an example. The same technique can be used in other situations, for example in obtaining better error terms in Darboux's theorem [87].

Example 11.4. *Permutations with distinct cycle lengths.* Example 8.5 showed that for the function $f(z)$ defined by Eq. (8.58), $[z^n]f(z) \sim \exp(-\gamma)$ as $n \to \infty$. This coefficient is the probability that a random permutation on n letters has distinct cycle lengths. The more precise

estimate (8.59) was derived by Greene and Knuth [177] by working with recurrences for the coefficients of $f(z)$ and auxiliary functions. Another approach to deriving fuller asymptotic expansions for $[z^n]f(z)$ is to use the method outlined above. It suffices to show that the function $g(z)$ defined by Eq. (8.62) has a nice expansion in the closed disk $|z| \leq 1$. Since

$$g(z) = -z + \sum_{m=2}^{\infty} \frac{(-1)^{m-1}}{m} \{\mathrm{Li}_m(z^m) - z^m\} \ , \tag{11.38}$$

where the $\mathrm{Li}_m(w)$ are the polylogarithm functions [251], one can use the theory of the $\mathrm{Li}_m(w)$. A simpler way to proceed is to note, for example, that

$$\sum_{k=2}^{\infty} \frac{z^{2k}}{k^2} = \sum_{k=2}^{\infty} \frac{z^{2k}}{k(k-1)} + r(z) \ , \tag{11.39}$$

where

$$r(z) = -\sum_{k=2}^{\infty} \frac{z^{2k}}{k^2(k-1)} \ , \tag{11.40}$$

and so $r'(z)$ is bounded and continuous for $|z| \leq 1$, as are the terms in (8.62) with $m \geq 3$. On the other hand,

$$\sum_{k=2}^{\infty} \frac{z^{2k}}{k(k-1)} = z^2 + (1-z^2)\log(1-z^2) \ , \tag{11.41}$$

so we can write $g(z) = g_1(z) + g_2(z)$, where $g_1(z)$ is an explicit function (given by Eq. (11.41)) such that the coefficients of $\exp(g_1(z))$ can be estimated asymptotically using transfer methods or other techniques, and $g_2(z)$ has the property that $g_2'(z)$ is bounded and continuous in $|z| \leq 1$. Continuing this process, we can find, for every K, an expansion for the coefficients of $f(z)$ that has error term $O(n^{-K})$. To do this, we write $g(z) = G_1(z) + G_2(z)$. In this expansion $G_1(z)$ will be explicitly given and analytic inside $|z| < 1$ and analytically continuable to some region that extends beyond the unit disk with the exception of cuts from a finite number of points on the unit circle out to infinity. Further, $G_2(z)$ will have the property that $G_2^{(K)}(z)$ is bounded and continuous in $|z| \leq 1$. This will then give the desired expansion for the coefficients of $f(z)$. ■

12. Large singularities of analytic functions

This section presents methods for asymptotic estimation of coefficients of generating functions whose dominant singularities are large.

12.1. The saddle point method

The saddle point method, also referred to as the method of steepest descent, is by far the most useful method for obtaining asymptotic information about rapidly growing functions. It is extremely flexible and has been applied to a tremendous variety of problems. It is also complicated, and there is no simple categorization of situations where it can be applied, much less of the results it produces. Given the purpose and limitations on the length of this chapter, we do not present a full discussion of it. For a complete and insightful introduction to this technique, the reader is referred to [63]. Many other books, such as [110, 115, 315, 385] also have extensive presentations. What this section does is to outline the method, show when and how it can be applied and what kinds of estimates it produces. Examples of proper and improper applications of the method are presented. Later subsections are then devoted to general results obtained through applications of the saddle point method. These results give asymptotic expansions for wide classes of functions without forcing the reader to go through the details of the saddle point method.

The saddle point method is based on the freedom to shift contours of integration when estimating integrals of analytic functions. The same principle underlies other techniques, such as the transfer method of Section 11.1, but the way it is applied here is different. When dealing with functions of slow growth near their principal singularity, as happens for transfer methods, one attempts to push the contour of integration up to and in some ways even beyond the singularity. The saddle point method is usually applied when the singularity is large, and it keeps the path of integration close to the singularity.

In the remainder of this section we will assume that $f(z)$ is analytic in $|z| < R \leq \infty$. We will also make the assumption that for some R_0, if $R_0 < r < R$, then

$$\max_{|z|=r} |f(z)| = f(r) \ . \tag{12.1}$$

This assumption is clearly satisfied by all functions with real nonnegative coefficients, which are the most common ones in combinatorial enumeration. Further, we will suppose that $z = r$ is the unique point with $|z| = r$ where the maximum value in (12.1) is assumed. When this assumption is not satisfied, we are almost always dealing with some periodicity in the asymptotics of the coefficients, and we can then usually reduce to the standard case by either changing variables or rewriting the generating function as a sum of several others, as was discussed in Section 10. (Such a reduction cannot be applied to the function of Eq. (9.39),

though.)

The first step in estimating $[z^n]f(z)$ by the saddle point method is to find the saddle point. Under our assumptions, that will be a point $r \in (R_0, R)$ which minimizes $r^{-n}f(r)$. We have encountered this condition before, in Section 8.1. The minimizing $r = r_0$ will usually be unique, at least for large n. (If there are several $r \in (R_0, R)$ for which $r^{-n}f(r)$ achieves its minimum value, then $f(z)$ is pathological, and the standard saddle point method will not be applicable. For functions $f(z)$ with nonnegative coefficients, it is easy to show uniqueness of the minimizing r, as was already discussed in Section 8.1.) Cauchy's formula (10.6) is then applied with the contour $|z| = r_0$. The reason for this choice is that for many functions, on this contour the integrand is large only near $z = r_0$, the contributions from the region near $z = r_0$ do not cancel each other, and remaining regions contribute little. This is in contrast to the behavior of the integrand on other contours. By Cauchy's theorem, any simple closed contour enclosing the origin gives the correct answer. However, on most of them the integrand is large, and there is so much cancellation that it is hard to derive any estimates. The circle going through the saddle point, on the other hand, yields an integral that can be controlled well by techniques related to Laplace's method and the method of stationary phase that were mentioned in Section 5.5. We illustrate with an example, which is a totally self-contained application of the saddle point method to an extremely simple situation.

Example 12.1. *Stirling's formula.* We estimate $(n!)^{-1} = [z^n]\exp(z)$. The saddle point, according to our definition above, is that $r \in \mathbb{R}^+$ that minimizes $r^{-n}\exp(r)$, which is clearly $r = n$. Consider the contour $|z| = n$, and set $z = n\exp(i\theta)$, $-\pi \le \theta \le \pi$. Then

$$\begin{aligned} [z^n]\exp(z) &= \frac{1}{2\pi i}\int_{|z|=n} \frac{\exp(z)}{z^{n+1}}dz \\ &= \frac{1}{2\pi}\int_{-\pi}^{\pi} n^{-n}\exp(ne^{i\theta} - ni\theta)d\theta \ . \end{aligned} \tag{12.2}$$

Since $|\exp(z)| = \exp(\mathrm{Re}(z))$, the absolute value of the integrand in (12.2) is $n^{-n}\exp(n\cos\theta)$, which is maximized for $\theta = 0$. Now

$$e^{i\theta} = \cos\theta + i\sin\theta = 1 - \theta^2/2 + i\theta + O(|\theta|^3) \ ,$$

so for any $\theta_0 \in (0, \pi)$,

$$\int_{-\theta_0}^{\theta_0} n^{-n}\exp(ne^{i\theta} - ni\theta)d\theta = \int_{-\theta_0}^{\theta_0} n^{-n}\exp(n - n\theta^2/2 + O(n|\theta|^3))d\theta \ . \tag{12.3}$$

(It is the cancellation of the $ni\theta$ term coming from $ne^{i\theta}$ and the $-ni\theta$ term that came from change of variables in z^{-n} that is primarily responsible for the success of the saddle point method.) The $O(n|\theta|^3)$ term in (12.3) could cause problems if it became too large, so we will select $\theta_0 = n^{-2/5}$, so that $n|\theta|^3 \le n^{-1/5}$ for $|\theta| \le \theta_0$, and therefore

$$\exp(n - n\theta^2/2 + O(n|\theta|^3)) = \exp(n - n\theta^2/2)(1 + O(n^{-1/5})) \ . \tag{12.4}$$

Hence

$$\int_{-\theta_0}^{\theta_0} n^{-n} \exp(ne^{i\theta} - ni\theta)d\theta = (1 + O(n^{-1/5}))n^{-n}e^n \int_{-\theta_0}^{\theta} \exp(-n\theta^2/2)d\theta \ .$$

But

$$\begin{aligned} \int_{-\theta_0}^{\theta_0} \exp(-n\theta^2/2)d\theta &= \int_{-\infty}^{\infty} \exp(-n\theta^2/2)d\theta - 2\int_{\theta_0}^{\infty} \exp(-n\theta^2/2)d\theta \\ &= (2\pi/n)^{1/2} - O(\exp(-n^{1/5}/2)) \ , \end{aligned}$$

so

$$\int_{-\theta_0}^{\theta_0} n^{-n} \exp(ne^{i\theta} - ni\theta)d\theta = (1 + O(n^{-1/5}))(2\pi/n)^{1/2}n^{-n}e^n \ . \tag{12.5}$$

On the other hand, for $\theta_0 < |\theta| \le \pi$,

$$\cos\theta \le \cos\theta_0 = 1 - \theta_0^2/2 + O(\theta_0^4) \ ,$$

so

$$n\cos\theta \le n - n^{1/5}/2 + O(n^{-3/5}) \ ,$$

and therefore for large n

$$\left| \int_{\theta_0}^{\pi} n^{-n} \exp(ne^{i\theta} - ni\theta)d\theta \right| \le n^{-n} \exp(n - n^{1/5}/3) \ ,$$

and similarly for the integral from $-\pi$ to $-\theta_0$. Combining all these estimates we therefore find that

$$(n!)^{-1} = [z^n] \exp(z) = (1 + O(n^{-1/5}))(2\pi n)^{-1/2}n^{-n}e^n \ , \tag{12.6}$$

which is a weak form of Stirling's formula (4.3). (The full formula can be derived by using more precise expansions for the integrand.)

Suppose we try to push through a similar argument using the contour $|z| = 2n$. This time, instead of Eq. (12.2), we find

$$[z^n] \exp(z) = \frac{1}{2\pi} \int_{-\pi}^{\pi} 2^{-n}n^{-n} \exp(2ne^{i\theta} - ni\theta)d\theta \ . \tag{12.7}$$

At $\theta = 0$, the integrand is $2^{-n}n^{-n}\exp(2n)$, which is $\exp(n)$ times as large as the value of the integrand in (12.2). Since the two integrals do produce the same answer, and from the analysis above we see that this answer is close to $n^{-n}\exp(n)$ in value, the integral in (12.7) must involve tremendous cancellation. That is indeed what we see in the neighborhood of $\theta = 0$. We find that

$$\exp(2ne^{i\theta} - ni\theta) = \exp(2n - n\theta^2 + ni\theta + O(n|\theta|^3)) \ , \tag{12.8}$$

and the $\exp(ni\theta)$ term produces wild oscillations of the integrand even over small ranges of θ. Trying to work with the integral (12.7) and proving that it equals something exponentially smaller than the maximal value of its integrand is not a promising approach. By contrast, the saddle point contour used to produce Eq. (12.2) gives nice behavior of the integrand, so that it can be evaluated. ■

The estimates for $n!$ obtained in Example 10.1 came from a simple application of the saddle point method. The motivation for the choice of the contour $|z| = n$ is provided by the discussion at the end of the example; other choices lead to oscillating integrands that cannot be approximated by a Gaussian, nor by any other nice function. The example above treated only the exponential function, but it is easy to see that this phenomenon is general; a rapidly oscillating term $\exp(ni\alpha)$ for $\alpha \neq 0$ is present unless the contour passes through the saddle point. When we do use this contour, and the Gaussian approximation is valid, we find that for functions $f(z)$ satisfying our assumptions we have the following estimate.

Saddle point approximation

$$[z^n]f(z) \sim (2\pi b(r_0))^{-1/2} f(r_0) r_0^{-n} \quad \text{as} \quad n \to \infty \ , \tag{12.9}$$

where r_0 is the saddle point (where $r^{-n}f(r)$ is minimized, so that $r_0 f'(r_0)/f(r_0) = n$) and

$$b(r) = r\frac{f'(r)}{f(r)} + r^2\frac{f''(r)}{f(r)} - r^2\left(\frac{f'(r)}{f(r)}\right)^2 = r\left(r\frac{f'(r)}{f(r)}\right)' \ . \tag{12.10}$$

Example 12.2. *Bell numbers.* Example 5.4 showed how to estimate the Bell number B_n by elementary methods, starting with the representation (5.38). The exponential generating function

$$B(z) = \sum_{n=0}^{\infty} B_n \frac{z^n}{n!} \tag{12.11}$$

satisfies

$$B(z) = \exp(\exp(z) - 1) \ ,$$

as can be seen from (5.38) or by other methods (cf. [81]). The saddle point occurs at that $r_0 > 0$ that satisfies

$$r_0 \exp(r_0) = n \ , \tag{12.12}$$

and

$$b(r_0) = r_0(1 + r_0) \exp(r_0) \ , \tag{12.13}$$

so the saddle point approximation says that as $n \to \infty$,

$$B_n \sim n!(2\pi r_0^2 \exp(r_0))^{-1/2} \exp(\exp(r_0) - 1) r_0^{-n} \ . \tag{12.14}$$

The saddle point approximation can be justified even more easily than for the Stirling estimate of $n!$. ■

The above approximation is widely applicable and extremely useful, but care has to be exercised is applying it. This is shown by the next example.

Example 12.3. *Invalid application of the saddle point method.* Consider the trivial example $f(z) = (1 - z)^{-1}$, so that $[z^n]f(z) = 1$ for all $n \geq 0$. Then $f'(r)/f(r) = (1 - r)^{-1}$, and so the saddle point is $r_0 = n/(n + 1)$, and $b(r_0) = r_0/(1 - r_0)^2 = n(n + 1)$. Therefore if the approximation (12.9) were valid, it would give

$$\begin{aligned} [z^n]f(z) &\sim (2\pi n(n+1))^{-1/2}(n+1)\left(1 + \frac{1}{n}\right)^n \\ &\sim (2\pi)^{-1/2} e \quad \text{as} \quad n \to \infty \ . \end{aligned} \tag{12.15}$$

Since $(2\pi)^{-1/2} e = 1.0844\ldots \neq 1 = [z^n]f(z)$, something is wrong, and the estimate (12.9) does not apply to this function. ■

The estimate (12.9) gave the wrong result in Example 12.3 because the Gaussian approximation on the saddle point method contour used so effectively in Example 12.1 (and in almost all cases where the saddle point method applies) does not hold over a sufficiently large region for $f(z) = (1 - z)^{-1}$. In Example 12.1 we used without detailed explanation the choice $\theta_0 = n^{-2/5}$, which gave the approximation (12.5) for $|\theta| \leq \theta_0$, and yet led to an estimate for the integral over $\theta_0 < |\theta| \leq \pi$ that was negligible. This was possible because the third order term

(i.e., $n|\theta|^3$) in Eq. (12.5) was small. When we try to imitate this approach for $f(z) = (1-z)^{-1}$, we fail, because the third order term is too large. Instead of $ne^{i\theta} - ni\theta$, we now have

$$-\log(1 - r_0 e^{i\theta}) - ni\theta = -\log(1 - r_0) - \frac{1}{2}n(n+1)\theta^2 - \frac{i}{6}n^2(n+1)\theta^3 + \cdots . \tag{12.16}$$

More fundamentally, the saddle point method fails here because the function $f(z) = (1-z)^{-1}$ does not have a large enough singularity at $z = 1$, so that when one traverses the saddle point contour $|z| = r_0$, the integrand does not drop off rapidly enough for a small region near the real axis to provide the dominant contribution.

When can one apply the saddle point approximation (12.9)? Perhaps the simplest, yet still general, set of sufficient conditions for the validity of (12.9) is provided by requiring that the function $f(z)$ be Hayman-admissible. Hayman admissibility is described in Definition 12.1, in the following subsection. Generally speaking, though, for the saddle point method to apply we need the function $f(z)$ to have a large dominant singularity at R, so that $f(r)$ grows at least as fast as $\exp((\log(R-r))^2)$ as $r \to R^-$ for $R < \infty$, and as fast as $\exp((\log r)^2)$ as $r \to \infty$ for $R = \infty$. The faster the growth rate, the easier it usually is to apply the method, so that $\exp(1/(1-z))$ or $\exp(\exp(1/(1-z)))$ can be treated easily.

In our application of the saddle point method to $\exp(z)$ in Example 12.1 we were content to obtain a poor error term, $1 + O(n^{-1/5})$, in Stirling's formula for $n!$. This was done to simplify the presentation and concentrate only on the main factors that make the saddle point method successful. With more care devoted to the integral one can obtain the full asymptotic expansion of $n!$. (Only the range $|\theta| \le \theta_0$ has to be considered carefully.) This is usually true when the saddle point method is applicable.

This section provided a sketchy introduction to the saddle point method. For a much more thorough presentation, including a discussion of the topographical view of the integrand and the "hill-climbing" interpretation of the contour of integration, see [63].

12.2. Admissible functions

The saddle point method is a powerful and flexible tool, but in its full generality it is often cumbersome to apply. In many situations it is possible to apply general theorems derived using the saddle point method that give asymptotic approximations that are not the sharpest possible, but which allow one to avoid the drudgery of applying the method step by step. The general theorems that we present were proved by Hayman [204] and by Harris and Schoenfeld

[198]. We next describe the classes of functions to which these theorems apply, and then present the estimates one obtains for them. It is not always easy to verify that these definitions hold, but it is almost always easier to do this than to apply the saddle point method from scratch. It is worth mentioning, furthermore, that for many generating functions, there are conditions that guarantee that they satisfy the hypotheses of the Hayman and the Harris-Schoenfeld theorems. These conditions are discussed later in this section.

The definition below is stated somewhat differently than the original one in [204], but can be shown to be equivalent to it.

Definition 12.1. *A function*

$$f(z) \;=\; \sum_{n=0}^{\infty} f_n z^n \tag{12.17}$$

is admissible in the sense of Hayman (or H-admissible) if

i) $f(z)$ *is analytic in* $|z| < R$ *for some* $0 < R \leq \infty$,

ii) $f(z)$ *is real for* z *real,* $|z| < R$,

iii) for $R_0 < r < R$,

$$\max_{|z|=r} |f(z)| \;=\; f(r)\;, \tag{12.18}$$

iv) for

$$a(r) \;=\; r\,\frac{f'(r)}{f(r)}\;, \tag{12.19}$$

$$b(r) \;=\; ra'(r) \;=\; r\,\frac{f'(r)}{f(r)} + r^2\frac{f''(r)}{f(r)} - r^2\left(\frac{f'(r)}{f(r)}\right)^2\;, \tag{12.20}$$

and for some function $\delta(r)$, *defined in the range* $R_0 < r < R$ *to satisfy* $0 < \delta(r) < \pi$, *the following three conditions hold:*

$$a) \quad f(re^{i\theta}) \sim f(r)\;\exp(i\theta a(r) - \theta^2 b(r)/2)$$
$$\text{as } r \to R \text{ uniformly for } |\theta| < \delta(r), \tag{12.21}$$

$$b) \qquad f(re^{i\theta}) \;=\; o(f(r)b(r)^{-1/2})$$
$$\text{as } r \to R \text{ uniformly for } |\theta| < \delta(r), \tag{12.22}$$

$$c) \qquad b(r) \to \infty \quad \text{as} \quad r \to R. \tag{12.23}$$

For H-admissible functions, Hayman [204] proved a basic result that gives the asymptotics of the coefficients.

Theorem 12.1. *If $f(z)$, defined by Eq. (12.17), is H-admissible in $|z| < R$, then*

$$f_n = (2\pi b(r))^{-1/2} f(r) r^{-n} \left\{ \exp\left(-\frac{(a(r)-n)^2}{b(r)} \right) + o(1) \right\} \tag{12.24}$$

as $r \to R$, with the $o(1)$ term uniform in n.

If we choose $r = r_n$ to be a solution to $a(r_n) = n$, then we obtain from Theorem 12.1 a simpler result. (The uniqueness of r_n follows from a result of Hayman [204] which shows that $a(r)$ is positive increasing in some range $R_1 < r < R$, $R_1 > R_0$.)

Corollary 12.1. *If $f(z)$, defined by Eq. (12.17), is H-admissible in $|z| < R$, then*

$$f_n \sim (2\pi b(r_n))^{-1/2} f(r_n) r_n^{-n} \quad \text{as} \quad n \to \infty \ , \tag{12.25}$$

where r_n is defined uniquely for large n by $a(r_n) = n$, $R_0 < r_n < R$.

Corollary 12.1 is adequate for most situations. The advantage of Theorem 12.1 is that it gives a uniform estimate over the approximate range $|a(r) - n| \precsim b(r)^{1/2}$. (Note that the estimate (12.24) is vacuous for $|a(r) - n|\ b(r)^{-1/2} \to \infty$.) Theorem 12.1 shows that the $f_n r^n$ are approximately Gaussian in the central region.

There are many direct applications of the above results.

Example 12.4. *Stirling's formula.* Let $f(z) = \exp(z)$. Then $f(z)$ is H-admissible for $R = \infty$; conditions i)–iii) of Definition 12.1 are trivially satisfied, while $a(r) = r$, $b(r) = r$, so iv) also holds for $R_0 = 0$, $\delta(r) = r^{-1/3}$, say. Corollary 12.1 then shows that

$$f_n = \frac{1}{n!} \sim (2\pi n)^{-1/2} e^n n^{-n} \quad \text{as} \quad n \to \infty \ , \tag{12.26}$$

since $r_n = n$, which gives a weak form of Stirling's approximation to $n!$. ■

In many situations the conditions of H-admissibility are much harder to verify than for $f(z) = \exp(z)$, and even in that case there is a little work to be done to verify that condition iv) holds. However, many of the generating functions one encounters are built up from other, simpler generating functions, and Hayman [204] has shown that often the resulting functions are guaranteed to be H-admissible. We summarize some of Hayman's results in the following theorem.

Theorem 12.2. *Let $f(z)$ and $g(z)$ be H-admissible for $|z| < R \leq \infty$. Let $h(z)$ be analytic in $|z| < R$ and real for real z. Let $p(z)$ be a polynomial with real coefficients.*

i) If the coefficients a_n of the Taylor series of $\exp(p(z))$ are positive for all sufficiently large n, then $\exp(p(z)))$ is H-admissible in $|z| < \infty$.

ii) $\exp(f(z))$ and $f(z)g(z)$ are H-admissible in $|z| < R$.

iii) If, for some $\eta > 0$, and $R_1 < r < R$,

$$\max_{|z|=r} |h(z)| = O(f(r)^{1-\eta}) \ , \tag{12.27}$$

then $f(z) + h(z)$ is H-admissible in $|z| < R$. In particular, $f(z) + p(z)$ is H-admissible in $|z| < R$ and, if the leading coefficient of $p(z)$ is positive, $p(f(z))$ is H-admissible in $|z| < R$.

Example 12.5. *H-admissible functions.* a) By i) Theorem 12.2, $\exp(z)$ is H-admissible, so we immediately obtain the estimate (12.26), which yields Stirling's formula. b) Since $\exp(z)$ is H-admissible, part iii) of Theorem 12.2 shows that $\exp(z) - 1$ is H-admissible. c) Applying part ii) of Theorem 12.2, we next find that $\exp(\exp(z) - 1)$ is H-admissible, which yields the asymptotics of the Bell numbers. ■

Hayman's results give only first order approximations for the coefficients of H-admissible functions. In some circumstances it is desirable to obtain full asymptotic expansions. This is possible if we impose additional restrictions on the generating function. We next state some results of Harris and Schoenfeld [198].

Definition 12.2. *A function $f(z)$ defined by Eq. (12.17) is* HS-admissible *provided it is analytic in $|z| < R$, $0 < R \leq \infty$, is real for real x, and satisfies the following conditions:*

A) There is an R_0, $0 < R_0 < R$ and a function $d(r)$ defined for $r \in (R_0, R)$ such that

$$\begin{gathered} 0 < d(r) < 1 \ , \\ r\{1 + d(r)\} < R \ , \end{gathered} \tag{12.28}$$

and such that $f(z) \neq 0$ for $|z - r| < rd(r)$.

B) If we define, for $k \geq 1$,

$$A(z) = \frac{f'(z)}{f(z)}, \quad B_k(z) = \frac{z^k}{k!} A^{(k-1)}(z), \quad B(z) = \frac{z}{2} B_1(z) \ , \tag{12.29}$$

then we have

$$B(r) > 0 \quad \textit{for} \quad R_0 < r < R \quad \textit{and} \quad B_1(r) \to \infty \quad \textit{as} \quad r \to R \ .$$

C) For sufficiently large R_1 and n, there is a unique solution $r = u_n$ to

$$B_1(r) = n + 1, \quad R_1 < r < R \ . \tag{12.30}$$

Let

$$C_j(z,r) = \frac{-1}{B(r)} \left\{ B_{j+2}(z) + \frac{(-1)^j}{j+2} B_1(r) \right\} \ . \tag{12.31}$$

There exist nonnegative D_n, E_n, and n_0 such that for $n \geq n_0$,

$$|C_j(u_n, u_n)| \leq E_n D_n^j, \quad j = 1, 2, \dots \ . \tag{12.32}$$

D) As $n \to \infty$,

$$\begin{aligned} & B(u_n) d(u_n)^2 \to \infty \ , \\ & D_n E_n B(u_n) d(u_n)^3 \to 0 \ , \\ & D_n d(u_n) \to 0 \ . \end{aligned} \tag{12.33}$$

For *HS*-admissible functions, Harris and Schoenfeld obtain complete asymptotic expansions.

Theorem 12.3. *If $f(z)$, defined by (12.17), is* HS*-admissible, then for any $N \geq 0$,*

$$f_n = 2(\pi\beta_n)^{-1/2} f(u_n) u_n^{-n} \left\{ 1 + \sum_{k=1}^{N} F_k(n) \beta_n^{-k} + O(\phi_N(n;d)) \right\} \ \textit{as} \ n \to \infty \ , \tag{12.34}$$

where

$$\beta_n = B(u_n) \ , \tag{12.35}$$

$$F_k(n) = \frac{(-1)^k}{\sqrt{\pi}} \sum_{m=1}^{2k} \frac{\Gamma(m+k+\frac{1}{2})}{m!} \sum_{\substack{j_1+\cdots+j_m=2k \\ j_1,\dots,j_m \geq 1}} \gamma_{j_1}(n) \cdots \gamma_{j_m}(n) \ , \tag{12.36}$$

$$\gamma_j(n) = C_j(u_n, u_n) \ , \tag{12.37}$$

and

$$\phi_N(n;d) = \max\{\mu(u_n, d), E_n'(D_n E_n'' \beta_n^{-1/2})^{2N+2}\} \ ,$$

with

$$E'_n = \min(1, E_n), \quad E''_n = \max(1, E_n) \ , \tag{12.38}$$

$$\mu(r,d) = \max\left\{\lambda(r;d)B(r)^{1/2}, \ \frac{\exp(-B(r)d(r)^2)}{d(r)B(r)^{1/2}}\right\} \ , \tag{12.39}$$

where $\lambda(r;d)$ *is the maximum value of* $|f'(z)/f(z)|$ *for* z *on the oriented path* $Q(r)$ *consisting of the line segment from* $r + ird(r)$ *to* $(1-d(r)^2)^{1/2} + ird(r)$ *and of the circular arc from the last point to* ir *to* $-r$.

The conditions for *HS*-admissibility are often hard to verify. However, there is a theorem [311] which guarantees that they do hold for a large class of interesting functions.

Theorem 12.4. *If* $g(z)$ *is* H*-admissible, then* $f(z) = \exp(g(z))$ *is* HS*-admissible. Furthermore, the error term* $\phi_N(n;d)$ *of Theorem 12.3 is then* $o(\beta_n^{-N})$ *as* $n \to \infty$ *for every fixed* $N \geq 0$.

Example 12.6. *Bell numbers and* HS*-admissibility.* Since $\exp(x) - 1$ is H-admissible, as we saw in Example 12.5, we find that $\exp(\exp(z) - 1)$ is HS-admissible, and Theorem 12.3 yields a complete asymptotic expansion of the Bell numbers. ■

Theorem 12.4 does not apply when $g(z)$ is a polynomial. As is pointed out by Schmutz [339], for $g(z) = z^4 - z^3 + z^2$ the function $f(z) = \exp(g(z))$ is *HS*-admissible, but Theorem 12.3 does not give an asymptotic expansion because the error term $\phi_N(n;d)$ is too large. Schmutz [339] has obtained necessary and sufficient conditions for Theorem 12.3 to give an asymptotic expansion for the coefficients of $f(z) = \exp(g(z))$ when $g(z)$ is a polynomial.

12.3. Other saddle point applications

Section 12.1 presented the basic saddle point method and discussed its range of applicability. Section 12.2 was devoted to results derived using this method that are general and yet can be applied in a cook-book style, without a deep understanding of the saddle point technique. Such a cook-book approach is satisfactory in many situations. However, often one encounters asymptotic estimation problems that are not covered by any of general results mentioned in Section 12.2, but can be solved using the saddle point method. This section mentions several such results of this type that illustrate the range of problems to which this method is applicable. Additional applications will be presented in Section 15, where other techniques are combined with the saddle point method.

Example 12.7. *Stirling numbers.* The Stirling numbers of the first kind, $s(n,k)$, satisfy (6.5) as well as [81]

$$\sum_{k=0}^{n} s(n,k) z^k = z(z-1)\cdots(z-n+1) \ . \tag{12.40}$$

Since $(-1)^{n+k} s(n,k) > 0$, (which is reflected in the behavior of the generating function (12.40), which grows faster along the negative real axis than along the positive one), we rewrite it as

$$\sum_{k=0}^{n} (-1)^{n+k} s(n,k) z^k = z(z+1)\cdots(z+n-1) \ . \tag{12.41}$$

The function on the right-hand side behaves like a good candidate for an application of the saddle point method. For details, see [295, 296]. ■

The estimates mentioned in Example 12.7 are far from best possible in either the size of the error term or (more important) in the range of validity. References for the best currently known results about Stirling numbers of both the first and second kind are given in [363]. Some of the results in the literature are not rigorous. For example, [363] presents elegant and uniform estimates based on an application of the saddle point method. They are likely to be correct, but the necessary rigorous error analysis has not been performed yet, although it seems that this should be doable. Other results, like those of [232] are obtained by methods that there does not seem to be any hope of making rigorous in the near future. Some of the results, though, such as the original ones of Moser and Wyman [295, 296], and the more recent one of Wilf [378], are fully proved.

The saddle point method can be used to obtain full asymptotic expansions. These expansions are usually in powers of $n^{-1/2}$ when estimating $[z^n]f(z)$, and they hardly ever converge, but are asymptotic expansions as defined by Poincaré (as in Eq. (2.2)). The usual forms of the saddle point method are incapable of providing expansions similar to the Hardy-Ramanujan-Rademacher convergent series for the partition function $p(n)$ (Eq. (3.1)). However, the saddle point method can be applied to estimate $p(n)$. There are technical difficulties, since the generating function

$$f(z) = \sum_{n=0}^{\infty} p(n) z^n = \prod_{k=1}^{\infty} (1-z^k)^{-1} \tag{12.42}$$

has a large singularity at $z = 1$, but in addition has singularities at all other roots of unity. The contribution of the integral for z away from 1 can be crudely estimated to be $O(n^{-1} \exp(Cn^{1/2}/2))$ (the last term in Eq. (1.5)). A simple estimate of the integral near $z = 1$ yields the asymptotic expansion of Eq. (1.6). A more careful treatment of the integral, but

one that follows the conventional saddle point technique, replaces the $1 + O(n^{-1/2})$ term in Eq. (1.6) by an asymptotic (in the sense of Poincare, so nonconvergent) series $\sum c_k n^{-k/2}$. To obtain Eq. (1.5), one needs to choose the contour of integration near $z = 1$ carefully and use precise estimates of $f(z)$ near $z = 1$.

De Bruijn [63] also discusses applications of the saddle point method when the saddle point is not on the real axis, and especially when there are several saddle points that contribute comparable amounts. This usually occurs when there are oscillations in the coefficients. When the oscillations are irregular, the tricks mentioned in Section 10 of changing variables do not work, and the contributions of the multiple saddle points have to be evaluated.

Example 12.8. *Oscillating sequence.* Consider the sequence a_n of Examples 9.4 and 10.1. As is shown in Example 9.4, its ordinary generating function is given by (9.39). It has an essential singularity at $z = 1$, but is analytic every place else. This function is not covered by our earlier discussion. For example, its maximal value is in general not taken on the positive real axis. It can be shown that the Cauchy integral has two saddle points, at approximately $z = 1-(2n)^{-1} \pm in^{-1/2}(1-(4n)^{-1})^{1/2}$. Evaluating $[z^n]f(z)$ by using Cauchy's theorem with the contour chosen to pass through the two points in the correct way yields the estimate (9.38). ■

In applying the saddle point method, a general principle is that multiplying a generating function $f(z)$ with dominant singularity at R by another function $g(z)$ which is analytic in $|z| < R$ and has much lower growth rate near $z = R$ yields a function $f(z)g(z)$ whose saddle point is close to that of $f(z)$. Usually one can obtain a relation of the form

$$[z^n](f(z)g(z)) \sim g(r_0)([z^n]f(z)) \ , \tag{12.43}$$

where r_0 is the saddle point for $f(z)$. This principle (which is related to the one behind Theorem 7.1) is useful, but has to be applied with caution, and proofs have to be provided for each case. For fuller exposition of this principle and general results, see [157]. The advantage of this approach is that often $f(z)$ is easy to manipulate, so the determination of a saddle point for it is easy, whereas multiplying it by $g(z)$ produces a messy function, and the exact saddle point for $f(z)g(z)$ is difficult to determine.

Example 12.9. *Boolean lattice of subsets of* $\{1, \ldots, n\}$. The number a_n of Boolean sublattices of the Boolean lattice of subsets of $\{1, \ldots, n\}$ has the exponential generating function [162]

$$A(z) = \sum_{n=0}^{\infty} a_n \frac{z^n}{n!} = \exp(2z + \exp(z) - 1) \ . \tag{12.44}$$

We can write $A(z) = \exp(2z)B(z)$, where $B(z)$ is the exponential generating function for the Bell numbers (Example 12.2). Since $B(z)$ grows much faster than $\exp(2z)$, it is easy to show that (12.43) applies, and so

$$a_n \sim \exp(2r_0)B_n \quad \text{as} \quad n \to \infty \ , \tag{12.45}$$

where r_0 is the saddle point for $B(z)$. Using the approximation (12.12) of Example 12.2, we find that

$$a_n \sim (n/\log n)^2 B_n \quad \text{as} \quad n \to \infty \ . \tag{12.46}$$

■

The insensitivity of the saddle point approximation to slight perturbations is reflected in slightly different definitions of a saddle point that are used. The saddle point approximation (12.9) for $[z^n]f(z)$ is stated in terms of r_0, the point that minimizes $f(r)r^{-n}$. The discussion of the saddle point emphasized minimization of the peak value of the integrand in Cauchy's formula, which is the same as minimizing $f(r)r^{-n-1}$, since the contour integral (10.6) involves $f(z)z^{-n-1}$. Some sources call the point minimizing $f(r)r^{-n-1}$ the saddle point. It is not important which definition is adopted. The asymptotic series coefficients look slightly differently in the two cases, but the final asymptotic series, when expressed in terms of n, are the same. The reason for slightly preferring the definition that minimizes $f(r)r^{-n}$ is that when the change of variable $z = r\exp(i\theta)$ is made in Cauchy's integral, there is no linear term in θ, and the integrand involves $\exp(-cn\theta^2 + O(|\theta|^3))$. If we minimized $f(r)r^{-n-1}$, we would have to deal with $\exp(-c'i\theta - c''n\theta^2 + O(|\theta|^3))$, which is not much more difficult to handle but is less elegant.

The same principle can be applied when the exact saddle point is hard to determine, and it is awkward to work with an implicit definition of this point. When that happens, there is often a point near the saddle point that is easy to handle, and for which the saddle point approximation holds. We refer to [157] for examples and discussion of this phenomenon.

12.4. The circle method and other techniques

As we mentioned in Section 12.3, the saddle point method is a powerful method that estimates the contribution of the neighborhood of only a single point, or at most a few points. The convergent series of Eq. (1.3) for the partition function $p(n)$ (as well as the earlier non-convergent but asymptotic and very accurate expansion of Hardy and Ramanujan) is obtained

by evaluating the contribution of the other singularities of $f(z)$ to the integral. The m-th term in Eq. (1.3) comes from the primitive m-th roots of unity. To obtain this expansion one needs to use a special contour of integration and detailed knowledge of the behavior of $f(z)$. The details of this technique, called the circle method, can be found in [13, 23].

Convergent series can be obtained from the circle method only when the generating function is of a special form. For results and references, see [8, 10].

Nonconvergent but accurate asymptotic expansions can be derived from the circle method in a much wider variety of applications. It is especially useful when there is no single dominant singularity. For the partition function $p(n)$, all the singularities away from $z = 1$ contribute little, and it is $z = 1$ that creates the dominant term and yields Eq. (1.6). For other functions this is often false. For example, when dealing with additive problems of Waring's type, where one studies $N_{k,m}(n)$, the number of representations of a nonnegative integer n as

$$n = \sum_{j=1}^{m} x_j^k, \quad x_j \in \mathbb{Z}^+ \cup \{0\} \quad \text{for all} \quad j \ , \tag{12.47}$$

the natural generating function to study is

$$\sum_{n=0}^{\infty} N_{k,m}(n) z^n = g(z)^m \ , \tag{12.48}$$

where

$$g(z) = \sum_{h=0}^{\infty} z^{h^k} \ . \tag{12.49}$$

The function $g(z)$ has a natural boundary at $|z| = 1$, but it again grows fastest as z approaches a root of unity from within $|z| < 1$, so it is natural to speak of $g(z)$ having singularities at the roots of unity. The singularity at $z = 1$ is still the largest, but not by much, as other roots of unity contribute comparable amounts, with the contribution of other roots of unity ζ diminishing as the order of ζ increases. All the contributions can be estimated, and one can obtain solutions to Waring's problem (which was to show that for every k, there is an integer m such that $N_{k,m}(n) > 0$ for all n) and other additive problems. For details of this method see [23]. We mention here that for technical reasons, one normally works with generating functions of the form $G_n(z)^m$, where

$$G_n(z) = \sum_{h=0}^{\lfloor n^{1/k} \rfloor} z^{h^k} \ , \tag{12.50}$$

(so that the generating function depends on n), and analyzes them for $|z| = 1$ (since they are now polynomials), but the basic explanation above of why this process works still applies.

13. Multivariate generating functions

A major difficulty in estimating the coefficients of multivariate generating functions is that the geometry of the problem is far more difficult. It is harder to see what are the critical regions where the behavior of the function determines the asymptotics of the coefficients, and those regions are more complicated. Singularities and zeros are no longer isolated, as in the one-dimensional case, but instead form $(k-1)$-dimensional manifolds in k variables. Even rational multivariate functions are not easy to deal with.

One basic tool in one-dimensional complex analysis is the residue theorem, which allows one to move a contour of integration past a pole of the integrand. (We derived a form of the residue theorem in Section 10, in the discussion of poles of generating functions.) There is an impressive generalization by Leray [4, 250] of this theory to several dimensions. Unfortunately, it is complicated, and with few exceptions (such as that of [252], see also [49]) so far it has not been applied successfully to enumeration problems. On the other hand, there are some much simpler tools that can frequently be used to good effect.

An important tool in asymptotics of multivariate generating functions is the multidimensional saddle point method.

Example 13.1. *Alternating sums of powers of binomial coefficients.* Consider

$$S(s,n) = \sum_{k=0}^{2n} (-1)^{k+n} \binom{2n}{k}^s , \tag{13.1}$$

where s and n are positive integers. It has been known for a long time that $S(1,n) = 0$, $S(2,n) = (2n)!(n!)^{-2}$, $S(3,n) = (3n)!(n!)^{-3}$. However, no formula of this type has been known for $s > 3$. De Bruijn (see Chapter 4 of [63]) showed that $S(s,n)$ for integer $s > 3$ cannot be expressed as a ratio of products of factorials. Although his proof is not presented as an application of the multidimensional saddle point method, it is easy to translate it into those terms. $S(s,n)$ is easily seen to equal the constant term in

$$F(z_1, \ldots, z_{s-1}) = (-1)^n (1+z_1)^{2n} \ldots (1+z_{s-1})^{2n} (1 - (z_1 \ldots z_{s-1})^{-1})^{2n} , \tag{13.2}$$

and so

$$S(s,n) = (2\pi i)^{-s+1} \int \cdots \int F(z_1, \ldots, z_{s-1}) z_1^{-1} \ldots z_{s-1}^{-1} dz_1 \ldots dz_{s-1} , \tag{13.3}$$

where the integral is taken with each z_j traversing a circle, say. De Bruijn's proof in effect shows that for s fixed and $n \to \infty$, there are two saddle points at $z_1 = \cdots = z_{s-1} = \exp(2i\alpha)$,

with $\alpha = \pm(2s)^{-1}$, and this leads to the estimate

$$S(s,n) \sim \left\{2\cos\left(\frac{\pi}{2s}\right)\right\}^{2ns+s-1} 2^{2-s}(\pi n)^{(1-s)/2} s^{-1/2} \quad \text{as} \quad n \to \infty \ , \tag{13.4}$$

valid for any fixed integer $s \geq 2$. Since $\cos(\pi(2s)^{-1})$ is algebraic but irrational for $s \geq 4$, the asymptotic estimate (13.4) shows that $S(s,n)$ cannot be expressed as a ratio of finite products of $(a_j n)!$ for any fixed finite set of integers a_j.

In Chapter 6 of [63], de Bruijn derives the asymptotics of $S(s,n)$ as $n \to \infty$ for general real s. The approach sketched above no longer applies, and de Bruijn uses the integral representation

$$S(s,n) = \int_C \left(\frac{\Gamma(2n+1)}{\Gamma(n+z+1)\Gamma(n-z+1)}\right)^s \frac{dz}{2i\sin\pi z} \ ,$$

where C is a simple closed curve that contains the points $-n, -n+1, \ldots, -1, 0, 1, \ldots, n$ in its interior and has no other integer points on the real axis in its closure. A complicated combination of analytic techniques, including the one-dimensional saddle point method, then leads to the final asymptotic estimate of $S(s,n)$. ■

The multidimensional saddle point method works best when applied to large singularities. Just as for the basic one-dimensional method, it does not work when applied to small singularities, such as those of rational functions. Fortunately, there is a trick that often succeeds in converting a small singularity in n dimensions into a large one in $n-1$ dimensions. The main idea is to expand the generating function with respect to one of the variables through partial fraction expansions or other methods. It is hard to write down a general theorem, but the next example illustrates this technique.

Example 13.2. *Alignments of k sequences.* Let $f(k,n)$ denote the number of $k \times m$ matrices of 0's and 1's such that each column sum is ≥ 1 and each row sum is exactly n. (The number of columns, m, can vary, although obviously $k \leq m \leq kn$.) We consider k fixed, $n \to \infty$ [178]. If we let $N(r_1, \ldots, r_k)$ denote the number of $0,1$ matrices with k rows, no columns of all 0's, and row sums $r_1, \ldots, r_k$, then it is easy to see [178] that

$$F(z_1, \ldots, z_k) = \sum_{r_1, \ldots, r_k \geq 0} N(r_1, \ldots, r_k) z_1^{r_1} \cdots z_k^{r_k} = \left(2 - \prod_{j=1}^{k}(1+z_j)\right)^{-1} . \tag{13.5}$$

We have $f(k,n) = N(n, \ldots, n)$, and so we need the diagonal terms of $F = F(z_1, \ldots, z_k)$. The function F is rational, so its singularity is small. Moreover, the singularities of F are difficult

to visualize. However, in any single variable F is simple. We take advantage of this feature. Let

$$A(z) = \prod_{j=1}^{k-1}(1+z_j)\ , \tag{13.6}$$

where z stands for $(z_1,\dots,z_{k-1}) \in \mathbb{C}^{k-1}$, and expand

$$\left(2-\prod_{j=1}^{k}(1+z_j)\right)^{-1} = (2-A(z)(1+z_k))^{-1} = \sum_{m=0}^{\infty}\frac{A(z)^m z_k^m}{(2-A(z))^{m+1}}\ . \tag{13.7}$$

Therefore

$$N(r_1,\dots,r_{k-1},m) = \frac{1}{(2\pi i)^{k-1}}\int\ \cdots\ \int \frac{A(z)^m}{(2-A(z))^{m+1}}\,\frac{dz_1}{z_1^{r_1+1}}\ \cdots\ \frac{dz_{k-1}}{z_{k-1}^{r_{k-1}}}\ . \tag{13.8}$$

The function whose coefficients we are trying to extract is now $A(z)^m/(2-A(z))^{m+1}$, which is still rational. However, the interesting case for us is $m\to\infty$, which transforms the singularity into a large one. We are interested in the case $r_1 = r_2 = \cdots = r_{k-1} = r = n$. Then the integral in (13.8) can be shown to have a saddle point at $z_j = \rho$, $1 \le j \le k-1$, where $\rho = 2^{1/k}-1$, and one obtains the estimate [178]

$$f(k,n) = r^n n^{-(k-1)/2}\{(\rho\pi^{(k-1)/2}k^{1/2})^{-1}2^{(k^2-1)/(2k)} + O(n^{-1/2})\} \quad \text{as} \quad n\to\infty\ . \qquad \blacksquare \tag{13.9}$$

The examples above of applications of the multidimensional saddle point method all dealt with problems in a fixed dimension as various other parameters increase. A much more challenging problem is to apply this method when the dimension varies. A noteworthy case where this has been done successfully is the asymptotic enumeration of graphs with a given degree sequence by McKay and Wormald [279].

Example 13.3. *Simple labeled graphs of high degree.* Let $G(n;d_1,\dots,d_n)$ be the number of labeled simple graphs on n vertices with degree sequence $d_1,d_2,\dots,d_n$. Then $G(n;d_1,\dots,d_n)$ is the coefficient of $z_1^{d_1}z_2^{d_2}\cdots z_n^{d_n}$ in

$$F = \prod_{\substack{j,k=1\\ j<k}}^{n}(1+z_jz_k)\ , \tag{13.10}$$

and so by Cauchy's theorem

$$G(n;d_1,\dots,d_N) = (2\pi i)^{-n}\int\cdots\int F z_1^{-d_1-1}\cdots z_n^{-d_n-1}dz_1\cdots dz_n\ , \tag{13.11}$$

where each integral is on a circle centered at the origin. Let all the radii be equal to some $r > 0$. The integrand takes on its maximum absolute value on the product of these circles at precisely the two points $z_1 = z_2 = \cdots = z_n = r$ and $z_1 = z_2 = \cdots = z_n = -r$. If $d_1 = d_2 = \cdots = d_n$, so that we consider only regular graphs, McKay and Wormald [279] show that for an appropriate choice of the radius r, these two points are saddle points of the integrand, and succeed through careful analysis in proving that if dn is even, and $\min(d, n-d-1) > cn(\log n)^{-1}$ for some $c > 2/3$, then

$$G(n, d, d, \ldots, d) = 2^{1/2}(2\pi n\lambda^{d+1}(1-\lambda)^{n-d})^{-n/2} \exp\left(\frac{-1+10\lambda-10\lambda^2}{12\lambda(1-\lambda)} + O(n^{-\zeta})\right) \quad (13.12)$$

as $n \to \infty$ for any $\zeta < \min(1/4, 1/2 - 1/(3c))$, where $\lambda = d/(n-1)$.

McKay and Wormald [279] also succeed in estimating the number of irregular graphs, provided that all the degrees d_j are close to a fixed d that satisfies conditions similar to those above. The proof is more challenging because different radii are used for different variables and the result is complicated to state. ■.

The McKay-Wormald estimate of Example 13.3 is a true tour de force. The problem is that the number of variables is n and so grows rapidly, whereas the integrand grows only like $\exp(cn^2)$ at its peak. More precisely, after transformations that remove obvious symmetries are applied the integrand near the saddle point drops off like $\exp(-n\sum\theta_j^2)$. This is just barely to allow the saddle point method to work, and the symmetries in the problem are exploited to push the estimates through. This approach can be applied to other problems (cf. [278]), but it is hard to do. On the other hand, when the number of variables grows more slowly, multidimensional saddle point contributions can be estimated without much trouble.

So far this section has been devoted primarily to multivariate functions with large singularities. However, there is also an extensive literature on small singularities. The main thread connecting most of these works is that of central and local limit theorems. Bender [32] initiated this development in the setting of two-variable problems. We present some of his results, since they are simpler than the later and more general ones that will be mentioned at the end of this section.

Consider a double sequence of numbers $a_{n,k} \geq 0$. (Usually the $a_{n,k}$ are $\neq 0$ only for $0 \leq k \leq n$.) We will assume that

$$A_n = \sum_k a_{n,k} < \infty \quad (13.13)$$

for all n, and define the normalized double sequence

$$p_n(k) = a_{n,k}/A_n \ . \tag{13.14}$$

We will say that $a_{n,k}$ satisfies a central limit theorem if there exist functions σ_n and μ_n such that

$$\lim_{n\to\infty} \sup_x \left| \sum_{k \le \sigma_n x + \mu_n} p_n(k) - (2\pi)^{-1/2} \int_{-\infty}^{x} \exp(-t^2/2) dt \right| = 0 \ . \tag{13.15}$$

Equivalently, $p_n(k)$ is asymptotically normal with mean μ_n and variance σ_n^2.

Theorem 13.1. [32]. *Let $a_{n,k} \ge 0$, and set*

$$f(z,w) = \sum_{n,k\ge 0} a_{n,k} z^n w^k \ . \tag{13.16}$$

Suppose that there are (i) a function $g(s)$ that is continuous and $\neq 0$ near $s = 0$, (ii) a function $r(s)$ with bounded third derivative near $s = 0$, (iii) an integer $m \ge 0$, and (iv) $\epsilon, \delta > 0$ such that

$$\left(1 - \frac{z}{r(s)}\right)^m f(z, e^s) - \frac{g(z)}{1 - z/r(s)} \tag{13.17}$$

is analytic and bounded for

$$|z| < \epsilon, \quad |z| < |r(0)| + \delta \ . \tag{13.18}$$

Let

$$\mu = -r'(0)/r(0), \quad \sigma^2 = \mu^2 - r''(0)/r(0) \ . \tag{13.19}$$

If $\sigma \neq 0$, then (13.15) holds with $\mu_n = n\mu$ and $\sigma_n^2 = n\sigma^2$.

A central limit theorem is useful, but it only gives information about the cumulative sums of the $a_{n,k}$. It is much better to have estimates for the individual $a_{n,k}$. We say that $p_n(k)$ (and $a_{n,k}$) satisfy a local limit theorem if

$$\lim_{n\to\infty} \sup_x \left| \sigma_n p_n(\lfloor \sigma_n x + \mu_n \rfloor) - (2\pi)^{-1/2} \exp(-x^2/2) \right| = 0 \ . \tag{13.20}$$

In general, we cannot derive (13.20) from (13.15) without some additional conditions on the $a_{n,k}$, such as unimodality (see [32]). The other approach one can take is to derive (13.20) from conditions on the generating function $f(z,w)$.

Theorem 13.2. [32]. *Suppose that* $a_{n.k} \geq 0$, *and let* $f(z,w)$ *be defined by (13.16). Let* $-\infty < a < b < \infty$. *Define*

$$R(\epsilon) = \{z : a \leq Re(z) \leq b,\ |Im(z)| \leq \epsilon\}\ . \tag{13.21}$$

Suppose there exist $\epsilon > 0$, $\delta > 0$, *an integer* $m \geq 0$, *and function* $g(s)$ *and* $r(s)$ *such that*

(i) $g(s)$ *is continuous and* $\neq 0$ *for* $s \in R(\epsilon)$,

(ii) $r(s) \neq 0$ *and has a bounded third derivative for* $s \in R(\epsilon)$,

(iii) for $s \in R(\epsilon)$ *and* $|z| \leq |r(s)|(1+\delta)$, *the function defined by (13.17) is analytic and bounded,*

(iv)

$$\left(\frac{r'(\alpha)}{r(\alpha)}\right)^2 \neq \frac{r''(\alpha)}{r(\alpha)} \quad for \quad a \leq \alpha \leq b\ , \tag{13.22}$$

(v) $f(z, e^s)$ *is analytic and bounded for*

$$|z| \leq |r(Re(s))|(1+\delta) \quad and \quad s \leq |Im(s)| \leq \pi\ .$$

Then

$$a_{n,k} \sim \frac{n^m e^{-\alpha k} g(\alpha)}{m! r(\alpha)^m \sigma_\alpha (2\pi)^{1/2}} \quad as \quad n \to \infty \tag{13.23}$$

uniformly for $a \leq \alpha \leq b$, *where*

$$\frac{k}{n} = -\frac{r'(\alpha)}{r(\alpha)}\ , \tag{13.24}$$

$$\sigma_\alpha^2 = \left(\frac{k}{n}\right)^2 - \frac{r''(\alpha)}{r(\alpha)}\ . \tag{13.25}$$

There have been many further developments of central and local limit theorems for asymptotic enumeration since Bender's original work [32]. Currently the most powerful and general results are those of Gao and Richmond [155]. They apply to general multivariate problems, not only two-variable ones. Other papers that deal with central and local limit theorems or other multivariate problems with small singularities are [38, 42, 65, 96, 142, 143, 183, 227].

14. Mellin and other integral transforms

When the best generating function that one can obtain is an infinite sum, integral transforms can sometimes help. There is a large variety of integral transforms, such as those of

Fourier and Laplace. The one that is most commonly used in asymptotic enumeration and analysis of algorithms is the Mellin transform, and it is the only one we will discuss extensively below. The other transforms do occur, though. For example, if $f(x) = \sum a_n x^n/n!$ is an exponential generating function of the sequence a_n, then the ordinary generating function of a_n can be derived from it using the Laplace transform

$$\begin{aligned} \int_0^\infty f(xy)\exp(-x)dx &= \sum_n a_n y^n (n!)^{-1} \int_0^\infty x^n \exp(-x)dx \\ &= \sum_n a_n y^n \ . \end{aligned} \tag{14.1}$$

(This assumes that the a_n are small enough to assure the integrals above converge and the interchange of summation and integration is valid.) Related integral transforms can be used to transform generating functions into other forms. For example, to transform an ordinary generating function $F(u) = \sum a_n u^n$ into an exponential one, we can use

$$\frac{1}{2\pi i}\int_{|u|=r} F(u)\exp(w/u)du \ . \tag{14.2}$$

The basic references for asymptotics of integral transforms are [89, 95, 299, 347]. This section will only highlight some of the main properties of Mellin transforms and illustrate how they are used. For a more detailed survey, especially to analysis of algorithms, see [137].

Let $f(t)$ be a measurable function defined for real $t \geq 0$. The *Mellin transform* $f^*(z)$ of $f(t)$ is a function of the complex variable z defined by

$$f^*(z) = \int_0^\infty f(t)t^{z-1}dt \ . \tag{14.3}$$

If $f(t) = O(t^\alpha)$ as $t \to 0^+$ and $f(t) = O(t^\beta)$ as $t \to \infty$, then the integral in (14.3) converges and defines $f^*(z)$ to be an analytic function inside the "fundamental domain" $-\alpha < \mathrm{Re}(z) < -\beta$. As an example, for $f(t) = \exp(-t)$, we have $f^*(z) = \Gamma(z)$ and $\alpha = 0$, $\beta = -\infty$. There is an inversion formula for Mellin transforms which states that

$$f(t) = \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} f^*(z)t^{-z}dz \ , \tag{14.4}$$

and the integral is over the vertical line with $\mathrm{Re}(z) = c$. The inversion formula (14.4) is valid for $-\alpha < c < -\beta$, but much of its strength in applications comes from the ability to shift the contour of integration into wider domains to which $f^*(z)$ can be analytically continued.

The advantage of the Mellin transform is due largely to a simple property, namely that if $g(t) = af(bx)$ for b real, $b > 0$, then

$$g^*(z) = ab^{-z}f^*(z) \ . \tag{14.5}$$

This readily extends to show that if

$$F(t) = \sum_k \lambda_k f(\eta_k t) \tag{14.6}$$

(where the λ_k and $\eta_k > 0$ are such that the sum converges and $F(t)$ is well behaved), then

$$F^*(z) = \left(\sum_k \lambda_k \eta_k^{-z} \right) f^*(z) \ . \tag{14.7}$$

In particular, if

$$F(t) = \sum_{k=1}^{\infty} f(kt) \ , \tag{14.8}$$

then

$$F^*(z) = \left(\sum_{k=1}^{\infty} k^{-z} \right) f^*(z) = \zeta(z) f^*(z) \ , \tag{14.9}$$

where $\zeta(z)$ is the Riemann zeta function.

Example 14.1. *Runs of heads in coin tosses.* What is R_n, the expected length of the longest run of heads in n tosses of a fair coin? Let $p(n,k)$ be the probability that there is no run of k heads in a coin tosses. Then

$$R_n = \sum_{k=1}^{n} k(p(n,k+1) - p(n,k)) \ . \tag{14.10}$$

We now apply the estimates of Example 9.2. To determine $p(n,k)$, we take $A = 00\cdots0$, and then $C_A(z) = z^{k-1} + z^{k-2} + \cdots + z + 1$, so $C_A(1/2) = 1 - 2^{-k}$. Hence (9.19) shows easily that in the important ranges where k is of order $\log n$, we have

$$p(n,k) \cong \exp(-n2^{-k}) \ , \tag{14.11}$$

and there R_n is approximated well by

$$r(n) = \sum_{k=0}^{\infty} k(\exp(-n2^{-k-1}) - \exp(-n2^{-k})) \ . \tag{14.12}$$

The function $r(t)$ is of the form (14.6) with

$$\lambda_k = k, \quad \eta_k = 2^{-k}, \quad f(t) = \exp(-t/2) - \exp(-t) \ , \tag{14.13}$$

is easily seen to be well behaved, and so for $-1 < \mathrm{Re}(z) < 0$,

$$r^*(z) = \left(\sum_{k=0}^{\infty} k2^{kz} \right) f^*(z) = 2^z(1-2^z)^{-2} f^*(z) \ . \tag{14.14}$$

Next, to determine $f^*(z)$, we note that for $\mathrm{Re}(z) > 0$ we have

$$\begin{aligned} f^*(z) &= \int_0^\infty f(t)t^{z-1}dt = \int_0^\infty e^{-t/2}t^{z-1}dt - \int_0^\infty e^{-t}t^{z-1}dt \\ &= (2^z - 1)\Gamma(z) \ . \end{aligned} \tag{14.15}$$

By analytic continuation this relation holds for $-1 < \mathrm{Re}(z)$, and we find that for $-1 < \mathrm{Re}(z) < 0$,

$$r^*(z) = 2^z(2^z - 1)^{-1}\Gamma(z) \ . \tag{14.16}$$

We now apply the inversion formula to obtain

$$r(t) = \frac{1}{2\pi i}\int_{-1/2-i\infty}^{-1/2+i\infty} 2^z(2^z - 1)^{-1}\Gamma(z)t^{-z}dz \ . \tag{14.17}$$

The integrand is a meromorphic function in the whole complex plane that drops off rapidly on any vertical line. We move the contour of integration to the line $\mathrm{Re}(z) = 1$. The new integral is $O(t^{-1})$, and the residues at the poles (all on $\mathrm{Re}(z) = 0$) will give the main contribution to $r(t)$. There are first order poles at $z = 2\pi i m \log 2$ for $m \in \mathbb{Z} \setminus \{0\}$ coming from $2^z = 1$, and a single second order pole at $z = 0$, since $\Gamma(z)$ has a first order pole there as well. A short computation of the residues gives

$$r(t) = \log_2 t - \sum_{h=-\infty}^{\infty} (\log 2)^{-1}\Gamma(-2\pi i h(\log 2)^{-1}) \exp(2\pi i h \log_2 t) + O(t^{-1}) \ . \tag{14.18}$$

■

There are other ways to obtain the same expansion (14.18) for $r(t)$ (cf. [181]). The periodic oscillating component in $r(t)$ is common in problems involving recurrences over powers of 2. This happens, for example, in studies of register allocation and digital trees [136, 138, 141]. The periodic function is almost always the same as the one in Eq. (14.18), even when the combinatorics of the problem varies. Technically this is easy to explain, because of the closely related recurrences leading to similar Mellin transforms for the generating functions.

Mellin transforms are useful in dealing with problems that combine combinatorial and arithmetic aspects. For example, if $S(n)$ denotes the total number of 1's in the binary representations of $1, 2, \ldots, n-1$, then it was shown by Delange that

$$S(n) = \frac{1}{2}n\log_2 n + nu(\log_2 n) + o(n) \quad \text{as} \quad n \to \infty \ , \tag{14.19}$$

where $u(x)$ is a continuous, nowhere differentiable function that satisfies $u(x) = u(x+1)$. The Fourier coefficients of $u(x)$ are known explicitly. Perhaps the best way to obtain these results is by using Mellin transforms. See [129, 353] for further information and references.

Mellin transforms are often combined with other techniques. For example, sums of the form $s_n = \sum a_k \binom{n}{k}$ with oscillating a_k lead to generating functions

$$s(z) = \sum_k a_k w(z)^k \ . \tag{14.20}$$

The asymptotic behavior of $s(z)$ near its dominant singularity can sometimes be determined by applying Mellin transforms. For a detailed explanation of the approach, see [137]. Examples of the application of this technique can be found in [13, 280].

15. Functional equations, recurrences, and combinations of methods

Most asymptotic enumeration results are obtained from combinations of techniques presented in the previous sections. However, it is only rarely that the basic asymptotic techniques can be applied directly. This section describes a variety of methods and results that are not easy to categorize. They use combinations of methods that have been presented before, and sometimes develop them further. In most of the examples that will be presented, some relations for generating functions are available, but no simple closed-form formulas, and the problem is to deduce where the singularities lie and how the generating functions behave in their neighborhoods. Once that task is done, previous methods can be applied to obtain asymptotics of the coefficients.

15.1. Implicit functions, graphical enumeration, and related topics

Example 15.1. *Rooted unlabeled trees.* We sketch a proof that T_n, the number of rooted unlabeled trees with n vertices, satisfies the asymptotic relation (1.9). The functional equation (1.8) holds with $T(z)$ regarded as a formal power series. The first step is to show that $T(z)$ is analytic in a neighborhood of 0. This can be done by working exclusively with Eq. (1.8). (There is an argument of this type in Section 9.5 of [188].) Another way to prove analyticity of $T(z)$ is to use combinatorics to obtain crude upper bounds for T_n. We use a combination of these approaches. If a tree with $n \geq 2$ vertices has at least two subtrees at the root, we can decompose it into two trees, the first consisting of one subtree at the root, the other of the root and the remaining subtrees. This shows that

$$T_n \leq T_{n-1} + \sum_{k=1}^{n-1} T_k T_{n-k} \ , \qquad n \geq 2 \ . \tag{15.1}$$

Therefore, if we define $a_1 = 1$, and

$$a_n = a_{n-1} + \sum_{k=1}^{n-1} a_k a_{n-k} \ , \qquad n \geq 2 \ , \tag{15.2}$$

then we have $T_n \leq a_n$. Now if

$$A(z) = \sum_{n=1}^{\infty} a_n z^n \ ,$$

then the defining relation (15.2) yields the functional equation

$$A(z) - z = zA(z) + A(z)^2 \ , \tag{15.3}$$

so that

$$A(z) = (1 - z - (1 - 6z + z^2)^{1/2})/2 \ . \tag{15.4}$$

Since $A(z)$ is analytic in $|z| < 3 - 2\sqrt{2} = 0.17157\ldots$, we have

$$0 \leq T_n \leq a_n = O(6^n) \ . \tag{15.5}$$

It will also be convenient to have an exponential lower bound for T_n. Let b_n be the number of rooted unlabeled trees in which every internal vertex has ≤ 2 subtrees. Then $b_1 = 1$, $b_2 = 1$, and

$$b_n \geq \sum_{k=1}^{\lfloor (n-1)/2 \rfloor} b_k b_{n-k-1} \qquad \text{for} \qquad n \geq 3 \ . \tag{15.6}$$

We use this to show that $b_n \geq (6/5)^n$ for $n \geq 7$. Direct computation establishes this lower bound for $7 \leq n \leq 14$, and for $n \geq 15$ we use induction and $b_n \geq b_k b_{n-k-1}$ with $k = \lfloor (n-1)/2 \rfloor$.

Since $T_n \geq b_n \geq (6/5)^n$, $T(z)$ converges only in $|z| < r$ for some r with $r < 1$. Since $T(0) = 0$, $|T(z)| \leq C_\delta |z|$ in $|z| \leq r - \delta$ for every $\delta > 0$, and therefore

$$u(z) = \sum_{k=2}^{\infty} T(z^k)/k \tag{15.7}$$

is analytic in $|z| < r^{1/2}$, and in particular at $z = r$. Therefore, although we know little about r and $u(z)$, we see that $T(z)$ satisfies $G(z, T(z)) = T(z)$, where

$$G(z, w) = z \exp(w + u(z)) \tag{15.8}$$

is analytic in z and w for all w and for $|z| < r^{1/2}$.

We will apply Theorem 10.6. First, though, we need to establish additional properties of $T(z)$. We have

$$T(z) \exp(-T(z)) = z \exp(u(z)) \to r \exp(u(r)) \quad \text{as} \quad z \to r^- \ , \tag{15.9}$$

and $0 < r\exp(u(r)) < \infty$. Since $T(z)$ is positive and increasing for $0 < z < r$, $T(r)$, the limit of $T(z)$ as $z \to r^-$ must exist and be finite.

We next show that $T(r) = 1$. We have

$$\frac{\partial}{\partial w} G(z,w) = G(z,w) \ . \tag{15.10}$$

We know that $G(z,T(z)) = T(z)$ for $|z| < r$, and in particular for some z arbitrarily close to r. If $T(r) \neq 1$, then by (15.10)

$$\frac{\partial}{\partial w}(G(z,w) - w)\Big|_{w=T(z)} \neq 0 \tag{15.11}$$

in a neighborhood of $z = r$, and therefore $T(z)$ could be continued analytically to a neighborhood of $z = r$. This is impossible, since r is the radius of convergence of $T(z)$, and $T_n \geq 0$ implies by Theorem 10.3 that $T(z)$ has a singularity at $z = r$. Therefore we must have $T(r) = 1$, and $G_w(r,T(r)) = 1$.

We have now shown that conditions (i) and (ii) of Theorem 10.6 hold with the r of that theorem the same as the r we have defined and $s = T(r) = 1$, $\delta = r^{1/2} - r$. Condition (iii) is easy to verify. Finally, the conditions on the coefficients of $T(z)$ and $G(z,w)$ are clearly satisfied.

Since Theorem 10.6 applies, we do obtain an asymptotic expansion for T_n of the form (1.9), with C given by the formula (10.64). It still remains to determine r and C. No closed-form expressions are known for these constants. They are conjectured to be transcendental and algebraically independent of standard constants such as π and e, but no proof is available. Numerically, however, they are simple to compute. Note that

$$\begin{aligned} G_z(r,1) &= \exp(1+u(r))(1+ru'(r)) \\ &= r^{-1} + u'(r) \ , \qquad (15.12) \\ G_{ww}(r,1) &= 1 \ , \qquad (15.13) \end{aligned}$$

so we only need to compute r and $u'(r)$. These quantities can be computed along with $u(r)$ in the same procedure. The basic numerical procedure is to determine r as the positive solution to $T(r) = 1$. To determine $T(x)$ for any positive x, we take any approximation to the $T(x^k)$, $k \geq 1$ (starting initially with x^k as an approximation to $T(x^k)$, say), and combine it with (1.8) (applied with $z = x^m$, $m \geq 1$) to obtain improved approximations. This procedure can be made rigorous. Upper bounds for r, $u(r)$, and $u'(r)$ are especially easy. Since $T_1 = 1$, $T(x) \geq x$

for $0 < x < 1$, and therefore, $T(x^k) \geq x^k$ for $k \geq 1$. Suppose that we start with a fixed value of x and derive some lower bounds of the form $T(x^k) \geq u_k^{(1)} \geq 0$ for $k \geq 1$. Then the functional equation (1.8) implies

$$T(x^m) \geq u_m^{(2)} = x \exp\left(\sum_{k=1}^{\infty} u_{km}/k\right) \qquad m \geq 1 \ . \tag{15.14}$$

This process can be iterated several more times, and to keep the computation manageable, we can always set $u_k^{(j)} = 0$ for $k \geq k_0$. If we ever find a lower bound $T(x) > 1$ by this process, then we know that $r < x$, since $T(r) = 1$. Lower bounds for r are slightly more complicated. ■

We mention here that if U_n denotes the number of unlabeled trees, then the ordinary generating function $U(z) = \sum U_n z^n$ satisfies

$$U(z) = T(z) - T(z)^2/2 + T(z^2)/2 \ . \tag{15.15}$$

Using the results from Example 15.1 about the analytic behavior of $T(z)$, it can be shown that

$$U_n \sim C' r^{-n} n^{-5/2} \ , \tag{15.16}$$

where $r = 0.3383219\ldots$ is the same as before, while $C' = 0.5349485\ldots$.

Example 15.2. *Leftist trees.* Let a_n denote the number of leftist trees of size n (i.e., rooted planar trees with n leaves, such that in any subtree S, the leaf nearest to the root of S is in the right subtree of S [237]). Then $a_1 = a_2 = a_3 = 1$, $a_4 = 2$, $a_5 = 4$. No explicit formula for a_n is known. Even the recurrences for the a_n are complicated, and involve auxiliary sequences. If

$$f(z) = \sum_{n=1}^{\infty} a_n z^n \tag{15.17}$$

denotes the ordinary generating function of a_n, then the combinatorially derived recurrences for the a_n show that [224]

$$f(z) = z + \frac{1}{2} f(z)^2 + \frac{1}{2} \sum_{m=1}^{\infty} g_m(z)^2 \ , \tag{15.18}$$

where the auxiliary generating functions $g_m(z)$ (which enumerate leftist trees with the leftmost leaf at distance $m-1$ from the root) satisfy

$$g_1(z) = z, \quad g_2(z) = z f(z), \quad g_{m+1}(z) = g_m(z) \left[f(z) - \sum_{j=1}^{m-1} g_j(z) \right], \quad m \geq 2 \ , \tag{15.19}$$

and

$$f(z) = \sum_{m=1}^{\infty} g_m(z) \ . \tag{15.20}$$

These generating function relations might not seem promising. If r is the smallest singularity of $f(z)$, then $\sum g_m(z)^2$ is not analytic at r, so we cannot apply Theorem 10.6 in the way it was used in Example 15.1. However, Kemp [224] has sketched a proof that the analytic behavior of $f(z)$ is of the same type as that involved in functions covered by Theorem 10.6, so that it has a dominant square root singularity, and therefore

$$a_n = \alpha c^n n^{-3/2} + O(c^n n^{-5/2}) \ , \tag{15.21}$$

where

$$\alpha = 0.250363429 \ldots , \quad c = 2.749487902 \ldots \ . \tag{15.22}$$

The constants α and c are not known explicitly in terms of other standard numbers such as π or e, but they can be computed efficiently. The $\alpha c^n n^{-3/2}$ term in (15.21) gives an approximation to a_n that is accurate to within 4% for $n = 10$, and within 0.4% for $n = 100$. Thus asymptotic methods yield an approximation to a_n which is satisfactory for many applications. Further results about leftist trees can be found in [225]. ■

15.2. Nonlinear iteration and tree parameters

Example 15.3. *Heights of binary trees.* A binary tree [DEK] is a rooted tree with unlabeled nodes, in which each node has 0 or 2 successors, and left and right successors are distinguished. The size of a binary tree is the number of internal nodes, i.e., the number of nodes with two successors. We let B_n denote the number of binary trees of size n, so that $B_0 = 1$ (by convention), $B_1 = 1$, $B_2 = 2$, $B_3 = 5, \ldots$. Let

$$B(z) = \sum_{n=0}^{\infty} B_n z^n \ . \tag{15.23}$$

Since each nonempty binary tree consists of the root and two binary trees (the left and right subtrees), we obtain the functional equation

$$B(z) = 1 + zB(z)^2 \ . \tag{15.24}$$

This implies that

$$B(z) = \frac{1 - (1 - 4z)^{1/2}}{2z} \ , \tag{15.25}$$

so that

$$B_n = \frac{1}{n+1}\binom{2n}{n} , \tag{15.26}$$

and the B_n are the Catalan numbers. The formula (4.4) (easily derivable from Stirling's formula (4.1)) shows that

$$B_n \sim \pi^{-1/2} n^{-3/2} 4^n \quad \text{as} \quad n \to \infty . \tag{15.27}$$

The height of a binary tree is the number of nodes along the longest path from the root to a leaf. The distribution of heights in binary trees of a given size does not have exact formulas like that of (15.26) for the number of binary trees of a given size. There are several problems on heights that have been answered only asymptotically, and with varying degrees of success. The most versatile approach is through recurrences on generating functions. Let $B_{h,n}$ be the number of binary trees of size n and height $\leq h$, and let

$$b_h(z) = \sum_{n=0}^{\infty} B_{h,n} z^n . \tag{15.28}$$

Then

$$b_0(z) = 0, \quad b_1(z) = 1 , \tag{15.29}$$

and an extension of the argument that led to the relation (15.24) yields

$$b_{h+1}(z) = 1 + z b_h(z)^2 , \quad h \geq 0 . \tag{15.30}$$

The $b_h(z)$ are polynomials in z of degree $2^{h-1} - 1$ for $h \geq 1$. Unfortunately there is no simple formula for them like Eq. (15.25) for $B(z)$, and one has to work with the recurrence (15.30) to obtain many of the results about heights of binary trees. Different problems involve study of the recurrence in different ranges of values of z, and the behavior of the recurrence varies drastically.

For any fixed z with $|z| \leq 1/4$, $b_h(z) \to B(z)$ as $h \to \infty$. For $|z| > 1/4$ the behavior of $b_h(z)$ is more complicated, and is a subject of of nonlinear dynamics [91]. (It is closely related to the study of the Mandelbrot set.) For any real z with $z > 1/4$, $b_h(z) \to \infty$ as $h \to \infty$. To study the distribution of the $B_{h,n}$ as n varies for h fixed, but large, it is necessary to investigate this range of rapid growth. It can be shown [133] that for any λ_1 and λ_2 with $0 < \lambda_1 < \lambda_2 < 1/2$,

$$B_{h,n} = \frac{\exp(2^{h-1}(\beta(r) - r\beta'(r)\log r))}{2^{(h-1)/2}(2\pi(r^2\beta''(r) + r\beta'(r)))^{1/2}}(1 + O(2^{-h/2})) \tag{15.31}$$

uniformly as $h, n \to \infty$ with

$$\lambda_1 < n/2^h < \lambda_2 \ , \tag{15.32}$$

where the function $\beta(x)$ is defined for $1/4 < x < \infty$ by

$$\beta(x) = \log x + \sum_{j=1}^{\infty} 2^{-j} \log\left(1 + \frac{1}{b_j(x) - 1}\right) \ , \tag{15.33}$$

and r is the unique solution in $(1/4, \infty)$ to

$$r\beta'(r) = n2^{-h+1} \ . \tag{15.34}$$

The formula (15.31) might appear circular, in that it describes the behavior of the coefficients $\beta_{h,n}$ of the polynomial $b_h(z)$ in terms of the function $\beta(z)$, which is defined by $b_h(z)$ and all the other $b_j(z)$. However, the series (15.33) for $\beta(z)$ converges rapidly, so that only the first few of the $b_h(z)$ matter in obtaining approximate answers, and computation using (15.33) is efficient. The function $\beta(z)$ is analytic in a region containing the real half-line $x > 1/4$, so the behavior of the $B_{h,n}$ is smooth. It is also known [133] that the behavior of $B_{h,n}$ as a function of n is Gaussian near the peak, which occurs at $n \sim 2^{h-1} \cdot 0.628968\ldots$. The distribution of $B_{h,n}$ is not Gaussian throughout the range (15.32), though.

The proof of the estimate (15.31) is derived from the estimate

$$b_h(z) = \exp(2^{h-1}\beta(z) - \log z)(1 + O(\exp(-\epsilon 2^h))) \ , \tag{15.35}$$

valid in a region along the half-axis $x > 1/4$. The estimates for the coefficients $B_{h,n}$ are obtained by applying the saddle point method. Because of the doubly-exponential rate of growth of $b_h(z)$ for z close to the real axis, it is easy to show that on the circle of integration, the region away from the real axis contributes a negligible amount to $B_{h,n}$. The relation (15.35) is sufficient, together with the smoothness properties of $\beta(z)$, to estimate the contribution of the integral near the real axis. To prove (15.35), one proceeds as in Example 9.7. However, greater care is required because of the complex variables that occur and the need for estimates that are uniform in the variables. The basic recurrence (15.30) shows that

$$\begin{aligned} \log b_{h+1}(z) &= 2\log b_h(z) + \log z + \log\left(1 + \frac{1}{z b_h(z)^2}\right) \\ &= 2\log b_h(z) + \log z + \log\left(1 + \frac{1}{b_{h+1}(z) - 1}\right) \ . \end{aligned} \tag{15.36}$$

Iterating this relation, we find that for $h \geq 1$,

$$\begin{aligned} \log b_{h+1}(z) &= 2^{h+1} \log b_1(z) + (2^h - 1) \log z + \sum_{k=0}^{h-1} 2^k \log \left(1 + \frac{1}{b_{h+1-k}(z) - 1} \right) \\ &= 2^h \left\{ \log z + \sum_{j=1}^{h+1} 2^{-j} \log \left(1 + \frac{1}{b_j(z) - 1} \right) \right\} - \log z \ . \end{aligned} \tag{15.37}$$

The basic equation (15.35) then follows. The technical difficulty is in establishing rigorous bounds for the error terms in the approximations. Details are presented in [133].

Most of the binary trees of a given height h are large, with about $0.3 \cdot 2^h$ internal nodes. This might give the misleading impression that most binary trees are close to the full binary tree of a similar size. However, if we consider all binary trees of a given size n, the average height is on the order of $n^{1/2}$, so that they are far from the full balanced binary trees. The methods that are used to study the average height are different from those used for trees of a fixed height. The basic approach of [133] is to let

$$H_n = \sum_{\substack{T \\ |T|=n}} \mathrm{ht}(T) \ ,$$

where the sum is over the binary trees T of size n, and $\mathrm{ht}(T)$ is the height of T. Then the average height is just H_n / B_n.

The generating function for the H_n is

$$H(z) = \sum_{n=0}^{\infty} H_n z^n = \sum_{h \geq 0} (B(z) - b_h(z)) \ , \tag{15.38}$$

and the analysis of [133] proceeds by investigating the behavior of $H(z)$ in a wedge-shaped region of the type encountered in Section 11.1. If we let

$$\epsilon(z) = (1 - 4z)^{1/2} \ , \tag{15.39}$$

$$e_h(z) = (B(z) - b_h(z))/(2B(z)) \ , \tag{15.40}$$

then the recurrence (15.30) yields

$$e_{h+1}(z) = (1 - \epsilon(z)) e_h(z) (1 - e_h(z)) \ , \quad e_0(z) = 1/2 \ . \tag{15.41}$$

Extensive analysis of this relation yields an approximation to $e_h(z)$ of the form

$$e_h(z) \approx \frac{\epsilon(z)(1 - \epsilon(z))^h}{1 - (1 - \epsilon(z))^h} \ , \tag{15.42}$$

valid for $|\epsilon(z)|$ sufficiently small, $|\mathrm{Arg}\ \epsilon(z)| < \pi/4 + \delta$ for a fixed $\delta > 0$. (The precise error terms in this approximation are complicated, and are given in [133].) This then leads to an expansion for $H(z)$ in a sector $|z - 1/4| < \alpha$, $\pi/2 - \beta < |\mathrm{Arg}(z - 1/4)| < \pi/2 + \beta$ of the form

$$H(z) = -2\log(1 - 4z) + K + O(|1 - 4z|^v) \ , \tag{15.43}$$

where v is any constant, $v < 1/4$, and K is a fixed constant. Transfer theorems of Section 11.1 now yield the asymptotic estimate

$$H_n \sim 2n^{-1}4^n \quad \text{as} \quad n \to \infty \ . \tag{15.44}$$

When we combine (15.44) with (15.27), we obtain the desired result that the average height of a binary tree of size n is $\sim 2(\pi n)^{1/2}$ as $n \to \infty$.

Distribution results about heights of binary trees can be obtained by investigating the generating functions

$$\sum_{h \geq 0} h^r (B(z) - b_h(z)) \ . \tag{15.45}$$

This procedure, carried out in [133] by using modifications of the approach sketched above for the average height, obtains asymptotics of the moments of heights. The method mentioned in Section 6.5 then leads to a determination of the distribution. However, the resulting estimates do not say much about heights far away from the mean. A more careful analysis of the behavior of $e_h(z)$ can be used [126] to show that if $x = h/(2n^{1/2})$, then

$$\frac{B_{h,n} - B_{h-1,n}}{B_n} \sim 2xn^{-1/2} \sum_{m=1}^{\infty} m^2(2m^2x^2 - 3)e^{-m^2x^2} \tag{15.46}$$

as $n, h \to \infty$, uniformly for $x = o((\log n)^{1/2})$, $x^{-1} = o((\log n)^{1/2})$.

For extremely small and large heights, different methods are used. It follows from [126] that

$$\frac{B_{h,n} - B_{h-1,n}}{B_n} \leq \exp(-c(h^2/n + n/h^2)) \tag{15.47}$$

for a constant $c > 0$, which shows that extreme heights are infrequent. (The estimates in [126] are more precise than (15.47).) Bounds of the above form for small heights are obtained in [126] by studying the behavior of the $b_h(z)$ almost on the boundary between convergence and divergence, using the methods of [399]. Let x_h be the unique positive root of $b_h(z) = 2$. Note that $B(1/4) = 2$, and each coefficient of the $b_h(z)$ is nondecreasing as $h \to \infty$. Therefore $x_2 > x_3 > \cdots > 1/4$. More effort shows [126] that x_h is approximately $1/4 + \alpha h^{-2}$ for a certain

$\alpha > 0$. This leads to an upper bound for $B_{h,n}$ by Lemma 8.1. Bounds for trees of large heights are even easier to obtain, since they only involve upper bounds for the $b_h(z) - b_{h-1}(z)$ inside the disk of convergence $|z| < 1/4$. ■

In addition to the methods of [132, 133, 126] that were mentioned above, there are also other techniques for studying heights of trees, such as those of [60, 331]. However, there are problems about obtaining fully rigorous proofs that way. (See the remarks in [126] on this topic.) Most of these methods can be extended to study related problems, such as those of diameters of trees [357].

The results of Example 15.3 can be extended to other families of trees (cf. [132, 133, 126]). What matters in obtaining results such as those of the above example are the form of the recurrences, and especially the positivity of the coefficients.

Example 15.4. *Enumeration of 2,3-trees* [300]. Height-balanced trees satisfy different functional equations than unrestricted trees, which results in different analytic behavior of the generating functions, and different asymptotics. Consider $2,3$-trees; i.e., rooted, oriented trees such that each nonleaf node has either two or three successors, and in which all root-to-leaf paths have the same length. If a_n is the number of $2,3$-trees with exactly n leaves, then $a_1 = a_2 = a_3 = a_4 = 1$, $a_5 = 2, \ldots$, and the generating function

$$f(z) = \sum_{n=1}^{\infty} a_n z^n \tag{15.48}$$

satisfies the functional equation

$$f(z) = z + f(z^2 + z^3) \ . \tag{15.49}$$

Iteration of the recurrence (15.49) leads to

$$f(z) = \sum_{k=0}^{\infty} Q_k(z) \ , \tag{15.50}$$

where $Q_0(z) = z$, $Q_{k+1}(z) = Q_k(z^2 + z^3)$, provided the series (15.50) converges. The Taylor series (15.48) converges only in $|z| < \phi^{-1}$, where $\phi = (1 + 5^{1/2})/2$ is the "golden ratio." Study of the polynomials $Q_k(z)$ shows that the expansion (15.50) converges in a region

$$D = \{z : |z| < \phi^{-1} + \delta, \ |\mathrm{Arg}(z - \phi^{-1})| > \pi/2 - \epsilon\} \tag{15.51}$$

for certain δ, $\epsilon > 0$, and that inside D,

$$f(z) = -c\log(\phi^{-1} - z) + w(\log(\phi^{-1} - z)) + O(|\phi^{-1} - z|) \ , \tag{15.52}$$

where $c = [\phi \log(4 - \phi)]^{-1}$, and $w(t)$ is a nonconstant function, analytic in a strip $|\mathrm{Im}\,(t)| < \eta$ for some $\eta > 0$, such that $w(t + \log(4 - \phi)) = w(t)$. The expression (15.52) only has to be proved in a small vicinity of ϕ^{-1} (intersected with D, of course). Since

$$Q(\phi^{-1} + \nu) = \phi^{-1} + (4 - \phi)\nu + O(|\nu|^2) \tag{15.53}$$

(so that ϕ^{-1} is a repelling fixed point of Q), behavior like that of (15.52) is to be expected, and with additional work can be rigorously shown to hold. Once the expansion (15.52) is established, singularity analysis techniques can then be applied to deduce that

$$a_n \sim \frac{\phi^n}{n} u(\log n) \quad \text{as} \quad n \to \infty \ , \tag{15.54}$$

where $u(t)$ is a positive nonconstant continuous function that satisfies $u(t) = u(t + \log(4 - \phi))$, and has mean value $(\phi \log(4 - \phi))^{-1}$. For details, see [300].

The same methods can be applied to related families of trees, such as those of B-trees. ■

The results of Example 15.3 and the generalizations mentioned above all apply only to the standard counting models, in which all trees with a fixed value of some simple property, such as size or height, are equally likely. Often, especially in computer science applications, it is necessary to study trees produced by some algorithm, and consider all outputs of this algorithm as equally likely. For example, in sorting it is natural to consider all permutations of n elements as equally probable. If random permutations are used to construct binary search trees, then the distribution of heights will be different from that in the standard model, and the two trees of maximal height will have probability of $2/n!$ of occurring. The average height turns out to be $\sim c \log n$ as $n \to \infty$, for $c = 4.311\ldots$ a certain constant given as a solution to a transcendental equation. This was shown by Devroye [92] (see also [93]) by an application of the theory of branching processes. For a detailed exposition of this method and other applications to similar problems, see [270]. The basic generating function approach that we have used in most of this chapter leads to functional iterations which have not been solved so far.

15.3. Differential and integral equations

Section 9.2 showed that differential equations arise naturally in analyzing linear recurrences of finite order with rational coefficients. There are other settings when they arise even more naturally. As is true of nonlinear iterations in the previous section and the functional equations of the next one, differential and integral equations are typically used to extract information about singularities of generating functions. We have already seen in Example 9.3 and other cases that differential equations can yield an explicit formula for the generating function, from which it is easy to deduce what the singularities are and how they affect the asymptotics of the coefficients. Most differential equations do not have a closed-form solution. However, it is often still possible to derive the necessary information about analytic behavior even when there is no explicit formula for the solution. We demonstrate this with a brief sketch of a recent analysis of this type [131]. Other examples can be found in [270].

Example 15.5. *Search costs in quadtrees* [131]. Quadtrees are a well-known data structure for multidimensional data storage [168]. Consider a d-dimensional data space, and let n points be drawn independently from the uniform distribution in the d-dimensional unit cube. We take d fixed and $n \to \infty$. Suppose that the first $n-1$ points have already been inserted into the quadtree, and let D_n be the search cost (defined as the number of internal nodes traversed) in inserting the n-th item. The result of Flajolet and Lafforgue [131] is that D_n converges in distribution to a Gaussian law when $n \to \infty$. If μ_n and σ_n denote the mean and standard deviation of D_n, respectively, then

$$\mu_n \sim 2d^{-1} \log n, \quad \sigma_n \sim d^{-1}(2 \log n)^{1/2} \quad \text{as} \quad n \to \infty \ , \tag{15.55}$$

and for all real $\alpha < \beta$, as $n \to \infty$,

$$Pr(\alpha \sigma_N < D_n - \mu_n < \beta \sigma_n) \sim (2\pi)^{-1/2} \int_\alpha^\beta \exp(-x^2/2) dx \ . \tag{15.56}$$

The results for μ_n and σ_n had been known before, and required much simpler techniques for their solution, see [270]. It was only necessary to study asymptotics of ordinary differential equations in a single variable. To obtain distribution results for search costs, it was necessary to study bivariate generating functions. The basic relation is

$$\sum_k Pr\{D_n = k\} u^k = (2^d u - 1)^{-1} (\phi_n(u) - \phi_{n-1}(u)) \ , \tag{15.57}$$

where the polynomials $\phi_n(u)$ have the bivariate generating function

$$\Phi(u,z) = \sum_{n=0}^{\infty} \phi_n(u) z^n \ . \tag{15.58}$$

which satisfies the integral equation

$$\begin{aligned}\Phi(u,z) = 1 + 2^d u \int_0^z \frac{dx_1}{x_1(1-x_1)} \int_0^{x_1} \frac{dx_2}{x_2(1-x_2)} \int_0^{x_2} \frac{dx_3}{x_3(1-x_3)} \cdots \\ \int_0^{x_{d-2}} \frac{dx_{d-1}}{x_{d-1}(1-x_{d-1})} \int_0^{x_{d-1}} \Phi(u,x_d) \frac{dx_d}{1-x_d} \ .\end{aligned} \tag{15.59}$$

This integral equation can easily be reduced to an equivalent differential equation, which is what is used in the analysis. For $d = 1$ there is an explicit solution

$$\Phi(u,z) = (1-z)^{-2u} \ , \tag{15.60}$$

which shows that D_n can be expressed in terms of Stirling numbers. This is not surprising, since for $d = 1$ the quadtree reduces to the binary search tree, for which these results were known before. For $d = 2$, $\Phi(u,z)$ can be expressed in terms of standard hypergeometric functions. However, for $d \geq 3$ there do not seem to be any explicit representations of $\Phi(u,z)$. Flajolet and Lafforgue use a singularity perturbation method to study the behavior of $\Phi(u,z)$. They start out with the differential system derivable in standard way from the differential equation associated to (15.59) (i.e., a system of d linear differential equations in z with coefficients that are rational in z). Since only values of u close to 1 are important for the distribution results, they regard u as a perturbation parameter of this system. For every fixed u, they determine the dominant singularity of the linear differential system in the variable z, using the indicial equations that are standard in this setting. It turns out that the dominant singularity is a regular one at $z = 1$, and

$$\Phi(u,z) \approx c(u)(1-z)^{-2u^{1/d}} \ , \tag{15.61}$$

at least for z and u close to 1. This behavior of $\Phi(u,z)$ is then used (in its more precise form, with explicit error terms) to deduce, through the transfer theorem methods explained in Section 11, the behavior of $\phi_n(u)$:

$$\phi_n(u) \approx c(u)\Gamma(2u^{1/d})^{-1} n^{2u^{1/d}-1} \ . \tag{15.62}$$

This form, again in a more precise formulation, is then used to deduce that the behavior of D_n is normal near its peak, and that the tails of the distribution are small. ■

15.4. Functional equations

One area that needs and undoubtedly will receive much more attention is that of complicated nonlinear relations for generating functions. Even in a single variable our knowledge is limited. Some of the work of Mahler [267, 268, 269], devoted to functions $f(z)$ satisfying equations of the form $p(f(z), f(z^g)) = 0$, where $p(u, v)$ is a polynomial, shows that it is possible to extract information about the analytic behavior of $f(z)$ near its singularities. This can then be used to study the coefficients.

Sometimes seemingly complicated functional equations do have easy solutions.

Example 15.6. *A pebbling game.* In a certain pebbling game [76], minimal configurations of size n are counted by $T_n(0)$, where $T_n(x)$ is a polynomial that satisfies $T_n(x) = 0$ for $0 \le n \le 2$, $T_3(x) = 4x + 2x^2$, and for $n \ge 3$,

$$T_{n+1}(x) = x^{-1}(1+x)^2 T_n(x) - x^{-1} T_n(0) + x T_n'(0) + n x^n \ . \tag{15.63}$$

The coefficients of $T_n(x)$ are ≥ 0, and

$$T_{n+1}(1) \le 4T_n(1) + T_n(1) + 1 \le 6T_n(1) \ , \tag{15.64}$$

so clearly each coefficient of $T_n(x)$ is $\le 6^n$, say. Let

$$f(x, y) = \sum_{n=0}^{\infty} T_n(x) y^n \ . \tag{15.65}$$

The bound on $T_n(1)$ shows that $f(x, y)$ is analytic in x and y for $|x| < 1$, $|y| < 1/6$, say, with x and y complex. Then the recurrence (15.63) leads to the functional equation

$$\begin{aligned} (x - y(1+x)^2) f(x, y) &= 2x^2(2+x)y^3 + x^2y^2(1 - 2x^2y^2)(1 - xy)^{-2} \\ &\quad - y f(0, y) + x^2 y f_x(0, y) \ , \end{aligned} \tag{15.66}$$

where $f_x(x, y)$ is the partial derivative of $f(x, y)$ with respect to x. We now differentiate the equation (15.66) with respect to x and set $x = 0$. We find that

$$(1 - 2y) f(0, y) = y f_x(0, y) \ , \tag{15.67}$$

and therefore

$$\begin{aligned} (x - y(1+x)^2) f(x, y) &= 2x^2(2+x)y^3 + x^2y^2(1 - 2x^2y^2)(1 - xy)^{-2} \\ &\quad - [y + (2y - 1)x^2] f(0, y) \ . \end{aligned} \tag{15.68}$$

When

$$x = y(1+x)^2 \ , \tag{15.69}$$

the left side of Eq. (15.68) vanishes, and Eq. (15.68) yields the value of $f(0,y)$. Now Eq. (15.69) holds for

$$x = (2y)^{-1}(1-2y \pm (1-4y)^{1/2}) \ .$$

To ensure that (15.69) holds for x and y both in a neighborhood of 0, we set

$$g(y) = (2y)^{-1}(1-2y-(1-4y)^{1/2}) \ . \tag{15.70}$$

Then $g(y) = y(1+g(y))^2$, $g(y)$ is analytic for $|y|$ small, and so substituting $x = g(y)$ in Eq. (15.68) yields

$$\begin{aligned} [y+(2y-1)g(y)^2]f(0,y) &= 2g(y)^2(2+g(y))y^3 \\ &\quad + y^2g(y)^2(1-2y^2g(y)^2)(1-yg(y))^{-2} \ . \end{aligned} \tag{15.71}$$

Thus $f(0,y)$ is an algebraic function of y. Eq. (15.71) was proved only for $|y|$ small, but it can now be used to continue $f(0,y)$ analytically to the entire complex plane with the exception of a slit from $1/4$ to infinity along the positive real axis. There is a first order pole at $y = 1/r$, with $r = 4.1478990357\ldots$ the positive root of

$$r^3 - 7r^2 + 14r - 9 = 0 \ , \tag{15.72}$$

and no other singularities in $|y| < 1/4$. Hence we obtain

$$T_n(0) = [y^n]f(0,y) = cr^n + O((4+\epsilon)^n) \tag{15.73}$$

as $n \to \infty$, for every $\epsilon > 0$, where c is an algebraic number that can be given explicitly in terms of r.

The value of $f(0,y)$ is determined by Eq. (15.71), and together with Eq. (15.68) gives $f(x,y)$ explicitly as an algebraic function of x and y. The resulting expression can then be used to determine other coefficients of the polynomials $T_n(x)$. ■

Example 15.6 was easy to present because of the special structure of the functional equation. The main trick was to work on the variety defined by Eq. (15.69), on which the main term vanishes, so that one can analyze the remaining terms. The same basic approach also works

in more complicated situations. The analysis of certain double queue systems leads to two-variable generating functions for the equilibrium probabilities that satisfy equations such as the following one, obtained by specializing the problem treated in [145]:

$$Q(z,w)f(z,w) = 2z(w-1)f(z,0) + 3w(z-1)f(0,w) \ , \tag{15.74}$$

valid for complex z and w with $|z|, |w| \le 1$, where

$$Q(z,w) = 6zw - 3w - 2z - z^2w^2 \ . \tag{15.75}$$

The generating function $f(z,w)$ is analytic in z and w. What makes this problem tractable is that on the algebraic curve in two-dimensional complex space defined by $Q(z,w) = 0$, the quantity on the right-hand side of Eq. (15.74) has to vanish, and this imposes stringent conditions on $f(z,0)$ and $f(0,w)$, which leads to their determination. Once $f(z,0)$ and $f(0,w)$ are found, $f(z,w)$ is defined by Eq. (15.74), and one can determine the asymptotics of its coefficients. Treatment of functional equations of the type (15.74) was started by Malyshev [274]. For recent work and references to other papers in this area, see [144, 145]. This approach has so far been successful only for two-variable problems with $Q(z,w)$ of low degree. Moreover, the mathematics of the solution is far deeper than that used in Example 15.6.

16. Other methods

This section mentions a variety of methods that are not covered elsewhere in this chapter but are useful in asymptotic enumeration. Most are discussed briefly, since they belong to large and well developed fields that are beyond the scope of this survey.

16.1. Permanents

Van der Waerden's conjecture, proved by Falikman [113] and Egorychev [98], can be used to obtain lower bounds for certain enumeration problems. It states that if A is an $n \times n$ matrix that is doubly stochastic (entries ≥ 0, all row and column sums equal to 1) then the permanent of A satisfies $\mathrm{per}(A) \ge n^{-n}n!$. (For most asymptotic problems it is sufficient to rely on an earlier result of T. Bang [26] and S. Friedland [148] which gives a lower bound of $\mathrm{per}(A) \ge e^{-n}$ that is worse only by a factor of $n^{1/2}$.) There is also an upper bound for permanents. Minc's conjecture, proved first by Bragman and in a simpler way by Schrijver [340] states that an

$n \times n$ matrix A with $0,1$ entries and row sums $r_1, \ldots, r_n$ has

$$\mathrm{per}(A) \le \prod_{j=1}^{n} (r_j!)^{1/r_j} \ .$$

We now show how these results can be applied.

Example 16.1. *Latin rectangles.* Suppose we are given a $k \times n$ Latin rectangle, $k < n$, so that the symbols are $1, 2, \ldots, n$, and no symbol appears twice in any row or column. In how many ways can we extend this rectangle to a $(k+1) \times n$ Latin rectangle? To get a lower bound, form an $n \times n$ matrix $B = (b_{ij})$, with $b_{ij} = 1$ if i does not appear in column j of the rectangle, and $b_{ij} = 0$ otherwise. Then the row and column sums of B are all equal to $n - k$, so $(n-k)^{-1}B$ is doubly stochastic. Therefore $\mathrm{per}(B)$, which equals the desired number of ways of extending the rectangle, is $\ge (n-k)^n n^{-n} n!$ by van der Waerden's conjecture. By Minc's conjecture, we also have $\mathrm{per}(B) \le ((n-k)!)^{n/(n-k)}$. If we let $L(k,n)$ denote the number of $k \times n$ Latin rectangles, then $L(1,n) = n!$, and the bounds derived above for the number of ways to extend any given rectangle give

$$L(k,n) \ \ge \ \prod_{j=0}^{k-1} \{(n-j)^n n^{-n} n!\} = n^{-kn} (n!)^{2n} ((n-k)!)^{-n} \ , \tag{16.1}$$

$$L(k,n) \ \le \ \prod_{j=0}^{k-1} \{(n-j)!\}^{n/(n-j)} \ . \tag{16.2}$$

Sharper estimates for $L(k,n)$ have been obtained through more powerful and complicated methods by Godsil and McKay [163]. They obtain an asymptotic relation for $L(k,n)$ that is valid for $k = o(n^{6/7})$, and improved estimates for other k. (It is known that for any fixed k, the sequence $L(k,n)$ satisfies a linear recurrence with polynomial coefficients [160].) ■

There are problems in which inequalities for permanents give the correct asymptotic estimates. One such example is presented in [318] which discusses a variation on the "problème des rencontres."

16.2. Probability theory and branching process methods

Many combinatorial enumeration results can be phrased in probabilistic language, and a few probabilistic techniques have appeared in the preceding sections. However, the stress throughout this chapter has been on elementary and generating function approaches to asymptotic enumeration problems. Probabilistic methods provide another way to approach many of

these problems. This has been appreciated more in the former Soviet Union than in the West, as can be seen in the books [240, 241, 338].

The last few years have seen a great increase in the applications of probabilistic methods to combinatorial enumeration and analysis of algorithms. Many powerful tools, such as martingales, branching processes, and Brownian motion asymptotics have been brought to bear on this topic. General introductions and references to these topics can be found in Chapter ? as well as in [5, 11, 20, 21, 27, 92, 93, 108, 258, 260, 262, 270].

16.3. Statistical physics

There is an extensive literature in mathematical physics concerned with asymptotic enumeration, especially in Ising models of statistical mechanics and percolation methods. Many of the methods are related to combinatorial enumeration. For an introduction to them, see Chapter ? or the books [30, 226].

16.4. Classical applied mathematics

There are many techniques, such as the ray method and the WKB method, that have been developed for solving differential and integral equations in what we might call classical applied mathematics. An introduction to them can be found in [31]. They are powerful, but they have the disadvantage that most of them are not rigorous, since they make assumptions about the form or the stability of the solution that are likely to be true, but have not been established. Therefore we have not presented such methods in this survey. For some examples of the nonrigorous applications of these methods to asymptotic enumeration, see the papers of Knessl and Keller [231, 232]. It is likely that with additional work, more of these methods will be rigorized, which will increase their utility.

17. Algorithmic and automated asymptotics

Deriving asymptotic expansions often involves a substantial amount of tedious work. However, much of it can now be done by computer symbolic algebra systems such as Macsyma, Maple, and Mathematica. There are many widely available packages that can compute Taylor series expansions. Several can also compute certain types of limits, and some have implemented Gosper's indefinite hypergeometric summation algorithm [171]. They ease the burden of carrying out the necessary but uninteresting parts of asymptotic analysis. They are especially

useful in the exploratory part of research, when looking for identities, formulating conjectures, or searching for counterexamples.

Much more powerful systems are being developed. Given a sequence, there are algorithms that attempt to guess the generating function of that sequence [46, 162]. It is possible to go much further than that. Many of the asymptotic results in this chapter are stated in explicit forms. As an example, the asymptotics of a linear recurrence is derived easily from the characteristic polynomial and the initial conditions, as was shown in Section 9.1. One needs to compute the roots of the characteristic polynomial, and that is precisely what computer systems do well. It is therefore possible to write programs that will derive the asymptotics behavior from the specification of the recurrence. More generally, one can analyze asymptotics of a much greater variety of generating functions. Flajolet, Salvy, and Zimmermann [124, 139] have written a powerful program for just such computations. Their system uses Maple to carry out most of the basic analytic computations. It contains a remarkable amount of automated expertise in recognizing generating functions, computing their singularities, and extracting asymptotic information about their coefficients. For example, if

$$f(z) = -\log[1 + z\log(1 - z^2)] + (1 - z^3)^{-5} + \exp(ze^z) \ , \tag{17.1}$$

then the Flajolet-Salvy-Zimmermann system can determine that the singularity of $f(z)$ that is closest to the origin is at $z = \rho$, where ρ is the smallest positive root of

$$1 = -\rho\log(1 - \rho^2) \ , \tag{17.2}$$

and then can deduce that

$$[z^n]f(z) = n^{-1}\rho^{-n} + O(n^{-2}\rho^{-n}) \quad \text{as} \quad n \to \infty \ . \tag{17.3}$$

The Flajolet-Salvy-Zimmermann system is even more powerful than indicated above, since it does not always require an explicit presentation of the generating function. Instead, often it can accept a formal description of an algorithm or data structure, derive the generating function from that, and then obtain the desired asymptotic information. For example, it can show that the average path length in a general planar tree with n nodes is

$$\frac{1}{2}\pi^{1/2}n^{3/2} + \frac{1}{2}n + O(n^{1/2}) \quad \text{as} \quad n \to \infty \ . \tag{17.4}$$

What makes systems such as that of [139] possible is the phenomenon, already mentioned in Section 6, that many common combinatorial operations on sets, such as unions and permutations, correspond in natural ways to operations on generating functions.

Further work extending that of [139] is undoubtedly going to be carried out. There are some basic limitations coming from the undecidability of even simple problems of arithmetic, which are already known to impose a limitation on the theories of indefinite integration. If we approximate a sum by an integral

$$\int_a^b x^{-\alpha} dx \ , \tag{17.5}$$

then as a next step we need to decide whether $\alpha = 1$ or not, since if $\alpha = 1$, this integral is $\log(b/a)$ (assuming $0 < a < b < \infty$), whereas if $\alpha \neq 1$, it is $(b^{1-\alpha} - a^{1-\alpha})/(1-\alpha)$. Deciding whether $\alpha = 1$ or not, when α is given implicitly or by complicated expressions, can be arbitrarily complicated. However, such difficulties are infrequent, and so one can expect substantial increase in the applicability of automated systems for asymptotic analysis.

The question of decidability of asymptotic problems and generic properties of combinatorial structures that can be specified in various logical frameworks has been treated by Compton in a series of papers [77, 78, 79]. There is the beautiful recent theory of 0-1 laws for random graphs, which says that certain (so-called first-order) properties are true with probability either 0 or 1 for random graphs. Compton proves that certain classes of asymptotic theories also have 0-1 laws, and describes general properties that have to hold for almost all random structures in certain classes. His analysis uses Tauberian theorems and Hayman admissibility to determine asymptotic behavior. For some further developments in this area, see also [35].

18. Guide to the literature

This section presents additional sources of information on asymptotic methods in enumeration and analysis of algorithms. It is not meant to be exhaustive, but is intended to be used as a guide in searching for methods and results. Many references have been presented already throughout this chapter. Here we describe only books that cover large areas relevant to our subject.

An excellent introduction to the basic asymptotic techniques is given in [175]. That book, intended to be an undergraduate textbook, is much more detailed than this chapter, and assumes no knowledge of asymptotics, but covers fewer methods. A less comprehensive and less elementary book that is oriented towards analysis of algorithms, but provides a good introduction to many asymptotic enumeration methods, is [177].

The best source from which to learn the basics of more advanced methods, including many of those covered in this chapter, is de Bruijn's book [63]. It was not intended particularly

for those interested in asymptotic enumeration, but almost all the methods in it are relevant. De Bruijn's volume is extremely clear, and provides insight into why and how various methods work.

General presentations of asymptotic methods, although usually with emphasis on applications to applied mathematics (differential equations, special functions, and so on) are available in the books [54, 100, 114, 115, 315, 344, 354, 372, 382, 385]. Integral transforms are treated extensively in [89, 95, 116, 299, 365]. Books that deal with asymptotics arising in the analysis of algorithms or probabilistic methods include [11, 55, 108, 209, 223, 240, 241, 270, 338].

Nice general introductions to combinatorial identities, generating functions, and related topics are presented in [81, 351, 377]. Further material can be found in [13, 88, 99, 173, 188, 335, 336].

A very useful book is the compilation [168]. While it does not discuss methods in too much detail, it lists a wide variety of enumerative results on algorithms and data structures, and gives references where the proofs can be found.

Last, but not least in our listing, is Knuth's three-volume work [235, 236, 237]. While it is devoted primarily to analysis of algorithms, it contains an enormous amount of material on combinatorics, especially asymptotic enumeration.

Acknowledgements

The author thanks R. Arratia, E. A. Bender, E. R. Canfield, H. Cohen, P. Flajolet, Z. Gao, D. E. Knuth, V. Privman, L. B. Richmond, E. Schmutz, N. J. A. Sloane, D. Stark, S. Tavaré, H. S. Wilf, D. Zagier and D. Zeilberger for their helpful comments on preliminary drafts of this chapter.

The rapid evolution of scholarly communication

Andrew Odlyzko
AT&T Labs – Research

ABSTRACT: Traditional journals, even those available electronically, are changing slowly. However, there is rapid evolution in scholarly communication. Usage is moving to electronic formats. In some areas, it appears that electronic versions of papers are being read about as often as the printed journal versions. Although there are serious difficulties in comparing figures from different media, the growth rates in usage of electronic scholarly information are sufficiently high that if they continue for a few years, there will be no doubt that print versions will be eclipsed. Further, much of the electronic information that is accessed is outside the formal scholarly publication process. There is also vigorous growth in forms of electronic communication that take advantage of the unique capabilities of the web, and which simply do not fit into the traditional journal publishing format. This paper presents some statistics on usage of print and electronic information. It also discusses some preliminary evidence about the changing patterns of usage. It appears that much of the online usage comes from new readers (esoteric research papers assigned in undergraduate classes, for example) and often from places that do not have access to print journals. Also, the reactions to even slight barriers to usage suggest that even high-quality scholarly papers are not irreplaceable. Readers are faced with a 'river of knowledge' that allows them to select among a multitude of sources, and to find near substitutes when necessary. To stay relevant, scholars, publishers and librarians will have to make even greater efforts to make their material easily accessible.

Andrew Odlyzko

Introduction

Traditional journals and libraries have been vital components of scholarly communication. They are evolving, but slowly. The reasons for this are discussed briefly in Section 1 and, in more detail, in Odlyzko.[1] The danger is that they might be rapidly losing their value, and could become irrelevant.

At first sight, there seems little cause for concern. Print journal subscriptions are declining, but gradually. One often hears of attrition in subscriptions of 3–5% per year. (For example, the American Physical Society, with high-quality and relatively inexpensive journals, has seen a steady decrease of about 3% per year.[2]) At those rates, it takes between 14 and 24 years to lose half the circulation. On internet time, that is almost an eternity. Preprints in most areas are still a small fraction of what gets published. Also, library usage is sometimes reported as declining, but again at modest rates. (For circulation figures for major research libraries in the US, see ARL.[3]) Yet these are not reasons for complacency. Why should there be any declines at all? Ours is an 'Information Age'; the number of people getting college and postgraduate education is growing rapidly, spending on R&D and implementation of new technologies is skyrocketing. Why should established journal subscriptions be dropping, and why should many of the recent specialized journals be regarded as successes if they reach a circulation of 300? Why should many research monographs be printed in runs smaller than the roughly 500 copies of the first edition of Copernicus's *De revolutionibus orbium coelestium* of 1543?

My conclusion is that the current scholarly information system is badly flawed, and that it does not provide the services that are required. This paper presents evidence that there is indeed a growing demand for

high-quality scholarly information, and that it can only be satisfied through easy availability on the web.

Tenopir *et al.*'s important study[4] does show that electronic resources are playing an increasing role, but current usage by established scholars is dominated by traditional media. However, it is important to look at growth rates rather than absolute numbers. In an early-1999 discussion in a librarians' mailing list, somebody pointed out that, in 1998, only 20% of the astronomy articles were submitted to Ginsparg's xxx paper archive (now called the arXiv: www.arxiv.org). An immediate rejoinder from another participant was that, while this was true, the corresponding percentage was around 7% in 1995. It is growth rates that tell us what is in our future.

This paper is only a brief attempt at finding patterns in usage of online information. What we need are careful studies, such as have been carried out for print media. (An excellent and up-to-date survey of those is presented in Tenopir and King;[5] see also a brief summary in King and Tenopir.[6]) At the moment, we do not even have much data about usage patterns online. This is especially regrettable since these patterns appear to be in the midst of substantial changes. Although the web in principle makes it possible to provide extremely detailed information about usage (and this has led to numerous privacy concerns), in practice there is little data collection and analysis, especially in scholarly publishing. Even when data are collected, they are seldom released. Thus one purpose in writing the initial draft of this paper was to stimulate further collection and dissemination of usage data. The main purpose, though, was to look for patterns, even with the scanty data that I was able to collect, to provide a starting point for further research.

We can expect the growth of online material to accelerate

Fortunately, many new studies of electronic resources have appeared very recently. Some of the notable ones will be referenced later.[4,7–11] In general, they do support most of the theses of this paper.

Some of the early studies of electronic usage, such as that in Lenares's interesting paper,[12] concentrated on faculty at leading research institutions. Change might be expected to be slow in such places. Although they usually have the resources to be pioneers, they have little incentive for it, since they do possess good libraries. The evidence to be presented later shows that the current system neglects the needs of growing ranks of scholars who are not at such institutions. Thus it is better to concentrate on usage of information that is freely available over the internet.

Later sections discuss in detail some statistics as well as some qualitative measures of usage of online resources. Here are some tentative conclusions:

1. Usage of online scholarly material is growing rapidly, and in some cases already appears to surpass the usage one could expect to see in traditional print journals. Much of the online usage appears to come from new readers (esoteric research papers assigned in undergraduate classes, for example) and often from places that do not have access to print journals. Evidence can be found in Guthrie[8] and Luther,[11] for example, and in later sections of this paper.
2. We can expect the growth of online material to accelerate, especially as the information about usage patterns becomes widely known. Until recently, scholars did not have much of an incentive for putting their works on the web, as this did not create many new readers. While we can expect that snobbery will retard this step ('I can reach the dozen top experts in my field by publishing in *Physical Review Letters*, or by sending them my preprint directly, why do I care about the great unwashed?'), the attraction of a much greater audience on the web, and the danger that anything not on the web will be neglected, are likely to become major spurs to scholars' migration of their works online. For example, a recent study[10] shows that papers in computer science that are freely available online are cited much more frequently than others. (Anderson *et al.*'s paper[7] might appear to suggest the opposite, since free online availability there was associated with lower citation frequency. However, that result is probably anomalous, in that the

freely available online-only articles in the journal under study were apparently perceived widely, even if incorrectly, as of inferior quality.)

3. The need for traditional peer review is overrated. Odlyzko[13] discusses extensively the inadequacy of conventional peer review, and how much more useful forms were likely to evolve on the internet. (That paper was written before the ascendancy of the web.) While open review and comments on published papers have been slow to take hold, something else is going on. People are coming to my web page in large numbers looking for specific papers. While in almost all cases I do not know what brings them there, it is pretty clear that they are getting pointers to the material from a variety of sources, such as bibliographies and references on other home pages. It is a form of peer review, and it brings many readers even for papers published in obscure and unrefereed places.
4. Concerns about information overload and chaos on the internet are exaggerated. While better organization of the material would surely be desirable, people are finding their way to the serious information sources in growing numbers as is.
5. Ease of access and ease of use are paramount. Material on the web is growing, and scholars, like the commercial content producers, are engaged in a 'war for the eyeballs'. Readers will settle for inferior forms of papers if those are the ones that can be reached easily.
6. Novel forms of scholarly communication are evolving that are outside the boundaries of traditional journals.

These conclusions and predictions are supported by data in the rest of this paper. It does appear that while journals are not changing fast, scholarly communication as a whole is evolving rapidly.

1. Rates of technological change

The conventional notion of 'internet time', in which technological change is accelerated tremendously, is a myth. Rapid change does occur occasionally, and the adoption of web browsers is frequently cited as an example. Less than 18 months after the release of the first preliminary version of the Mosaic browser, web transmissions constituted more than half of internet traffic. However, this was a singular exception. Cell phones, faxes and ATM machines took much longer to spread. Even on the internet, new systems are usually adopted much more slowly. How come IPv6 is still basically invisible? Why is HTTP1.1 spreading so slowly? How about TeX and its various dialects (which go back more than two decades)? Email itself took a while to diffuse, even at universities. The internet has changed much, but it has not made for a dramatic increase in the pace at which new technologies diffuse. A typical timescale for significant changes is still on the order of a decade. This was noted a long time ago:

> A modern maxim says: 'People tend to overestimate what can be done in one year and to underestimate what can be done in five or ten years'. (Licklider,[14] footnote on p. 17)

Concerns about information overload and chaos on the internet are exaggerated

Further discussion of rates of change is available in Odlyzko,[1] which presents many examples (such as music CDs, ATM machines, credit cards and cell phones) supporting the thesis that consumer adoption of new technologies is slow. (For more evidence, see also Klopfenstein[15] and the references therein.) Thus we should not be surprised if electronic scholarly communication does not turn on a dime.

The rare rapid adoptions of new technologies (aside from unusual situations such as that of the web) appear to be associated with the presence of forcing agents that can compel rapid change.[1] On the other hand, sociological changes tend to be very slow, taking a generation or two.

Aside from simply observing that, historically, new technologies have been taking of the order of a decade to be widely adopted, one can also build quantitative models that explain this time scale. Suppose we have two competing or nearly competing services, *A* and *B*. Suppose usage of *A* is static, while that of *B* increases at 50–100% per year, which in the business world

definitely qualifies as spectacular growth. One can easily imagine that *B* might not be noticed until its usage reaches 1% of the established service *A*. From the moment that 1% threshold is reached, even at growth rates of 50–100 % per year, it will take between 7 and 14 years before *B* reaches parity with *A*.

Usage of electronic forms of scholarly information has typically been growing at 50–100% per year, as is shown in various tables in this paper. On the other hand, print usage has shown little change, as far as anyone can tell. Thus the simple model above tells us that a decade is about the length of time we should expect for new modes of electronic communication to become dominant, if current growth rates continue.

2. Disruptive technologies

Even small barriers to access reduce usage significantly

Clayton Christensen's book has become a modern classic.[16] It helps explain the failure of successful organizations, such as 'Encyclopaedia Britannica', to adopt new technologies. The example of the *Britannica*,[13,17] is very instructive. It was and remains the most scholarly of the English-language encyclopaedias. However, it could not cope with the challenges posed first by inexpensive CD-ROM encyclopaedias, and more recently by the web.

What Christensen calls disruptive technologies tend to have three important characteristics:

1. initially underperform established products;
2. enable new applications for new customers;
3. performance improves rapidly.

Electronic publishing has these characteristics. Little material was available initially, screen resolution was poor, printers were not widely available and expensive, and so on. However, online material was easy to locate and access, and could provide novel features, such as the constant updating of the genome database. Moreover, costs, quality and availability have all been improving rapidly. (It should be noted that print also had these characteristics when compared with hand-written manuscripts.[18,19]) That is why direct comparisons of traditional journals or libraries with electronic collections are not directly relevant. For example, Stevens-Rayburn and Bouton's 1998 paper[20] is effective in demonstrating that the web at that time could not substitute for a regular library. It still can't, even in 2001. However, that is not the relevant question.

The mainframe was not dethroned by the PC directly. The PC could not do most of the tasks of the big machines in areas such as payroll processing. The computing power of the mainframes sold each year is still increasing, and has been increasing all along, even when IBM was going through its traumatic downsizing in the early 1990s. It is just that the PC market has been growing much faster, and the mainframe has been consigned to a small niche, and the revenues from that niche have been declining. I think this is a useful analogy to keep in mind. Traditional journals and libraries are still playing a vital role, but, 'journals are not where the interesting action is'.[1] The real issue is that, 'in this new electronic age, if it isn't online, for many purposes it might as well not exist'.[20] Further, even if it is online, it might not matter if it is not easy to access or is not timely.

3. Effects of barriers to use

Even small barriers to access reduce usage significantly. There are some wonderful statistics collected by Don King and his collaborators[21] (and Fig. 9.4 on p. 202 of Lesk,[22] reproduced from Griffiths and King[21]) which show that as the physical distance to a library increases, usage decreases dramatically. A recent statistical tidbit of a similar nature that I have collected is the reaction of the mathematicians at Penn State when all journal issues published before 1973 had to be sent to offsite storage because of space limitations. This move was widely disliked, even though any volume can be obtained within one day. The interesting thing is that the mathematical research community of about 200 faculty, visitors and graduate students asks

for only about 850 items to be recalled from storage per year. That is just over four items per person per year. It seems likely (based on extrapolations from circulation figures for bound journals that are immediately available on shelves) that usage of this material was much higher when it was easily accessible in the library in their building.

When subscriptions to journals are cancelled, articles from those journals are obtained through interlibrary loans or document delivery services. Some libraries (Louisiana State University's perhaps most prominent among them) have consciously decided to replace journal subscriptions with document delivery, after making a calculation of how much the journals cost per article read. While I do not have comprehensive statistics, my impression is that such moves save more than preliminary computations suggest. The dirty little secret behind this phenomenon is that usage of document delivery services is lower than that of journals available right on the spot. Having to fill out a request form and wait a day or a week reduces demand.

Librarians have known for a long time that ease of use is crucial. They experienced this with card catalogues, where materials whose catalogue entries were left in the paper card catalogues were not being used. Thus the current shift towards online usage had been anticipated.

> . . . there's a sense in which the journal articles prior to the inception of that electronic abstracting and indexing database may as well not exist, because they are so difficult to find. Now that we are starting to see, in libraries, full-text showing up online, I think we are very shortly going to cross a sort of critical mass boundary where those publications that are not instantly available in full-text will become kind of second-rate in a sense, not because their quality is low, but just because people will prefer the accessibility of things they can get right away. (Clifford Lynch, 1997, quoted in Stevens-Rayburn and Bouton[20])

Today, we have evidence than Lynch was correct. Note that *Encyclopaedia Britannica* has been a victim of this trend. Being the best did not protect it.

The shift to online usage is exposing many of the limitations of the traditional system. Research libraries are wonderful institutions. They provide the best service that is possible with print technology. However, in today's environment, that is not enough. Most printed scholarly papers are available typically in something like 1,000 research libraries. Those libraries are accessible to a decreasing fraction of the growing population of educated people who need them. Further, even for those scholars fortunate to be at an institution with a good library, the sizes of the collections are making material harder to access. Hours of availability are limited. Also, studies have shown that even when a book that is searched for is in a given library's collection, in about 40% of the cases it cannot be found when needed (see endnote 10 to Chapter 2 of Buckland[23] for references).

The shift to online usage is exposing many of the limitations of the traditional system

The basic problem, of course, is that it is impossible in the print world to make everything easily accessible even in the best library in the world. Space constraints mean that some material will be far from the user. In practice, most libraries can store only a tiny fraction of the material that might be of interest to their patrons. While they have been careful about selecting what seemed to be most relevant, experience shows that when easy electronic access is provided to large bodies of material not normally available in the library, there is demand for it.[11,24] That is a major factor propelling the move towards bundling of electronic journal offerings and consortium pricing.[17]

The easy access to online resources is leading to increasing usage, as will be discussed later, and is also documented elsewhere.[7,8,11,25] But not all online accesses are equal. Many scholars (including myself) use Amazon.com's search page as a first choice in doing bibliographic searches for recent books, since it is more user-friendly than the electronic catalogues of the Library of Congress, say. 'Both Academic Press and the American Institute of Physics (AIP) noted that they experienced surges in usage after they introduced new platforms that simplified navigation and access.'[11]

Ease of use has an important bearing on pricing. Odlyzko[13] predicted that pay-per-view was probably doomed to fail in scholarly publishing, because of its deterrent effect on usage. (More evidence and arguments supporting that prediction have been developed.[26,27]) Publishers have now (after experiments with PEAK and other pricing models) moved to this view as well. For example,

> [Elsevier's] goal is to give people access to as much information as possible on a flat fee/unlimited use basis. [Elsevier's] experience has been that as soon as the usage is metered on a per-article basis, there is an inhibition on use or a concern about exceeding some budget allocation.[9]

Authors like to think of their articles as precious resources that are absolutely unique

Similarly, 'Philosophically, Academic Press is opposed to a business model in which charges increase with use because it discourages use.'[11]

Easy access implies not only greater use, but also changing patterns of use. For example, a recent news story[28] discussed how the internet is altering the doctor–patient relationship. The example that opens that story is of a lady who is reluctantly told by the doctor she might have lupus, and leaves the clinic terrified of what this might be. She then proceeds to obtain information about this disease from the internet. When she returns to see a physician (a different, more pleasant one), she is well informed and prepared to question the diagnosis and possible treatment. What is remarkable about this story is that the basic approach of this patient was feasible before the arrival of the web. She could have gone to her local library, where the reference librarians would have been delighted to point her to many excellent print sources of medical information. However, few people availed themselves of such opportunities before. Now, with the easy availability of the web, we see a different story.

The arguments about effects of barriers to access and of lowering such barriers suggest that scholarly communication will undergo substantial changes. We should expect to see greater use of online material. We should also see much greater use of it by people outside the narrow disciplinary areas that produce it. Much of this use will come from outside the traditional academic and research institutions, but a considerable fraction is likely to come from other departments within an institution. Further, the increasing volume of material, as well as the decreasing role of traditional peer review, are likely to lead to greater demand for survey and handbook material. With lower barriers to interactions and access to specialized literature, we should also see more interdisciplinary work.

4. Scholarly information as a commodity

Authors like to think of their articles as precious resources that are absolutely unique and for which no substitutes can be found. Yet a more accurate picture is that any one article is just one item in a river of knowledge, and that this river is growing. Substitutes exist for almost everything. Some people interested in Fermat's Last Theorem will want, for historical or other reasons, to see Andrew Wiles's original paper.[29] Many others will be happy with a reference to where and when that paper was published, and others will be satisfied with various popular accounts of the proof. Even those interested in the technical details will often be satisfied with (and often be better served by) other presentations, such as that in the Darmon, Diamond and Taylor account of the proof.[30] Thinking about a river of knowledge instead of a collection of unique and irreplaceable nuggets helps explain why scholars manage to function even with a badly flawed information system. Even though in 40% of the cases a desired book cannot be retrieved, usually some other book covering the same topic can be found. Spending on libraries by research universities is correlated most strongly with the total budgets, and very weakly with the quality. Harvard spends about $70 million per year on its libraries, compared with $25 million spent by Princeton. Yet would anyone claim that a Harvard education or scholarly output is almost three times as good as that of Princeton?

The internet is reducing the costs of production and distribution of information.

Table 1. Library of Congress electronic resource usage statistics (For each month, shows total volume of material sent out that month, in gigabytes, and the number of requests.)

Month	GB	Requests (millions)
Feb. 1995	14.0	1.1
Feb. 1996	31.2	3.9
Feb. 1997	109.4	15.1
Feb. 1998	282.0	36.0
Feb. 1999	535.0	48.6
Feb. 2000	741.1	61.3
Feb. 2001	1202.6	86.7

As a result, there is a flood of material. Much is of low quality, but a substantial fraction is very good. The question is, are scholars using it? Before looking at that question, let us consider usage of print material.

5. Usage of print journals

We are fortunate to have an excellent recent survey of usage of print journals in the book by Carol Tenopir and Don King.[5] (A summary is presented in King and Tenopir.[6]) It shows that a typical technical paper is read (defined as not necessarily reading it carefully, but going beyond just glancing at the title and abstract) between 500 and 1500 times. These readings average about one hour in length, and in about half the cases represent the reader's first encounter with an article.

The estimate of 500–1500 readings per article is a much higher number than some earlier studies had come up with. It is based on careful studies, though. Those studies have biases that may raise the reading estimates above the true value. For example, they are based on self-reporting by technical professionals, who may overestimate their readings. (People usually report eating less chocolate and more salad than they actually consume.) Further, those figures include articles in technical journals with large circulations (such as *Science*, *Nature* and *IEEE Spectrum*) that are not typical of library holdings. If one considers library usage studies, such as those that have been carried out at the University of Wisconsin in Madison (www.wisc.edu/wendt/journals/costben.html), one comes up with somewhat lower estimates for the number of readings per paper. Still, the basic conclusion that a typical technical paper is read several hundred times appears valid.

Table 2. AT&T Labs – Research external web server statistics (Excludes most crawler activity. Number of hosts for Jan. 1997 is an estimate.)

Month	Requests	Hosts
Jan. 1997	542,644	17,886
Jan. 1998	754,477	35,943
Jan. 1999	1,204,664	67,191
Jan. 2000	1,843,319	100,077
Jan. 2001	4,190,362	178,923

The studies reported in Stevens-Rayburn and Bouton[20] also show that, in the print world, articles are usually read mostly in the first half a year after publication. Afterwards, usage drops off rapidly.

6. Growth in usage of electronic information

The internet is growing rapidly. Typical growth rates, whether of bytes of traffic on backbones, or of hosts, are of the order of 100% per year.[31,32] When one looks at usage of scholarly information online, typical growth rates are in the 50–100% range. For example, Table 1 shows the utilization of the online resources of the Library of Congress. Growth was about 100% per year for four years, and then, in 1999, it slowed down to 38%. It then increased to 62% in 2000. (These growth rates are for bytes transmitted.) Table 2 shows downloads from the AT&T Labs – Research website, www.research.att.com/, which contains a variety of papers, software, data and other technical information. The growth rate there has been around 50% per year for several years, but between 2000 and 2001, it jumped to over 120%.

It is hard to measure online activity accurately

It is hard to measure online activity accurately. The earliest and still widely used measure is that of 'hits', or requests for a file. Unfortunately, with the growth of complicated pages, that measure is harder to evaluate. When possible, I prefer to look at full article downloads. (That will be the

Table 3. Visits to Leslie Lamport's Temporal Logic of Actions web page (approximate counts)

Year	Visits	Hosts
1996	18,800	5,300
1997	19,000	5,600
1998	18,400	5,300
1999	31,100	8,000
2000	33,500	8,000

measure discussed in Sections 8 and 9 below.) Finally, as a conservative measure, one can look at the number of hosts (unique IP addresses) that requested information from a server. Even then, there are considerable uncertainties. The same person may send requests from several hosts. On the other hand, common employment of proxies and caches means that many people may hide behind a single host address, and a single download may lead to multiple users obtaining copies (as happens when papers are forwarded via email as well).

Some measures of electronic information usage are showing signs of decreasing growth

In addition to the uncertainties in interpreting the activity seen at a server, it is hard to compare data from different servers. Logs are set to record different things, and some web pages are much more complicated than others that have the same or equivalent content. Thus comparing different measures of online activity is of necessity like comparing apples, oranges, pears, bananas and onions. Some of the difficulties of such comparisons can be avoided by concentrating on rates of growth. If online information access is growing much faster than usage of print material, it will eventually dominate.

Some measures of electronic information usage are showing signs of decreasing growth, or even stability. For example, Table 3 shows utilization of Leslie Lamport's page devoted to material about a logic for specifying and reasoning about concurrent and reactive systems (www.research.digital.com/SRC/tla/). Usage had been pretty stable in 1996–1998. When I corresponded with him about this in 1999, he thought usage had reached a steady state, with the entire community interested in this esoteric technical subject already accessing the page as much as they would ever need to do. However, the final count for 1999 showed a substantial increase. The next few sections discuss data about several online information sources that are freely available on the internet.

7. Electronic journals and other organized databases

Some reports are already available on the dramatic increase in usage of scholarly information that is easily available. Traditionally, theses and dissertations have been practically invisible, and were used primarily within the institution where they were written, and even there, they were not accessed frequently. Free access to digital versions is now leading to an upsurge in usage.[33]

In the remainder of this section, as a first approximation, I will equate a full article download with a reading as measured by Don King and his collaborators.

The entire American Mathematical Society e-math system was running at about 1.2 million 'hits' per month in early 1999. The Ginsparg archive (arXiv) at Los Alamos was getting about 2 million hits per month. The netlib system of Jack Dongarra and Eric Grosse was at about 2.5 million hits per month.

By the end of 1999, usage of JSTOR was several million a month, whether one counts hits or full article downloads, and was growing at over 100% per year.[8]

The Brazilian SciELO (Scientific Electronic Library Online: www.scielo.br/scielo/scielo-an.htm) project started out in early 1998. It appears to be still going through the initial period of explosive growth, with the number of pages transmitted growing from 4,943 in Jan. 1999 to 63,695 a year later. (67,143 hosts requested pages in 1999, so it was not just a small group of users who were involved.) It is too early to tell about how fast it will continue to grow, but it seems worth listing this project to show that even the less industrialized countries are participating in making literature freely available.

Paul Ginsparg's arXiv had about 100,000 papers in early 1999, and was running at a rate of about 7 million full article downloads per year. Thus on average each article was downloaded about 70 times per year. Further, these download statistics were just for the main Los Alamos server. If we

assume that the more than a dozen mirrors collectively see as much activity as the main server, then we get a download rate of about 140 times per year per article. This is misleading, though, since it mixes old and new papers, which have different utilization patterns. If we look at download activity for arXiv articles as a function of time, we find (extrapolating very freely from data kindly supplied by Paul Ginsparg) that on average an article gets downloaded around 150 times within one year of its submission, and then 20–30 times a year in subsequent years. (In particular, even articles submitted around 1991 get downloaded that often. This is different from the pattern observed by King and other for printed journal articles. Those are read primarily in the six months after publication, and then the frequency with which they are accessed decreases.) Since this again covers just the main server, we probably should again multiply these numbers by two to get total activity. If we do that, we get into the range of readings per article that established journals experience.

The *Electronic Journal of Combinatorics* had published about 200 articles by early 1999, and had about 30,000 full article downloads from its main site each year. That is an average of 150 downloads per article. Multiplying that by two to account for the many mirror sites again gets us to about 300 downloads per article per year. (Data about distribution of downloads with time are not available.)

The general impression from the statistics quoted above is that articles in electronic archives and electronic journals may not yet be read as frequently as printed journal articles, but are getting close. On the other hand, some online sources appear to be used much more frequently than they would be in print.

8. *First Monday*

Additional evidence that online access changes scholars' reading patterns is provided by *First Monday*, 'the peer-reviewed journal of the internet' (http://firstmonday.org). Issues are made freely available on the first Monday of each month. *First Monday* started publication in May 1996. There are about 3,600 subscribers to the email notification service.

First Monday has provided me with access to the logs of their US web server from Jan. 1999 to Feb. 2000. (The data for Jan. 1999 are incomplete, since the main server was then in transition from Denmark to the US.) This is not sufficient for a careful statistical study, but some interesting patterns can be discerned in the data.

Over this period, the number of full paper downloads has grown from a range of 50,000–60,000 per month in early 1999, to between 110,000 and 120,000 per month in early 2000. Distinct hosts requesting articles have increased from 12–15,000 to over 20,000 each month. Thus the growth rate has been close to the 100% that we have seen occurs frequently on the internet. Since there are only 3,600 subscribers, this suggests many others learn of the material through word of mouth, email or other methods.

In a typical month, the largest number of downloads is to articles from that month's issue. In subsequent months, accesses to that issue drop in a pattern similar to that found by Don King in his studies of print journals. Half a year later, downloads are usually down to a quarter or even a sixth of the first month's rate. At that stage, though, the story changes. Whereas for print journals, usage continues to decrease with time, for *First Monday* it appears to increase. For example, there were 9,064 full article downloads from all the 1997 issues in Feb. 1999, and 19,378 in Feb. 2000. Thus accesses to the 1997 issues kept pace with the general growth of usage. Of the articles that were most frequently downloaded in 1999, 6 of the top 10 were published in previous years! This supports the thesis that easy online access leads to much wider usage of older materials.

articles in electronic archives and electronic journals may not yet be read as frequently as printed journal articles

9. My personal web page

Table 2 shows the statistics of the AT&T Labs – Research external web server, www.research.att.com. My personal web page, www.research.att.com/~amo, has also seen very rapid growth in usage. However, it is hard to discuss it meaningfully in a short

People are guided to web pages by a variety of cues

space, since most of the growth came from new papers in new areas. (The most frequently accessed papers on my home page are those on data networks. Then come papers on electronic publishing and electronic commerce. Those are followed by papers on cryptography, and the esoteric mathematics papers are last in frequency of access.) Instead, I will discuss some impressions from the usage patterns that I observe.

During Jan. 2000, there were 10,360 'hits' from 1,808 hosts on my home page, excluding .gif files, and hits from obvious crawlers. Most of these 1,808 hosts only looked at various index files. If we exclude those, as well as the ones that downloaded only my CV or only abstracts of papers, we are left with 656 hosts that downloaded 1,198 full copies of articles. Of those 656 hosts, 494 downloaded just a single paper. Many of those 494 requested a specific URL for an article (as opposed to looking at the home page for pointers) and then disappeared. Thus on average the people who visited my home page seemed to know what they were looking for, got it and moved on.

Visitors to my web page were remarkably quiet in the face of some obvious faults. Many of the papers posted on that page, especially old ones, are incomplete, in that they are early versions, and usually do not have figures that are present in the printed versions. Still, that occasions few complaints. As one example, about a year ago, a posting to a number theory mailing list resulted in 152 downloads of a paper in the space of less than two weeks. However, only one person complained about the lack of figures in the web version, even though they are very helpful in visualizing the behaviour shown in the paper.

Another anecdotal piece of evidence of what happens on the web: Several times I have encountered people who told me that they were really glad to meet me, as they had read my papers in one area or another, and benefited from them. Moreover, conversation showed that they indeed were familiar with the papers in question. However, they also told me that they had lost the URL, and would I please remind them where my home page was? Now it is pretty easy to find my home page on the web (my name is not a particularly common one), yet they obviously did not find it necessary to bother doing it. This, as well as the situation in the paragraph above, suggests a world of plenty. People are guided to web pages by a variety of cues, get whatever they can from those pages, and move on to other things. It is not a world of a few precious treasures that have no substitutes.

The importance of making material easily available was demonstrated in a very graphic form when I made PDF versions of my technical papers available in April 1998. There was an immediate jump in the rate of downloads. (Prior to that, mathematical papers were available only in Postscript and TeX formats, the ones on electronic publishing and related topics in Postscript and straight text.) Most PC owners do not have easy access to tools for reading Postscript papers, and were apparently bypassing the available material that required extra effort from them for reading. This is similar to observations of Academic Press and the American Institute of Physics[11] that better interfaces lead to higher usage.

The temporal pattern of article usage on my web page shows the behaviour that was already noted for arXiv and for *First Monday*. (As a matter of chronology, it was the observation about access patterns to my papers that led me to investigate the question in other online databases several years ago.) After an initial period, frequency of access does not vary with age of article, and stays pretty constant with time (after discounting for general growth in usage).

There is more evidence that easy online access leads to changes in usage patterns. For example, downloads from my home page go to a variety of sources all over the world. Some are leading to email correspondence from exotic places like Pakistan, the Philippines or Mexico. This is not surprising in itself, since those countries do have technically educated populations that are growing. What is interesting is that this correspondence predominantly refers to my papers that had been downloaded electronically (and sometimes requests copies of older papers that are not available in digital form, and which the requesters had learned

about from my home page). This does suggest strongly that easy availability is stimulating interest from a much wider audience. This conclusion is also supported by similar observations concerning correspondence with people in industrialized countries. Many come from outside the universities or large research institutions that have good libraries. They would be unlikely to read my papers in print. The referrer field on requests shows in a small fraction of cases where the requester found the URL. In many cases, such requests come from reading lists in college or graduate courses.

As a final note, there are often spikes in usage when one of my papers is mentioned in some newsletter or discussion group. For example, Bruce Schneier publishes *CRYPTO-GRAM*, a monthly email newsletter on cryptography and computer security. It has a circulation of about 20,000. In early Aug. 1999, it mentioned a recent preprint of mine (which I had not advertised much, and which has since appeared in a regular print journal). Over the next two weeks over a thousand copies were downloaded. I am convinced that this is a higher figure than the number of times the printed version will be read.

The *CRYPTO-GRAM* example as well as those of other visits to my home page suggest that informal versions of peer review are in operation. A recommendation from someone, or a reference in a paper that the reader trusts all serve to validate even unpublished preprints. Scholars pursue a variety of cues in selecting what material to access.

10. New forms of scholarly communication

A popular destination on the AT&T Labs – Research web server is my colleague Neil Sloane's 'On-Line Encyclopedia of Integer Sequences', accessible from his home page, at www.research.att.com/~njas/. In Jan. 2000, it attracted more than 6% of all the hits to the AT&T Labs – Research site (see Table 4). This 'encyclopedia' is a novel combination of a database, software and now also a new online journal. The integer sequence project enables people to find out what the next element is in a sequence such as

0, 1, 8, 78, 944, 13800, 237432, . . .

This might seem like recreational mathematics, but it is very serious, as many research papers acknowledge the assistance of Sloane's database (or, in earlier times, his books on this subject). It serves to tie mathematicians, computer scientists, physicists, chemists and engineers together, and stimulate further research. (For an account of the project, see Sloane's recent paper.[34]) It represents a novel form of communication that could not be captured in print form.

Table 4. Requests to Neil Sloane's sequence server (Hosts for 1997 estimated.)

Month	Requests	Hosts
Jan. 1997	6,646	550
Jan. 1998	33,508	2,294
Jan. 1999	58,655	3,996
Jan. 2000	135,843	7,851
Jan. 2001	222,795	11,105

Another popular site that is also a locus of mathematical activity is Steve Finch's 'Favorite Mathematical Constants' page (www.mathsoft.com/asolve/constant/constant.html). It is also showing rapid growth in usage (although one that is harder to quantify, since monitoring software was changed less than a year ago, so comparisons are harder to make). Just as with Sloane's integer sequence page, it is becoming a form of 'portal' to mathematics, one that does not fit easily into traditional publications models.

11. Conclusions and predictions

Many discussions of the future of scholarly publishing have been dominated by economic considerations. Digitization has often been seen as a solution to the 'library crisis', which forces libraries to cut down on subscriptions. So far there has been little effect in this area, as pricing trends have not changed much.[17] In the long run it has been clear that print would eventually become irrelevant, aside from any economic pressures, as it is simply too inflexible. Gutenberg's invention imprisoned scholarly

Digitization has often been seen as a solution to the 'library crisis'

Ease of access is likely to promote the natural evolution of scholarly work

publishing in a straitjacket that will eventually be discarded. However, the inertia of the scholarly publishing system is enormous, and so traditional journals have not changed much. They are in the process of migrating to the web, but operate just as they did in print. However, we are beginning to see the sprouting seeds of new ventures that will lead to new modes of operations. Still, it will be a while before they become a sizable fraction of the total scholarly publishing enterprise.

The large majority of scholarly publications are likely not to change much for several decades. However, there will be growing pressure to make them easily available. In particular, scholars are likely to press ever harder for free circulation and archiving of preprints. The realization will spread that anything not easily available on the web will be almost invisible. Whether they like it or not, scholars are engaged in a 'war for the eyeballs' just as much as commercial outfits, and ease of access will be seen as vital.

Ease of access is likely to promote the natural evolution of scholarly work. There will be more interdisciplinary research, and more survey publications. Some of these trends are beginning to appear in the data discussed in this paper, and we are likely to get more confirmations in the next few years.

FAMØS

Fagblad for Aktuar, Matematik, -Økonomi og Statistik
16. årgang, nr. 2, dec. 2002

Indhold

Velkommen

Ingen matematiker kan undgå at bemærke at det er nær jul; matematikkantinen bugner med diskontinuerte guirlander, jule-Möbius-bånd, spilteoretiske julehjerter og andet meget traditionelt julepynt.

- Med et helt semesters ny viden kan vi endelig slappe af med gode gamle FAMØS i hænderne; tabet af vore liv ville nu være et større spild end for blot et halvt år siden. Før vi dog officielt kan agte vore liv højere end tidligere, mangler naturligvis blot en påvisning af vor viden engang i Januar, til eksamen.

Men frygt ikke, thi januar er som bekendt næsten et år fra december og for tiden skriver vi netop december, så der skulle være god tid til rigtigt at nærlæse alle artiklerne i dette dejligt flappende blad. - Du kan endda lige akkurat nå at løse vor matematiker-kryds & tværs og sende den ind som en julegave til FAMØS - det ville varme vore hjerter i en sådan grad, at den behageligste løsning udløser en præmie.

Måske synes du at dit liv bevæger sig lige lukt i helvede for tiden, men det gør det ikke! - Eksaminerne er for langt væk til at de kan skues, og juleræset kan du lige så godt stå af med det samme, FAMØS er svaret! - Ta' et par blade, læg dem under juletræet, omslaget er allerede i julefarver, så du behøver end ikke at pakke dem ind! - Familien bliver ellevilde, især efter de til højtiden har afprøvet anagramhøjtlæsning over et muntert julelys. - Du vil endvidere blive en legende rundt om juletræet, hvis du ligeledes fremfører det tryllenummer Mikkel Øbro løfter sløret for om ikke mange sider.

Hvis du ikke finder din hjerne stor nok i år, kan vort blad naturligvis også supplere hertil; og således også i år redder FAMØS juletindingerne fra at sprænges. Nyd det - så længe de holder!

En tryllekunst

Mikkel Øbro

I det følgende præsenteres en ganske overbevisende tryllekunst, som nok kan tryllebinde familien over søndagskaffen eller vennerne over fredagsøllerne. Udførelsen af tryllekunsten forudsætter at man får hjælp af en kvik assistent, sædvanligvis en vimsende, letpåklædt blodine i lyserødt tylskørt.

> Et almindeligt sæt spillekort fremdrages. Publikum bedes udvælge fem tilfældige kort, se på dem og give dem til assistenten. Hun kigger på dem og lægger fire af dem på bordet – en efter en – foran tryllekunstneren. Og på forunderlig vis kan han "gætte" hvad det femte og sidste kort er.

Hvordan kan det nu lade sig gøre?

Lad os se assistenten i kortene - så at sige - og afsløre hemmeligheden bag tryllekunsten. Det gøres bedst ved at gennemgå et eksempel. Lad os sige at følgende fem kort er udtaget.

$$\clubsuit 9 \quad \spadesuit 3 \quad \diamondsuit 10 \quad \clubsuit 2 \quad \heartsuit \text{Dame}$$

Udtager man 5 kort blandt de 52 spillekort, vil der altid være to i samme kulør. I dette tilfælde $\clubsuit 9$ og $\clubsuit 2$. Vi vil gerne betragte klør-kortene som elementer i $\mathbb{Z}/13\mathbb{Z}$, så $\clubsuit n = [n]$ for $n = 2, \ldots, 10$. Derfor sætter vi

$$\clubsuit\text{Es} = [1] \quad \clubsuit\text{Knægt} = [11] \quad \clubsuit\text{Dame} = [12] \quad \clubsuit\text{Konge} = [13] = [0].$$

For ethvert par af elementer i $\mathbb{Z}/13\mathbb{Z}$ vil man altid kunne få det ene ved at lægge en restklasse mellem $[1]$ og $[6]$ til det andet. I vores tilfælde har vi givet $\clubsuit 9 = [9]$ og $\clubsuit 2 = [2]$, og $[9] + [6] = [15] = [2]$.

Assistenten vælger at lade $\clubsuit 2$ være det femte og sidste kort, dvs. det som tryllekunstneren skal gætte, og som det første kort lægger hun $\clubsuit 9$ frem på bordet.

Med de næste tre kort ønsker hun at signalere et tal mellem 1 og 6. I vores tilfælde ønsker hun at sende beskeden "6", for så ved tryllekunstneren at det sidste kort er $\clubsuit 2$, fordi $\clubsuit 9 + [6] = \clubsuit 2$. De tre kort assistenten vil lægge frem på bordet kan lægges i 3!=6 forskellige rækkefølger, og det går nu ud på at have valgt en nummerering af disse mulige rækkefølger.

På forhånd har tryllekunstneren og assistenten valgt en totalordning på de 52 spillekort. Det betyder, at når man står med tre kort i hånden, så kan man kalde det ene for *det største*, et andet for *det mindste* og det sidste for *det midterste*.

Har man valgt en totalordning, kan man lade hver af de seks forskellige rækkefølger, hvormed tre kort kan lægges, svare til et tal mellem 1 og 6.

De to optrædende har valgt følgende nummerering.

$$\begin{aligned}
1 &\sim \text{mindste}\,,\ \text{midterste}\,,\ \text{største}\\
2 &\sim \text{mindste}\,,\ \text{største}\,,\ \text{midterste}\\
3 &\sim \text{midterste}\,,\ \text{mindste}\,,\ \text{største}\\
4 &\sim \text{midterste}\,,\ \text{største}\,,\ \text{mindste}\\
5 &\sim \text{største}\,,\ \text{mindste}\,,\ \text{midterste}\\
6 &\sim \text{største}\,,\ \text{midterste}\,,\ \text{mindste}
\end{aligned}$$

Hvilken totalordning man benytter er ligegyldig, når blot tryllekunstner og assistent bruger den samme. Man kan f.eks. benytte den leksikografiske ordning på

$$\{\text{Es}, 2, \ldots, 10, \text{Knægt}, \text{Dame}, \text{Konge}\} \times \{\diamondsuit, \heartsuit, \clubsuit, \spadesuit\}.$$

Hvor $\{\text{Es}, 2, \ldots, 10, \text{Knægt}, \text{Dame}, \text{Konge}\}$ udstyres med ordningen

$$\text{Es} < 2 < \cdots < \text{Konge}$$

og $\{\diamondsuit, \heartsuit, \clubsuit, \spadesuit\}$ ordnes ved

$$\diamondsuit < \heartsuit < \clubsuit < \spadesuit.$$

På denne måde bliver f.eks.

$$\cdots < \clubsuit 2 < \spadesuit 2 < \diamondsuit 3 < \heartsuit 3 < \clubsuit 3 < \spadesuit 3 < \diamondsuit 4 < \heartsuit 4 < \cdots$$

I vores tilfælde har tryllekunstner og assistent på forhånd aftalt at benytte sig af nævnte leksikografiske ordning. Dermed er $\spadesuit 3 < \diamondsuit 10 < \heartsuit$Dame. Assistenten vil gerne signalere at tryllekunstneren skal lægge 6 til det første kort $\clubsuit 9$. Derfor lægger hun de tre kort i rækkefølgen $\heartsuit$Dame, $\diamondsuit 10$ og $\spadesuit 3$, dvs. i rækkefølgen *største, midterste, mindste*.

Og hokus pokus! Til publikums store forbløffelse kan tryllekunstneren gætte at det sidste kort er $\clubsuit 2$.

Det kan være en god ide at øve sig lidt, inden man kaster sig ud i en offentlig optræden. Her er et par opgaver. Svarene står til sidst i artiklen.

1. Kortene $\spadesuit 2$, $\diamondsuit$Knægt, $\diamondsuit 9$, $\clubsuit 7$ og $\heartsuit$Konge er trukket. Hvilke fire kort skal assistenten lægge frem på bordet og i hvilken rækkefølge?

2. Kortene ♣Dame, ♡2, ♠10, ♣6 er lagt på bordet i nævnte rækkefølge. Hvad er det sidste kort?
3. Kortene ♡10, ♠Es, ♠3, ♢Es og ♠8 er trukket. Assistenten vælger at ♠8 skal være det kort, som tryllekunstneren skal gætte. I hvilken rækkefølge skal kortene lægges?
4. De samme kort som i forrige opgave. Denne gang med ♠3 som det sidste kort.

Med lidt øvelse kan man faktisk blive ganske ferm. Bemærk i øvrigt at det i denne tryllekunst er assistenten, der skal være den kvikkeste.

Kan tryllekunsten forbedres?

De fleste mennesker i denne verden vil være tilfredse, nu hvor de kender hemmeligheden bag tryllekunsten og kan udføre den på forlangende. Men som matematiker er man ikke glad og tilfreds endnu. For man spørger sig selv, om tryllekunsten mon ikke kan forbedres. Kan man nøjes med at trække fire kort, lægge de tre frem og stadig være i stand til at gætte det sidste? Eller er det muligt at lave tryllekunsten ved at trække fem kort ud af et sæt på f.eks. 56, og ikke blot 52 som der er i et normalt sæt spillekort? I så fald skal assistenten og tryllekunstneren aftale et nyt system at lægge de udtrukne kort efter. Men hvornår er det teoretisk muligt at lave et system, så tryllekunsten kan udføres? Mere præcist:

> Der trækkes k kort fra et sæt med m kort, og der lægges $k-1$ kort ned på bordet i en rækkefølge. Hvad er den maksimale værdi af m, så det er muligt at lave et system, hvormed assistenten kan fortælle tryllekunstneren hvad det sidste kort er?

Lad os sige at M er en mængde med m elementer eller spillekort om man vil. Har man udtrukket k elementer fra M har man samtidig valgt et element α i $\mathcal{P}_k(M)$, som er mængden af delmængder af M med k elementer. Det valgte element α betegnes $\{a_1, a_2, \ldots, a_k\}$. Fra α skal man vælge $k-1$ elementer, som skal fremvises i en valgt rækkefølge. Det svarer til at vælge et element β i M^{k-1}, der opfylder $\beta = (a_{\sigma(1)}, a_{\sigma(2)}, \ldots, a_{\sigma(k-1)})$ for et eller andet σ i $S(k)$, som er gruppen af permutationer af k elementer.

At lave en afbildning $f : \mathcal{P}_k(M) \to M^{k-1}$, hvor

$$f(\{a_1, a_2, \ldots, a_k\}) = (a_{\sigma(1)}, a_{\sigma(2)}, \ldots, a_{\sigma(k-1)})$$

for et $\sigma \in S(k)$, er det samme som at udvælge $k-1$ elementer af enhver delmængde af M med k elementer, og lægge disse i en rækkefølge.

Hvis tryllekunstneren med garanti skal gætte rigtigt hver gang, så skal afbildningen f være injektiv.

Man kan hurtigt sætte en øvre grænse for m når k er givet. Skal f være injektiv, så skal der være flere elementer i den mulige billedmængde end i $\mathcal{P}_k(M)$. Den mulige billedmængde N for f i M^{k-1} består af $(k-1)$-tupler, hvor ingen af koordinaterne er ens. Derfor er

$$|N| = m \cdot (m-1) \cdots (m-k+2) = \frac{m!}{(m-k+1)!}.$$

Antallet af elementer i $\mathcal{P}_k(M)$ er

$$|\mathcal{P}_k(M)| = \binom{m}{k} = \frac{m!}{(m-k)! \cdot k!}.$$

En nødvendig betingelse for injektivitet af f bliver derfor

$$|\mathcal{P}_k(M)| \leq |N|,$$

hvoraf man får

$$m \leq k! + k - 1. \tag{1}$$

I tabellen nedenfor står listet den netop fundne øvre grænse for m givet k.

k	1	2	3	4	5	$\cdots$
$m \leq$	1	3	8	27	124	$\cdots$

Hvis betingelsen (1) er tilstrækkelig for eksistensen af den injektive afbildning f, så er det f.eks. muligt at udføre en tryllekunst, hvor der udtrækkes 5 kort ud af 124 og der lægges 4 frem på bordet. Det vil være en væsentlig forbedring af den tryllekunst, der blev beskrevet i starten af artiklen.

Om betingelsen (1) *også er tilstrækkelig er det ikke lykkedes skribenten at indse.* For $k = 1$ og $k = 2$ er det ligetil at finde en injektiv afbildning f for $m = k! + k - 1$. Med en smule arbejde er det også lykkedes at konstruere en injektiv f for $k = 3$ og $m = 8$. Men for $k = 4$ og $m = 27$ bliver det for uoverskueligt til at kunne udføre på papir. Og hvad med det generelle tilfælde $m = k! + k - 1$?

En passende afslutning på denne er artikel er derfor følgende opgave til læseren:

> **Opgave.** Find den største værdi af $m = |M|$, så der for givet k findes en injektiv afbildning $f : \mathcal{P}_k(M) \to M^{k-1}$, hvor
>
> $$f(\{a_1, a_2, \ldots, a_k\}) = (a_{\sigma(1)}, a_{\sigma(2)}, \ldots, a_{\sigma(k-1)})$$
>
> for et $\sigma \in S(k)$.

Og et passende sted at offentliggøre opgavebesvarelsen vil være i FAMØS.

Studenterkollokvierne

Sara Arklint

Efter jul er det ikke længere Mette Gerster og Lars Myrup Jensen der står for Studenterkollokvierne, da de hellere vil hellige sig deres specialer. To unge studerende, Marie Lund Christophersen og overtegnede, har meldt sig til at videreføre traditionerne – og skabe nye.

Da vi stadig ikke kender så meget til IMF's befolkning og endnu ikke har så stort et indblik i matematikkens mangfoldighed, vil vi nok ikke være i stand til selv at komme på interessante kollokviumsemner og -talere i samme grad som Mette og Lars gjorde det. Hvis der er et emne du gerne vil høre om eller en person du gerne vil høre på, må du derfor meget gerne sende os en mail om det, enten på `m02mlc@math.ku.dk` eller `m01sea@math.ku.dk`.

Selvom vi er to om at arrangere kollokvierne, kan vi sagtens være flere endnu. Så hvis du har lyst til at hjælpe med, må du også meget gerne sende en mail; der er ikke det store arbejde i det, men er vi flere, kan det blive sjovere.

Side 9-sætningen:
En sætning om partitioner

Jørn Børling Olsson

En *partition* λ af det naturlige tal n defineres som en sekvens

$$\lambda = (1^{m_1(\lambda)}, 2^{m_2(\lambda)}, \cdots, k^{m_k(\lambda)}),$$

hvor *multipliciteterne* $m_i(\lambda)$ er ikke-negative hele tal, $m_k(\lambda) > 0$ og $\sum_{i=1}^{k} i m_i(\lambda) = n$. Vi skriver så $\lambda \vdash n$, og siger at *delen* i forekommer med *multipliciteten* $m_i(\lambda)$ i λ.

Givet en partition $\lambda \vdash n$ som ovenfor defineres

$$a(\lambda) = \prod_i i^{m_i(\lambda)}$$

$$b(\lambda) = \prod_i m_i(\lambda)!$$

Så $a(\lambda)$ er produktet af alle λ's dele og $b(\lambda)$ er produktet af "fakulteterne" af multipliciteterne, der forekommer i λ.

Her er en tabel for $n = 5$:

λ :	(1^5)	$(1^3, 2)$	$(1^2, 3)$	$(1, 2^2)$	$(1, 4)$	$(2, 3)$	(5)
$a(\lambda)$:	1	2	3	4	4	6	5
$b(\lambda)$:	120	6	2	2	1	1	1

Det ses, at produkterne $A(5)$ (hhv. $B(5)$) af alle $a(\lambda)$'erne (hhv. $b(\lambda)$'erne) i tabellen er ens, nemlig 2880. Vores første sætning er, at dette er et generelt fænomen.

Sætning 1: *Lad for* $n \in \mathbb{N}$

$$A(n) = \prod_{\lambda \vdash n} a(\lambda), \;\; B(n) = \prod_{\lambda \vdash n} b(\lambda).$$

Så er $A(n) = B(n)$.

Dette resultat er blevet bemærket flere gange af forskellige matematikere og der findes også nogle beviser af forskellig natur i den matematiske litteratur. Hvis man taste de første værdier af $A(n)$ ind i Sloanes "On-Line Encyclopedia of Integer Sequences", så får man følgende svar:

This is from the On-Line Encyclopedia of Integer Sequences.
ID Number: A007870
Sequence: 1,2,6,96,2880,9953280,100329062400,10651768002183168000, ...
Name: Determinant of character table of symmetric group S_n.
References: F. W. Schmidt and R. Simion, On a partition identity,
J. Combin. Theory, A 36 (1984), 249-252.
Formula: Product of all parts of all partitions of n.

I Schmidt og Simions arbejde finder man to beviser for Sætning 1. I forbindelse med et forskningsarbejde fik jeg for nylig brug for en generalisering af Sætning 1, som jeg vil præsentere her.

Hvis t er et reelt tal betegner $\lfloor t \rfloor$ det største hele tal, der er mindre end eller lig t. Lad os for vilkårlige naturlige tal ℓ og n definere

$$r(\ell, n) = \sum_{i \geq 1} \lfloor \frac{n}{\ell^i} \rfloor,$$

og for en vilkårlig partition $\lambda = (i^{m_i(\lambda)})$ definere

$$r(\ell, \lambda) = \sum_{i \geq 1} r(\ell, m_i(\lambda)).$$

Vi bemærker, at hvis p er et *primtal*, så er $p^{r(p,n)}$ den højeste potens af p, der går op i $n!$ (Det skyldes, at i alt $\lfloor \frac{n}{p} \rfloor$ tal mellem 1 og n er delelige med p, $\lfloor \frac{n}{p^2} \rfloor$ tal er delelige med p^2, osv.)

Vi kalder λ (ℓ-)$regulr$, hvis $m_i(\lambda) = 0$, når $\ell | i$. Vores generalisering af Sætning 1 involverer for givne naturlige tal n og ℓ følgende:

$$A_\ell(n) = \prod_{\lambda \vdash n \ regulr} a(\lambda),$$

$$B_\ell(n) = \prod_{\lambda \vdash n \ regulr} b(\lambda),$$

$$r_\ell(n) = \sum_{\lambda \vdash n \ regulr} r(\ell, \lambda)\,.$$

Vi har så

Sætning 2: *Der gælder følgende formel:*

$$B_\ell(n) = A_\ell(n) \ell^{r_\ell(n)}.$$

Lad os bemærke, at hvis ℓ vælges større end n, så er alle partitioner af n regulære og $r_\ell(n) = 0$. Derfor er Sætning 2 en generalisering af Sætning 1. Når man beregner konkrete eksempler på Sætning 2's udsagn, så er det slet

ikke oplagt, hvorfor kvotienten mellem $B_\ell(n)$ og $A_\ell(n)$ bliver *en potens af* ℓ, i de tilfælde hvor ℓ ikke er et primtal. Man kan finde en relativ simpel formel for $r_\ell(n)$ udtrykt ved antallene af regulære partitioner af $n-\ell, n-2\ell, ...$

Bevis for Sætning 2: Betragt mængden $\mathcal{T}$ af tripler

$$\mathcal{T} = \{(\mu, i, j) \mid \mu \vdash n \, regulr, \; i, j \geq 1, \; m_i(\mu) \geq j\}.$$

Først vises at

$$A_\ell(n) = \prod_{(\mu,i,j)\in\mathcal{T}} i, \quad B_\ell(n) = \prod_{(\mu,i,j)\in\mathcal{T}} j.$$

Det følger fra den simple kendsgerning, at der for en fast regulær partition $\mu \vdash n$ og et fast i med $m_i(\mu) \geq 0$ gælder, at

$$(\mu, i, 1), \; (\mu, i, 2), \cdots, (\mu, i, m_i(\mu))$$

netop er listen af de elementer i $\mathcal{T}$ som begynder med μ og i. Disse $m_i(\mu)$ elementer giver et bidrag $i^{m_i(\mu)}$ til $A_\ell(n)$ (produktet af listens andenkoordinater) og et bidrag $m_i(\mu)!$ til $B_\ell(n)$ (produktet af listens trediekoordinater).

Vi definerer en involutorisk bijektion ι på $\mathcal{T}$ som følger. Når $(\mu, i, j) \in \mathcal{T}$, så vil ℓ ikke gå op i i, fordi μ er regulær. Endvidere indeholder μ ***mindst*** j dele i. Lad os skrive $j = \ell^v j'$, hvor v er et ikke-negativt heltal og $\ell \quad j'$. (Vi kalder så ℓ^v for $\ell-$***delen*** og j' for $\ell'-$***delen*** af j.) Herfter dannes partitionen $\mu_{(i,j)}$ ud fra μ ved at erstatte j dele lig med i i μ med $\ell^v i$ dele lig med j'. Vi definerer nu $\iota(\mu, i, j)$ som $(\mu_{(i,j)}, j', \ell^v i)$. Dette er igen et element i $\mathcal{T}$. Det er meget let at se, at ι^2 er den identitiske afbildning, så ι ***er*** involutorisk.

Bijektionen ι viser det andet lighedstegn i denne ligning:

$$A_\ell(n) = \prod_{(\mu,i,j)\in\mathcal{T}} i = \prod_{(\mu,i,j)\in\mathcal{T}} j',$$

hvor j' som før er $\ell'-$delen af j. Vi konkluderer, at kvotienten mellem $B_\ell(n)$ og $A_\ell(n)$ netop må være produktet af alle ℓ-dele af alle trediekoordinater af elementerne i $\mathcal{T}$. Men for en given regulær partition μ er produktet af ℓ-delene af trediekoordinaterne af alle $(\mu, i, j) \in \mathcal{T}$ netop $\ell^{r(\ell,\mu)}$.

Matematikseminaret

Katja og Malene

Vi søger nye arrangører til vores årlige seminar på matematikstudiet!

Matematikseminar er et seminar arrangeret af studerende på matematikstudiet. Seminaret henvender sig til både hoved- og bifagsstuderende i matematik på 3. år og op efter. Seminaret er oprindelig planlagt for disse studerende, da man først på 3. begynder at have valgfrie punkter.

Seminaret foregår som regel i en hytte, ikke så langt fra København, lige inden semesterstart i september. På seminaret bliver der informeret om alt fra bachelorprojekter, fagprojekter og specialer til udlandsrejser og jobmuligheder. Seminaret skulle derudover gerne give et overblik over, hvad Matematisk Institut kan tilbyde af kurser.

De fleste af forelæserne på 3. års kurserne og en del af forelæserne på overbygningskurserne vil holde et oplæg på seminaret, hvor de vil fortælle om deres kursus. Dette giver en god mulighed for at høre hvad de forskellige kurser går ud på, samt møde forelæserne inden semesterstart. Der vil ligeledes være mulighed for at møde kandidater, som har taget det store spring ud i erhvervslivet, samt andre studerende der deler ud af deres erfaringer vedr. projekter og udlandsophold.

Seminaret har ry for hyggeligt samvær, hvor man kan møde kommende studiekammerater, og ikke mindst den store fest sidste aften. Som seminararrangør skal du være med til at planlægge, forberede og afvikle selve seminaret, dvs. skaffe foredragsholdere, sælge billetter, sørge for hytte, lave madplan, arrangere fest m.m.

Som tidligere seminararrangører kan vi garantere, at det er sjovt og ikke så tidskrævende. Det kræver lidt planlægning i slutningen af semestret lige inden, da det er her, man skal tage kontakt til foredragsholderne samt sælge billetter til sine medstuderende. Derudover kræver det lidt arbejde i august måned, når de sidste detaljer skal falde på plads.

Vi har flere års erfaringer som vi selvfølgelig gerne giver videre, f.eks. madplaner, kontakter til foredragsholdere osv. Vi har i årenes løb holdt adskillige seminarmøder, nogle mere hektiske end andre, men det har nu altid været en hyggelig måde at møde andre studerende på. Seminaret har altid været en

hyggelige tur, som nok mest af alt går ud på at få nogle hyggelige dage med sine medstuderende.

Har du fået lyst til at arrangere matematikseminaret, kan du sende en mail til m99trk@math.ku.dk.

Opgaver

Sara Arklint

I hvert nummer udlover FAMØS en præmie til den der besvarer flest af de af FAMØS stillede opgaver. Vi må for god ordens skyld nu gøre det klart at redaktionsmedlemmer og disses familiemedlemmer ikke kan vinde præmierne.

Opgavebesvarelser

Vi har modtaget en besvarelse på en opgave. Opgaven gik ud på at bestemme $T, O, R, E, S, K \in \{0, \ldots, 9\}$ så $TO \cdot TRE = SEKS$ var opfyldt. Peter Arklint har sendt os 70 løsninger som han har fundet ved hjælp af SAS og følgende stump kode:

```
Data opgave;
Format t o r e s k 1.0;
Do t=0 to 9
 Do o=0 to 9
  Do r=0 to 9
   Do e = 0 to 9
    Do s = 0 to 9
     Do k= 0 to 9
      If (t*10+o)*(t*100+r*10+e)=s*1000+e*100+k*10+s
       Then output;
      End;
     End;
    End;
   End;
  End;
 End;
End;
Run;Proc Print;run;quit;
```

Vi er meget glade for Peters besvarelse af denne den letteste af de stillede opgaver; han har, ved næsten intet arbejde, vundet en rulle af Mølle-Skovlys

økologiske marcipan (den marcipan der fik højest karakter i Tænk+Tests marcipantest sidste jul).

Da Peter ikke længere kan vinde præmier (Why?), modtager vi nok ikke så mange besvarelser fra ham længere, så det ville være rart at modtage fra andre også.

Hvis du føler at FAMØS' opgaver er for lette, er du meget velkommen til at sende os en mail, og meget gerne en med opgaveforslag i. Alle er sådan set meget velkomne til at sende opgaver af alle sværhedsgrader ind, vi vil med glæde bringe dem.

Da vi ikke har fået besvarelser på de andre opgaver, og der heller ikke har været andre tegn på interesse for dem, bringer vi ikke besvarelser af dem; vi kender jo ellers alle de rigtige svar. Skulle du ønske at få et af disse svar åbenbaret, kan du kontakte FAMØS.

Nye opgaver

Hvorfor kan Peter ikke længere vinde præmier i FAMØS?
Den anden opgave kan du finde sidst i artiklen 'En tryllekunst'.

Fremtidens evaluering

Mathias Madsen og Simon Eirikson

Onsdag d. 27. november afholdt fællesmatematisk fagråd et debatmøde under titlen "Fremtidens evaluering". Temaet var evalueringen af de studerende på IMF, og anledningen var bl.a., at vi som studerende føler, at økonomien er begyndt at blive den vigtigste faktor for hvordan evalueringerne bliver udformet, og at vi har svært ved at se idéen og systemet bag de forskellige forsøg og alternative evalueringsformer, der bliver afprøvet. Vi ville derfor forsøge at etablere en kommunikation med instituttet, og spørge VIP'erne hvor vi er på vej hen, hvordan de forestiller sig fremtidens eksamens-/evalueringsformer, og hvilke erfaringer, de har gjort sig under tifligere forsøg.

Mødet var det meste af tiden en generel og principiel debat, hvor de forskellige tanker og holdninger kom fint til udtryk. Selvom den efterfølgende debat ikke ligefrem endte i enighed, udviste deltagerne langt hen af vejen en konstruktiv og åben holdning. Der var over tredive deltagere, hvoraf syv var VIP'ere og resten var studerende.

De indbudte talere var fire VIP'ere og en studerende. Jan Philip Solovej og Niels Grønbæk fortalte om deres egne erfaringer med anderledes evalueringsformer Mat 1GB og 2AN. Kjeld Bagger Laursen, som er centerleder på Center for Naturfagenes Didaktik, stod for den didaktiske vinkel på debatten. Jesper Lützen, der arbejder med implementeringen af den nye studiestruktur på IMF, holdt oplæg om perspektiverne for evaluering indenfor den nye studiestrukturs rammer.

Første taler var Jan Philip Solovej, og han samlede op på erfaringerne med de skriftlige afleveringer på Mat 1GB foråret 2002. På det kursus havde de studerende ugentligt afleveret tre til fem opgaver, hvoraf kun én blev rettet og blev tildelt en karakter. Der blev ialt stillet 10 ugeopgaver, og i slutningen af semesteret fik hver studerende udregnet gennemsnittet af sine 7 højeste opgavekarakterer. Efter mundtlig og skriftlig eksamen blev den samlede karakter udregnet som 20% af dette karaktergennemgennemsnit + 40% af karakteren for den mundtlige præstation + 40% af karakteren for den skriftlige.

Hen mod kursets afslutning (før eksamen) blev der gennemført en skriftlig evaluering af undervisningsforløbet. Her erklærede et stort flertal af de studerende, at de godt kunne leve med det benyttede system, men at de naturligvis hellere ville have rettet alle de afleverede opgaver.

Eksamensresultaterne var gode; Beståelsesprocenten var mærkbart højere end på Mat 1GB 2001, og en større andel af de studerende meldte sig til eksa-

men.

Jesper Lützen sidder i et udvalg, der beskæftiger sig med, hvordan matematikstudiet skal forme sig, når den nye studiestruktur bliver indført. Dette arbejde inkluderer også at gentænke undervisnings- og evalueringsformerne på matematik, og han opridsede i sit oplæg sin oplevelse af fortidens evalueringsformer og sine visioner for fremtidens.

Jesper Lützen berørte i sit oplæg nogle af de grundlæggende konflikter, der har præget debatten indtil nu; De studerende ved IMF har traditionelt kæmpet for frihed i læringen og retfærdighed i bedømmelsen, mens undervisere og ledelse lægger mere vægt på, at eksamenerne får de studerende til tilegne sig de relevante kompetencer og tester hvorvidt de har gjort det.

Niels Grønbæks oplæg handlede om tankerne bag og hans erfaringer med de to forsøg, han har kørt på 2AN. Det ene gik ud på, at de studerende parvis udvekslede opgaver og skulle rette hinandens skriftlige arbejde. Som gulerod fik de studerende, der deltog, lov til at blive eksamineret i et mindre pensum. Idéen var, at det skulle gøre de studerende bevidste om den kommunikative værdi i deres skriftlige arbejde og udsætte dem for en selvstændig arbejdssituation. De studerende følte sig dårligt rustet til den nye form, og forsøget medførte en storm af protester.

I det andet forsøg, som kører netop nu på 2AN, skal de studerende producere seks såkaldte temaopgaver om hver sit emne, der tilsammen berører det meste af kursets pensum. Til den mundtlige eksamen er der seks spørgsmål, der er identiske med overskrifterne på de seks temaopgaver, og de studerende eskamineres i deres egen tekst. Forsøget er blevet mødt med stor usikkerhed fra flere studerende, og nogle mener, at arbejdspresset er for stort.

En af pointerne i Niels Grønbæks oplæg var, at eksamen er et utrolig stærkt værktøj til at få de studerende til aktivt at tilegne sig viden, fordi flittigheden er nærmest grænseløs, når det handler om emner, der bliver testet. Han mente derfor, at det er vigtigt, at studenterevalueringen er konstrueret, så den bidrager til læring af brugbare kompetencer snarere end indholdstom eksamensteknik.

Dermed foregreb han Kjeld Bagger Laursens foredrag, som især kredsede om en kreativ, uortodoks og på nogle ekstremt provokerende vision han havde om hvordan et lineær algebra-kursus på matematikstudiets første semester kunne se ud i en ikke så fjern fremtid. Dette forslag inkluderede bl.a. skemalagte læse-/diskussionstimer, opprioritering af gruppearbejde og opgaveløsning og nedprioritering af forelæsningens rolle som kernen i et kursus. Som evalueringsform forestillede han sig løbende opgaveregning og en lille skriftlig eksamen i opgaveregning og tekstforståelse.

"Man må udtale explicit, hvad man ønsker de studerende skal lære og honorere dem, når de lærer det," sagde Kjeld Bagger og formulerede dermed grundtanken bag sit eksotiske "Mat 1GA".

Herefter holdt de studerendes repræsentant i studienævnet, Esben Flachs,

et oplæg om sin holdning til obligatorisk arbejde på matematikstudiet. Oplægget stod i en skærende kontrast til Kjeld Baggers forestilling om evaluering som undervisernes værktøj til at holde de studerende fast i et fornuftigt studiemønster. Bl.a. udtalte Esben, at et kendetegn ved universitetsundervisning i modsætning til skole-undervisning netop burde være, at de studerende selv har ansvaret for deres studier og muligheden for at læse på den måde, de selv følte var mest givende.

Hermed var bolden givet op til et tema, som kom til at præge debatmødet, nemlig spørgsmålet om de studerendes frihed til selv at vælge studieteknik. Fælles for de forslag, som VIP'erne præsenterede, var nemlig, at de forsøgte at tænke evalueringen mere ind i undervisningsforløbet end tilfældet er med den traditionelle summative knald-eller-fald-apokalyptiske sluteksamen. Flere studerende stejlede over denne tankegang, fordi de følte deres frihed i studiet ville blive krænket.

Denne holdning blev der sat store spørgsmålstegn ved fra VIP'ernes side. Niels Grønbæk hævdede, at debatten om frihed i studiet mest bliver rejst af de ressourcestærke studerende og at han er nervøs for, at der er et stort tavst flertal med andre, uartikulerede behov. Kjeld Bagger Laursen mente ligefrem, at idéen om "det frie studium" var en måde at kaste ansvaret af sig fra de studerendes side.

I den efterfølgende debat blev et par kæpheste luftet, og den debatten om obligatoriske opgaver eller ej blev vendt adskillige gange.

Søren Eilers refererede til et tidligere system på Mat 1, hvor de studerende havde mulighed for at aflevere ikke-obligatoriske opgaver. Kun ca. 25% af hver øvelseshold benyttede sig af denne mulighed, og det var typisk netop de personer som kunne deres stof og derfor ikke havde behov for at aflevere opgaver. "Vi tænkte: 'Hvorfor benytter de sig ikke af denne enestående mulighed?'," sagde Søren Eilers. Studieleder Jens Hugger udtalte om et andet kursus: "Hvis de studerende ikke regner opgaver, består de ikke. Hvis opgaverne ikke er obligatoriske, regner de dem ikke. Derfor gjorde vi opgaverne obligatoriske."

Esben havde svært ved at få øje på de studerendes ansvar for egen læring: "Vi har obligatoriske opgaver helt op til 3GT. Hvornår træder studiefriheden ind?"

Debatten ledte ikke til nogen endegyldig konklusion, sandsynligvis fordi underviserne og de studerende i realiteten ikke var enige om, hvad de diskuterede. Der kom imidlertid mange argumenter og personlige oplevelser på bordet, og eksmpelmaterialet var jo så at sige selv tilstede.

Debatmødet svingede mellem de visionære, pædagogiske idéer og de konkrete, politiske diskussioner. Selv om mødet ikke får nogle umiddelbare konsekvenser for studiet, har det forhåbentlig sat gang i tanker på bagge sider af bordet, og det kan blive starten på en fremtidig debat præget af samtale og kreativitet snarere end skyttegravskrig og snæversynethed.

Sierpinski problemet

Tarje Bargheer

Jorden vrimler med mennesker som forsøger at konstruere og bevise nye matematiske sætninger. For at opnå denne, for mange, store drøm vil en standardmetode være at tage hænderne ned i noget god og saftig matematisk muld; mens man nøje føler efter hvad der måtte springe frem af sammenhænge heri. Så snart man syner en sammenhæng begynde at spire frem af muldet, skal man skynde sig at formulere en påstand. Det eneste der mangler for at man selv kan tilføre matematikken det ønskede liv, er den store forkromede idé der beviser hele påstanden.

Sådan er det bare ikke altid! - Nogen gange kan man selvfølgelig ikke få ideen, andre gange finder man modeksempler til nok så plausible påstande, men helt andre gange er det simpelthen pure matematisk dovenskab, der gør at sandheden ikke kommer frem:

I 1960 beviste polakken Waclaw Sierpinski at der findes uendeligt mange følger af formen $(x_n)_{n=1}^{\infty} = k \cdot 2^n + 1, k$ fast, hvor alle x_n er sammensatte tal (altså ikke primtal). Et k der gør følgen primtalsfri kalder vi, med sædvanlig matematisk selvhøjtidelighed, for et Sierpinski tal.

Sætningen virker for så vidt ganske lille og uskyldig, havde det ikke været for John Selfridge der to år senere beviste at et eksempel på en sådan primtalsfri følge er $x_n = 78557 \cdot 2^n + 1$, og derudover havde han den frækhed at påstå at $k = 78557$ er det mindste Sierpinski tal.

For at bevise at denne påstand er sand kræves ingen gode ideer, blot en usandsynligt stor mængde papirer og blyanter; man skal nemlig bevæge sig op igennem samtlige følger med $k < 78557$, indtil man støder på et primtal (man kan dog undlade de lige tal, da et lige tal er 2 i en eller anden potens gange et ulige tal, og har man elimineret alle de følger med ulige k-værdi, kan man således opnå alle lige tal ved at gange med 2 tilstrækkeligt mange gange(fx. $6 \cdot 2^n + 1 = 3 \cdot 2^{n+1} + 1$, og $n = 1$ giver 13)). Selvom der, for den troende, kun er endeligt mange tal at tjecke igennem, er der ikke nogen matematiker der har orket at sætte sig ned for at løbe alle følgerne igennem og primteste de enorme tal der lige så stille opstår når n bevæger sig opad. - Matematisk Institut ville nok også hurtigt blive lukket af en vred regering, hvis man satte alle professorer og studerende til at arbejde på dette problem indtil det blev bevist!

Heldigvis er der håb for at den kære påstand kan komme ud af usikkerhedens dunkle tåger - Selvom man har vægtet det menneskelige liv højere end

viden om sætningens sandhedsværdi, har man (endnu) ikke samme store medfølelse for vore logisk begavede idioter. - Computere har knoklet på at løse problemet i de fyrre år som påstanden nu har stået ubevist hen!

Og computerne har arbejdet godt for sig, tilbage er nu kun at finde primtal i femten følger, før computere får føjet endnu et bevis, til deres liste; to af følgerne er blevet elimineret inden for den seneste uge, det har nemlig vist sig d. 27/11 - 2002 at tallet $46157 \cdot 2^{698207} + 1$ er et primtal, og d. 3/12 - 2002 at $65567 \cdot 2^{1013803} + 1$ ligeledes er et primtal; bemærk at disse tal er så store at deres decimalfremstilling ville fylde omkring hundrede normalsider; altså hvad der, hvis vi kan finde et tilstrækkeligt postmodernistisk forlag, bliver til en mindre roman! - Et tal af den kaliber kræver en usandsynligt stor regnekraft for at finde ud af om det er et primtal. - Derfor er det, i dette tilfælde, heldigt at verden netop har mange computere!

Måske har du også en computer derhejemme, og så har du muligheden for at sætte den til at deltage i jagten på sandheden. - På `www.seventeenorbust-.com`, kan man downloade et program (til, næsten, det styresystem du måtte ønske) der henter et muligt primtal fra en server i Amerika og herefter bruger den tid hvor din computer alligevel ville have CPU-tid ledigt til at arbejde på at finde ud af om tallet virkeligt er et primtal eller ej! Hjemmecomputere verden over står ofte tændt i længere perioder og bruger enormt meget af denne tid på at føre meningsløse dialoger (selv når man kører andre programmer) med sig selv til ingen anden nytte end at computeren til sidst bliver bange for sin egen sjæl.

`www.seventeenorbust.com` har delt tal ud til hele verden i nu otte måneder, men har dog kun fundet de to nævnte primtal indtil videre (de begynder dog, som man kan se på datoerne at dukke frem)! - Der ligger højst sandsynligt femten primtal mere derude, som bare venter på at måske din computer vækker dem til live!

Grunden til at så mange mennesker har hentet programmet er naturligvis håbet om at netop de er så heldige at finde et primtal (det tager for en almidelig hjemmecomputer en dag at teste om et tal er et primtal, så man kommer til at føle det lidt som om man har vundet i Lotto, hvis man finder et primtal), uden selv at have rørt en finger (da computeren kun udnytter, hvad der ellers havde været spildtid, har man heller ikke lidt under en langsommere computer)!- Som en særlig social gestus, kan man søge i flok, med mennesker man føler sig særligt knyttet til. Af særlig relevans for læsere af FAMØS er nok holdet `CampusHafnia`, der samler folk fra Københavns Universitet.

Denne, i mine øjne, meget sympatiske praksis med at lade hjemmecomputere arbejde på gigantiske datamængder, og således bidrage til forskningen, er ved at blive mere og mere populær. Af andre projekter som `www.seventeen-orbust.com` kan nævnes et projekt der undersøger om jorden skulle modtage tegn på intelligent liv fra andre steder end vores egen planet, forsøg på at finde en kur mod AIDS, samt at forudsige klimaet om 50 år! - Således er det

beskrevne problem altså kun et eksempel (med en vis relevans for matematikere) på hvad man kan sætte sin computer til at arbejde på af mere eller mindre absurde ting. For et bredere udsyn over hvordan du kan bruge den seje datakværn, der nok også står i dit hjem, til noget meningsfyldt, kan du besøge
`www.aspenleaf.com/distributed`.

OBS! Kort inden deadline havde `seventeenorbust.com` fundet at $44131 \cdot 2^{995972} + 1$ også er et primtal, og har således følger nu kun 14 følger. - Er en ny triologi, op ad tidens trend, på trapperne?

30: Den åbne kurvesammenhængende mængde

31: Delmængden af universet

Numerisk Analyse og lidt om Matematisk Modellering

Eva Willerslev

Forestil dig, at du står med et matematisk problem, som du ikke kan løse analytisk eller som er meget svært at løse. Det kan dreje sig om en *matematisk model*, som beskriver en eller anden kompleks sammenhæng fra den virkelige verden. Du har altså været stillet overfor et eller andet praktisk problem, som kræver en matematisk løsning. Du har brugt al din kreativitet til at afgrænse problemet og fastsætte variabler, uafhængige såvel som afhængige, og parametre, hvis talværdi du måske kan få oplyst eller beregne. Du har tænkt dig frem til variablenes indbyrdes relationer og opstillet de relevante ligninger. Nu står du så med en gigantisk model, som du ikke har nogen jordisk chance for at løse analytisk. Måske har modellen slet ikke en generel løsning. Det betyder, at du må bruge numeriske metoder, dvs. søge en god tilnærmelse til en løsning vha. numeriske (talmæssige) beregninger. Hvis det iøvrigt er en fornuftig og matematisk sund model, du arbejder med, vil du være istand til at bestemme en numerisk løsning, som giver dig svaret på det oprindelige, praktiske problem. Det er simpelthen dette, der er formålet med *numerisk analyse*.

Numeriske Algoritmer

Kernen i den *numeriske analyse* er selve udviklingen og den nøjere undersøgelse af de metoder, kaldet numeriske algoritmer, der kan bruges til at approksimere løsninger til ellers håbløse matematiske problemer. Det er også metoder, der kan bruges til at studere, hvordan særligt komplekse systemer opfører sig, når man f.eks. går ind og ændrer i parameterværdierne. Her vil jeg sige lidt om nogle af de mest brugte metoder.

Vi er vant til fra den rene matematik, at en funktion er kendt og veldefineret på hele sit domæne. Sådan er det ikke nødvendigvis i anvendt matematik. Her kan det forekomme, at en funktions værdier kun er kendt i nogle enkelte punkter. Det kan handle om nogle datapunkter stammende fra målinger eller observationer i felten. Eventuelt kan man være så heldig, at disse datapunkter sammen med ens viden iøvrigt om funktionssammenhængen er tilstrækkeligt til at bestemme alle de ukendte parametre og dermed opstille et numerisk udtryk for funktionen. Hvis funktionen for eksempel vides at skulle beskrive en logistisk vækst, da vil man søge det logistiske udtryk

for den, som bringer den tættest muligt på flest mulige datapunkter. Her vil man ofte søge at at minimere summen af kvadraterne på fejlene ved en metode kaldet *least squares error*. Ved man imidlertid ikke, hvilken type vækst eller udvikling funktionen beskriver, må man benytte en metode kaldet *interpolation* eller *datafitning* til at approksimere den. Det handler om at bestemme en funktion, som ikke blot går igennem de givne punkter, men som også følger den trend, som punkterne udstikker. Det mest almindelige er at interpolere med polynomier eller splines, som er glatte, stykkevis polynomiumsfunktioner. Når man søger funktionsværdier *udenfor* det domæne, som datapunkterne afgrænser, kaldes det *extrapolation*. Her er man ovre i prognoserne og naturligvis på mere usikker grund.

Størrelser, som ikke kan beregnes analytisk, må erstattes med numeriske approksimationer. Eksempelvis vil et bestemt integrale, som ikke har nogen analytisk løsning kunne tilnærmes ved hjælp af såkaldt *numerisk integration*, som i princippet er en endelig summation af funktionsværdier. Den afledede i et punkt kan tilnærmes med en differenskvotient, og det kan sammen med interpolation bruges til at bestemme hvad der svarer til den afledede af en funktion i et begrænset interval. Dette kaldes *numerisk differentiation*. Der er udviklet mange forskellige sådanne differentiations- og integrationsmetoder. De indgår som hovedbestanddele i de større algoritmer, der bruges på differentialligninger og randværdiproblemer. Visse typer af differentialligninger løses dog bedst ved den såkaldte *endelige differens metode*, hvor differentialligningen erstattes med en eller flere differensligninger. Hvilken metode og hvilken intervalindeling, man vælger, beror dels på det aktuelle problem og dels på hvor stor en fejl i løsningen, man er villig til at tolerere, og hvor meget tid eller computerregnekraft, man vil bruge. Jeg vender tilbage til denne problematik i afsnittet om den numeriske fejlanalyse.

Lineære ligningssystemer løses på den almindelige algebraiske facon med f.eks. *Gauss-elimination*. Men hvad er nu det særligt numeriske ved det? Jo, lad os sige at ligningssystemet faktisk er en matematisk model af et eller andet fysisk system. Så vil der, blandt andet på grund af måleusikkerheden, uundgåeligt være nogle ganske små fejl i de indgående parametre. Af denne grund har systemet ikke nogen egentlig analytisk løsning. Det vil Gauss-eliminationen vise. Havde der nu været tale om et rent matematisk problem, så ville man sige, at det var forkert stillet, fordi det ikke kan løses. Her vil man imidlertid være tilfreds med en næsten-løsning, fordi man gerne vil tillade den lille fejl i modellen at medføre en lille fejl i løsningen.

Systemer af ikke-lineære ligninger kan ofte løses effektivt ved *iteration*. Det handler om, at man ved gentagen indsættelse i samme ligningssystem opnår stadigt bedre og bedre approksimationer til løsningen. Endelig skal omtales *numerisk optimering*, der ofte involverer løsninger af såvel lineære som ikke-lineære systemer ved iteration.

Computeren
Når ens matematiske model er bragt på en form, hvor den kan løses med numeriske metoder, og man har opskrevet en passende algoritme som forhåbentlig løser problemet, så er næste skridt at implementere hele molevitten i et matematikprogram. Fordelen ved dette er selvfølgelig dels, at man kan udnytte computerens regnekraft til at eksperimentere med algoritmen, uden at skulle bruge en mennskealder på de ofte uhyggelig mange funktionsevalueringer. Og dels er det jo en stor fordel, at kunne gemme og genbruge algoritmen på et senere tidspunkt, for det kan godt være et større arbejde at skrive den op.

De mest brugte matematikprogrammer her på instituttet er vist nok *mathematica*, *maple* og *matlab*. Jeg tør selv stå inde for, at det godt kan lade sig gøre at lære at bruge *matlab*, uden at man på forhånd er en ørn til computere. Og det er sjovt nok meget forfriskende og anderledes at opleve matematikken indefra denne computerverden. På HCØ finder du *matlab* på serveren af navn *shannon*. Gå ind på den og skriv *matlab* i promten, så kommer det frem. Der er en udmærket hjælpefil, som hjælper en med at komme i gang og hvor man finder svar på alle spørgsmål. Men hvis man virkelig vil lære at bruge *matlab* eller et af de andre programmer, er det allerbedste selvfølgelig at følge et kursus eller læse en bog, som bruger dette program aktivt. Ønsker man *matlab* hjemme, kan studenterversionen erhverves direkte fra producenten *mathworks* for ca. 1000 kroner.

Fejlanalyse
Flere fejlkilder kan influere på den numeriske løsning af en given matematisk model. Lad os sige, at modellen er korrekt opstillet. Måske tager den ikke højde for alle faktorer og udgør dermed et forsimplet billede af den virkelige (fysiske, biologiske, sociale, økonomiske,...) situation, men den er så god den kan være uden at blive helt uoverskuelig. For at vurdere de parametre, der indgår i modellen, vil man være afhængig af et vist datamateriale, altså nogle konkrete målinger eller observationer. Disse kan meget nemt være behæftede med fejl, f.eks. på grund af måleusikkerheden. Dette er den første fejlkilde, som også omfatter indtastningsfejl og andre menneskelige fejl ved målingerne. Hvilket får en til at tænke på, at modelløren, matematikeren, nemt kan komme til at regne galt et sted eller bruge en uegnet metode. Dette er den anden fejlkilde. Begge kan selvsagt være helt ødelæggende for den endelige

løsning, og man kan kun anstrenge sig for at opdage disse fejl i tide og undgå eller minimere dem.

Den tredie kilde til fejl i beregningerne skyldes simpelthen *afrunding*. De fleste tal har jo uendelige decimalrepræsentationer, som må rundes af. Lommeregnerne og matematikprogrammer regner med 15-16 decimaler, hvad man umiddelbart skulle tro gav en fin præcision for de fleste formål. Men multiplikation med meget små tal kan gå hen og ødelægge præcisionen, så ikke engang de første decimaler er pålidelige. Det må man passe på med.

Endelig er der *trunkeringsfejlene*, som udgør den fjerde og ofte den største fejlkilde. Det er de fejl, der uundgåeligt er forbundet med regning med tilnærmede værdier eller mao. de fejl, der ligger implicit i selve de numeriske metoder. Navnet kommer af det engelske "truncate", som betyder afskære eller lemlæste, idet man jo egentlig lemlæster de uendeligdimensionale, analytiske metoder og gør dem til endeligdimensionale, numeriske metoder.

Man stræber selvfølgelig altid efter, at algoritmen skal være både pålidelig, præcis og effektiv. Pålideligheden er en ting. Det handler om, at algoritmen skal *konvergere* imod løsningen. Den må simpelthen ikke løbe løbsk i en gal retning. Den må for eksempel ikke nærme sig et lokalt ekstremum, hvis det er det globale, man er ude efter. Det er selvsagt meget vigtigt at analysere en algoritmes konvergensegenskaber. Man vil f.eks. gerne vide, hvor hurtigt algoritmen konvergerer i forhold til den valgte skridtlængde eller antallet af funktionsevalueringer.

Ambitionen om præcision mht. de tilnærmede værdier og ambitionen om effektivitet mht. anvendt regnekraft er desværre modsat rettede. Der er tale om en balancegang, idet stor præcision ofte koster dyrt mht. antal funtionsevalueringer, dvs. algoritmen arbejder langsomt og er altså mindre effektiv. Forvirrende nok vil alt for mange funktionsevalueringer virke negativt på præcisionen. Der sker nemlig det, at den totale fejl, som er summen af trunkerings- og afrundingsfejlene, for et stigende antal beregninger først vil aftage og siden stige igen. Et sted på vejen er den totale fejl altså mindst mulig. Derfor er det også af største betydning for den numeriske analytiker at kunne estimere såvel afrundingsfejlene som trunkeringsfejlene i de enkelte algoritmer. For eksempel ønsker man at vide, om en lille fejl på begyndelsesbetingelsen i en differentialligning også kun giver en lille fejl på den tilnærmede løsning. Er dette tilfældet kaldes problemet for *well-conditioned*. Et problem kaldes for *well-posed*, dersom man har mulighed for at gøre fejlen i løsningen så lille, man ønsker.

Opdag anvendt matematik

Det er en oplagt mulighed at lære noget om *numerisk analyse*, og herigennem noget om matematisk modellering, samtidig med at man lærer at bruge computeren til mere end bare tekstbehandling. Jeg vil virkelig opfordre mine medstuderende til at tage chancen mens den er der. Hvis du først opdager computeren og den anvendte matematik, når du er ved at være færdig, kan det være for sent, for så skal tiden og resten af punkterne pludselig bruges på specialet.

Det skal understreges, at selv om *numerisk analyse* i grunden er en *approksimationsteori*, så er den solidt funderet i den eksakte matematiske analyse, hvorfra den henter sine redskaber, bevisteknikker osv. Men den er typisk en gren, man ærger sig over at have opdaget for sent. Fordi den giver den ekstra dimension at kunne bruge den rene matematik til at løse problemer indenfor alle mulige andre felter. Man risikerer til og med at få et større udsyn.

Her til sidst vil jeg blot ganske kort omtale nogle andre grene af matematikken, som er beslægtede med *numerisk analyse*. Det drejer sig dels om *operationsanalyse*, der beskæftiger sig med strukturering og optimering af organisatoriske problemer. Det er selvsagt et emne af stor praktisk betydning og en meget spændende måde at bruge matematikken på. Dels drejer det sig om *differentialligninger*, som det også er kollosalt nyttigt at lære om, fordi de simpelthen bruges overalt i den anvendte matematik. Det er jo i bund og grund anvendelserne, som er selve meningen med matematikken.

Litteratur

F.R.Giordano, M.D.Weir og W.P.Fox, *A First Course in Mathematical Modeling*, 3.ed., Brooks/Cole-Thomson Learning, USA, 2003.

G.Lindfield og J.Penny, *Numerical Analysis using Matlab*, 2.ed., Prentice Hall, USA, 2000.

Der er skrevet bunker af bøger om matematisk modellering og numerisk analyse, men her er i hvert tilfælde to, jeg godt kan anbefale. Den første giver en lærerig rundtur i matematikkens mange og højst forskelligartede anvendelser. Du kan godt regne med at blive overrasket et par gange under læsningen. Den anden giver en letfattelig introduktion til *numerisk analyse* og simpel, matematisk programmering. Du må ikke lade dig skræmme af, at matematikken ikke er så svær i disse to bøger. Glæd dig i stedet for over at kunne forstå tingene til bunds for en gangs skyld.

Sagaen er vor jammer!!!

Mrs. dat-kranium og Darwin: Stenet hash-imam

Indledning

Nærværende artikel er et resultat af en håndfuld personers totale fravær af fornuft og manglende evne til at afholde sig fra at dedikere 30 til 50 % af al forelæsningstid til produktion af anagrammer. Enhver jordforbindelse er utilsigtet og tilfældig. Forfatterne tager ikke ansvar for evt. legemlig eller psykisk skade pådraget under læsningen.

definitioner og notation

Lad to endelige sproglige udtryk A og B være givet. Uagtet konsekvenserne af vores handlinger indfører vi følgende definition:

$$A \sim B \qquad \Longleftrightarrow \qquad \exists\,(\sigma : A \cap \text{alfabetet}^{(\mathbb{N})} \mapsto B \cap \text{alfabetet}^{(\mathbb{N})}), \text{ så } \sigma \text{ er bijektiv.}$$

Denne tilsyneladende fredelige ækvivalensrelation skal vise sig at føre til nogle overraskende resultater.

Generel lektorteori

Selv når vi restringerer vores undersøgelse til det videnskabelige personale på IMF, springer myriader af ækvivalenser i øjnene. Vi nævner i flæng:

$$\begin{aligned}
\text{Flemming Topsøe} &\sim \text{Menig poet-smølf} && (1)\\
\text{Gunnar Forst} &\sim \text{Ung, tror fans} && (2)\\
\text{Christian Berg} &\sim \text{Hent ribs, cigar} && (3)\\
&\sim \text{Grib is-te-ranch}^{1}\\
\text{Kjeld Bagger Laursen} &\sim \text{Guld-egenskab: Er jarl} && (4)\\
&\sim \text{Brugsklar jadeengel}^{2}\\
&\sim \text{Sej ulk, algebradreng.}
\end{aligned}$$

Følgende lemma vil afsløre en sandhed om Niels Grønbæks undervisning. Bemærk den indirekte bevisteknik, hvori vi benytter os af først en mere madvareorienteret beskrivelse af Niels Grønbæk, derefter en overvejende matematisk og til sidst undervisningsmæssig.

Lemma 1. *Niels Grønbæk* $\sim$ *Skøn belæring.*

Bevis:

$$\begin{aligned} \text{Niels Grønbæk} &\sim \text{Bønne, gær, slik} \\ &\sim \text{Løg nær biksen} \\ &\sim \text{Læs ingen brøk}^{3} \\ &\sim \text{Binær løgn, ske!}^{4} \\ &\sim \text{Løbsk geni nær} \\ &\sim \text{Skøn belæring.} \end{aligned}$$

□

Matematiske anvendelser

Besidder ens mødrene ophav ingen matematiske færdigheder, samtidig med at hun nærer et brændende ønske om at vide mere om vektorrumsbaser af ortogonale enhedsvektorer kan man jo blot henvise til

Sætning 2. *(Annagramteoriens fundamentalsætning)*

Gram-Schmidt orthonormalisering $\sim$ "Grim retro-masochist-handling, mor".

Ellers fortæl om

$$\begin{aligned} \text{Cantors mængde} &\sim \text{Arg dæmons cent} \\ &\sim \text{Score tang-mænd} \\ &\sim \texttt{Rand-gæsten.com} \\ &\sim \text{"Dang, censor, mæt".} \end{aligned}$$

Sidstnævnte sætning kan man jo evt. også fremsige, hvis man i frokostpausen mellem eksaminationerne vitterlig ikke kan spise mere.

[1] Såfremt man lige har en sådan læskedriks-gård ved hånden
[2] Instant engel: Unwrap og du kan bruge ham sporenstregs
[3] matematisk opfordring 1
[4] matematisk opfordring 2

Traditionel mobning af et par faggrupper

Hvad skal man med en ækvivalensrelation, der ikke kan bruges til at mobbe dataloger med?

Med afsæt i sværhedsgraden af kurserne 1E og 1F (se afsnittet om det naturvidenskabelige fakultets ækvivalensklasse) på datalogis bacheloruddannelse indses nu, at

$$\text{Datalogistudierne} \sim \text{graduation ildeset},$$

hvormed vi også er klar til at etablere følgende ækvivalens (kendt som DIKU-egenskaben):

Sætning 3. *(DIKU-egenskaben)*
DIKU's øverste maskinstuer $\sim$ *Skuer nørdemassivitet, suk.*

Bevis: Ses let ved inspektion.

□

Nu vi er ved mobningen af faggrupper $\neq$ matematik, kan vi også indføje et mindre anvendeligt resultat (Damskur-formodningen), der først blev bevist i nyere tid og udtaler sig om karakteren af jurister:

$$\text{Dem der ikke hopper, de er jurister} \sim \text{Duksede terpere, empiriker-hjord}.$$

- og empirikere, dem kan vi jo ikke lide.

Anvendelser

Også arkitektonisk/æstetisk byder emnet på spændende resultater, og enkle udregninger vil give, at

$$\text{Naturvidenskabeligt Fakultet} \sim \text{Senil tun-arkitekt .. Gab, fladt vue!}$$

Er man endvidere ikke så begejstret for miljøet, strukturen og så videre kan man jo evt. benytte korollaret

$$\text{Naturvidenskabeligt Fakultet} \sim \text{Feudalt, uvenskabeligt TNT-Irak}.$$

Da vi nu alligevel er ved at bevæge os ind på det politiske, kan vi ligeså godt først som sidst løfte sløret for Helge Sander-ækvivalensen

$$\text{Universitetsreformen} \sim \text{Motiv er SU-interferens}.$$

Vi har vel alle lyst til afmægtigt at at anråbe statsministeren. Her er et godt grundlag for et sådant udråb.

$$\text{Anders Fogh Rasmussen} \sim \text{“Grusomheds-fan! Nar!” Ses!}$$

Noter og bemærkninger

Denne "artikel" er begået af Mrs. Dat-kranium $\sim$ Smart druk-mani $\sim$ Indsmurt karma $\sim$ Martin Damskur og Darwin: stenet hash-imam $\sim$ Mathias Winther Madsen.
Desuden medvirkede Savannen, hin enkle $\sim$ Anne Vinkel Hansen og "Aha! min hinke-IBM er en anatomi!" $\sim$ Mia Kit Arboe Heimann Heimann. Vi håber, at vi har fået slået fast, at sagaen er vor jammer $\sim$ "Mer nervegas, major M. !" $\sim$ James' gran-overarme $\sim$ Anagrammer er sjove.
De medskyldige siger tak til Rasmus Lerchedal Petersen $\sim$ Laps arresterede lunch-hems og Mathilde Louise Schousboe $\sim$ Ubeslutsomhed hos CIA-olie, fordi vi måtte lave permutationer af jeres navne.

En politisk leder

Tilsyneladende dovne studerende, som er skyld i, at de ikke selv bliver værdifulde samfundsborgere i passende expressfart. Et udsagn taget fra debatten om hvad universitetet bør levere til samfundet. Som en del af universitetet er vort kære institut en del af debatten, selvom den generelt er fraværende på stedet.

Da en uoverskuelig opsummering af en ikkeeksisterende debat ikke rigtig tjener noget formål vil vi tillade os at konkludere ganske unuanceret hvad debatten har medført af ændringer for de studerende på matematikuddannelserne.

Opmærksomheden omkring dovne studerende har betydet at det er blevet obligatorisk at være aktiv i løbet af semestret, og det lyder jo godt, men den har også betydet at den studerende i løbet af semestret springer fra den ene obligatoriske opgave til den næste uden tid til reflektion over dybderne i det matematiske hav.

Der er noget galt, når det eneste svar et studie har på dovne studerende er indførelsen af obligatorisk arbejde. Selve ordet obligatorisk opgave siger det hele; det er ikke lækkert.

De obligatoriske forløb vi er ude efter er ikke de meningsfyldte projekter på Statistik eller gennemtænkte projekter, her kunne man nævne 3MH, hvor projektet overtager forelæsningernes plads i 3 uger. Det er heller ikke projekter, der har til formål at forbedre læring af stoffet, som det der kører på 2AN. Det er heller ikke opgaver på 1. semester, hvor der kan være meget andet, som skal på plads end faglig fordybelse.

MEN, vi har noget mod opgaver HVIS ENESTE FUNKTION er at være obligatorisk, her kunne man nævne 2AL, 3RE, 3GT eller tidligere tiders 2AN. Det er tåbeligt. I det absurde, kunne hvert eneste 2 pkt. kursus få lyst til at man skulle lave obligatoriske opgaver, fordi man lige netop helst skal bruge sin tid på det kursus. Hvornår skulle de studerende få tid til at lære noget, får man lyst til at spørge?

Man får ved nærmere eftertanke også lyst til at spørge, hvorfor diagnosen hver eneste gang de studerende ikke lever op til den forventede arbejdsindsats bliver dårlig arbejdsmoral. Man skulle måske overveje om det kunne hænge sammen med umotiverende øvelser eller at tekniske forelæsninger er en uinspirerende form for undervisning.

Vi mener at de studerende bør tages mere med på råd. At de har en officiel plads i studienævnet hjælper ingen ting, så længe undervisere får lov til at

ændre undervisningen uden om studienævnet. Vel kan det være en klods om benet på forelæsere, som ønsker at være progressive at der sidder en flok reaktionære studerende, der ønsker velgennemtænkte forbedringer af studiet frem for at blive gjort til forsøgspersoner, der muligvis er heldige at deltage i et vellykket eksperiment.

Det er nu med den nye studiestruktur, at der er mulighed for at finde på andre svar end obligatoriske opgaver, når det drejer sig om tilsyneladende dovne studerende. Lad os håbe der bliver afsat tid til at finde dem.

FAMØS dec. 2002.
Fagblad for Aktuar-, Matematik-,
Økonomi- og Statistikstuderende ved
Københavns Universitet.

Deadline for næste nummer:
Fredag den 21. februar 2002

Indlæg modtages gerne og kan sendes til `famos@math.ku.dk` (meget gerne skrevet i LaTeX), eller afleveres på Matematisk Afdelings sekretariat i E 103.

FAMØS er et internt fagblad.

Fagbladet FAMØS
c/o Institut for matematiske fag
Matematisk Afdeling
Universitetsparken 5
2100 København Ø
`http://www.math.ku.dk/famos/`

Tryk: HCØ Tryk
Oplag: 600 stk.
ISSN 1395-2145

Kalenderen

- Tirsdag d. 10. december fylder Gustav Jacob Jacobi (1804-1851) fra Potsdam 198 determinerede år.
- Fredag d. 13. december fylder Søren Eilers(1967? -?) fra E-bygningen vores Fredag med et saligt foredrag om substitutionssystemer.
- Lørdag d. 21 december er der et kæmpe brag af en julefrokost for alle matematikere på Cafeen?.
- Søndag d. 22. december fortsætter festen hos Ludwig Hölder (1859 - 1937), fra Stuttgart, der fylder et ulige antal år: 143.
- Tirdag d. 24. december er det juleaften. Juhuu - Lad eksamensræset begynde!
- Onsdag d. 1. januar kommer efterfølgeren til dette år farende.
- Tirsdag d. 14. januar fylder unge Alfred Tarski (1902 - 1983) fra Warzawa 101 år, hvilket overhovedet ikke er paradoksalt.
- Torsdag d. 23. januar fylder David Hilbert (1862-1943) fra Kaliningrad 141 rummelige år.
- Lørdag d. 25. januar holder Joseph Louis Lagrange (1736 - 1813) fra Turin på Sardinien optimale 267 års-, og Hermann Amandus Schwarz (1843 - 1921) fra Hermsdorf (Polen) 160 års fødselsdag. - Det bliver en vild dag i matematikerhimlen!
- Søndag d. 9. februar fylder Lippót Féjer (1880 - 1959) fra Pécs (i Ungarn) 123 kernesunde år.
- Onsdag d. 12. februar bliver Peter Gustav Lejeune Dirichlet (1805 - 1859) fra Düren ligeledes 198 kernesunde somre lang.
- Fredag d. 21. februar er der deadline for indlæg til næste nummer FAMØS.
- Mandag d. 24. februar fylder vor allesammens Felix Bernstein (1878 - 1956) fra Halle fortjente 125 år. Og lige omkring denne store begivenhed cirkulerer endnu et nummer af FAMØS omkring i vandrehallen.

Har du et arrangement som du gerne vil have med i FAMØS' kalender, så send en mail til`famos@math.ku.dk` og kom med en beskrivelse, samt dato (mellem Marts og Maj), så presser vi det ind i FAMØS stramme tidsplan.

The Asymptotic Capacity of Multi-Dimensional Runlength-Limited Constraints and Independent Sets in Hypergraphs

Ordentlich, Erik; Roth, Ron M.

HPL-2002-348
20030108
External

Keyword(s): regular graphs; Hamming graphs; linear hypergraphs; multi-dimensional constraints; runlength-limited constraints

Abstract: Please Note. This abstract contains mathematical formulae which cannot be represented here. Let C(n,d) be the Shannon capacity of the n-dimensional (d, oo)- runlength-limited (RLL) constraint. Denote by I(n,q) the number of independent sets in the Hamming graph with vertices consisting of all n-tuples over an alphabet of size q and edges connecting pairs of vertices with Hamming distance 1. We show that lim(subscript n)->infinity C(n,d) =lim(subscript n)- >infinity(d+1) (superscript -n) log(subscript 2) I (n, d+1)=1/(d+1). Our method also leads to an improvement of a previous bound by Alon on the number of independent sets in regular graphs and to a generalization of this bound to a family of hypergraphs, of which the Hamming graphs can be thought of as a special case.

RESEARCH STATEMENT

ROBERT OSBURN

1. Introduction

Since the 1960's, relationships between algebraic K-theory and number theory have been investigated. For number fields F and their rings of integers $\mathcal{O}_F$, the K-groups $K_0(\mathcal{O}_F)$ and $K_1(\mathcal{O}_F)$ are related to classical objects in number theory. From [25] we have

$$K_0(\mathcal{O}_F) \cong \mathbb{Z} \times C(F)$$

where $C(F)$ is the ideal class group of F, and

$$K_1(\mathcal{O}_F) \cong \mathcal{O}_F^*,$$

the group of units of $\mathcal{O}_F$.

What can we say in general about $K_2(\mathcal{O}_F)$? For a ring R with unity, Milnor [25] defined $K_2(R)$ as the kernel of the natural surjection $St(R) \to E(R)$ where $St(R)$ is the Steinberg group of R and $E(R)$ is the direct limit of the group generated by elementary matrices. In particular, $K_2(R)$ is the center of $St(R)$, hence abelian. For a field F the group $K_2(F)$ has been computed by Matsumoto [24] as the universal symbol group:

$$K_2(F) = F^* \otimes_{\mathbb{Z}} F^* / < u \otimes (1-u) : u \neq 1 >.$$

The kernel of the surjective homomorphism

$$K_2(F) \to \bigoplus_{\mathfrak{p}} \left(\mathcal{O}_F/\mathfrak{p}\right)^*,$$

given by the "tame symbols" at all finite primes $\mathfrak{p}$ of F, is called the **tame kernel** of F and is known to be finite [13] and isomorphic to $K_2(\mathcal{O}_F)$ [40]. For this reason, $K_2(\mathcal{O}_F)$ is commonly referred to as the **tame kernel** of F. In 1970, J. Birch [4] and J. Tate [44] conjectured for totally real number fields F that the order of $K_2(\mathcal{O}_F)$ is related to the value of the Dedekind zeta-function of F at -1, i.e

$$\#K_2(\mathcal{O}_F) = |w_2(F) \cdot \zeta_F(-1)|$$

where $w_2(F)$ is a readily computable term (page 26 in [45]). The Birch-Tate conjecture is a special case of the Lichtenbaum conjecture [22] which attempts to generalize Dirichlet's class number formula. The Birch-Tate conjecture was confirmed up to powers of 2 by Wiles [49].

Determining the structure of $K_2(\mathcal{O}_F)$ remains a difficult and intriguing problem. Much research (e.g. [5], [7], [9], [11], [19], [20], [21], [36], [37], [38], [39], [46], [47], [48]) has focused on the 2-Sylow subgroup of $K_2(\mathcal{O}_F)$. We say the 2^j**-rank**, $j \geq 1$, of $K_2(\mathcal{O}_F)$ is the number of cyclic factors of

$K_2(\mathcal{O}_F)$ of order divisible by 2^j. A formula of Tate [43] computes the 2-rank of the tame kernel. If F is a quadratic number field, Browkin and Schinzel [6] simplified the 2-rank formula. What about the 4-rank of $K_2(\mathcal{O}_F)$?

2. RESULTS

In [36], [37], and [38], Qin determined the 4-rank of the tame kernel for quadratic number fields F in terms of indefinite quadratic forms. Hurrelbrink and Kolster [18] generalized Qin's approach and obtained 4-rank results by computing $\mathbb{F}_2$-ranks of certain matrices of local Hilbert symbols. This approach is an effective technique and has led to connections between densities of certain sets of primes and 4-rank values. In [33], the author considered the 4-rank of $K_2(\mathcal{O})$ for the fields $\mathbb{Q}(\sqrt{pl})$, $\mathbb{Q}(\sqrt{2pl})$, $\mathbb{Q}(\sqrt{-pl})$, $\mathbb{Q}(\sqrt{-2pl})$ for primes $p \equiv 7 \bmod 8$, $l \equiv 1 \bmod 8$ with $\left(\frac{l}{p}\right) = 1$. In [10], it was shown that for the fields $E = \mathbb{Q}(\sqrt{pl})$, $\mathbb{Q}(\sqrt{2pl})$ and $F = \mathbb{Q}(\sqrt{-pl})$, $\mathbb{Q}(\sqrt{-2pl})$,

$$4\text{-rank } K_2(\mathcal{O}_E) = 1 \text{ or } 2,$$

$$4\text{-rank } K_2(\mathcal{O}_F) = 0 \text{ or } 1.$$

The idea in [33] was to fix a prime $p \equiv 7 \bmod 8$ and consider the set

$$\Omega = \{l \text{ rational prime} : l \equiv 1 \bmod 8 \text{ and } \left(\frac{l}{p}\right) = 1\}.$$

In [33], we proved the following:

Theorem 2.1. *For the fields $\mathbb{Q}(\sqrt{pl})$ and $\mathbb{Q}(\sqrt{2pl})$, 4-rank 1 and 2 each appear with natural density $\frac{1}{2}$ in Ω. For the fields $\mathbb{Q}(\sqrt{-pl})$ and $\mathbb{Q}(\sqrt{-2pl})$, 4-rank 0 and 1 each appear with natural density $\frac{1}{2}$ in Ω.*

In [26], we extended the results in [33] by providing a complete densitiy picture for the 4-ranks of tame kernels of the fields $\mathbb{Q}(\sqrt{pl})$, $\mathbb{Q}(\sqrt{-pl})$ for primes p, l. One can show that 0, 1, or 2 are the possible 4-rank values for $K_2(\mathcal{O}_{\mathbb{Q}(\sqrt{pl})})$ and $K_2(\mathcal{O}_{\mathbb{Q}(\sqrt{-pl})})$. Now, for squarefree, odd integers d, consider the sets

$$X = \{d : d = pl\}$$

and

$$Y = \{d : d = -pl\}$$

for distinct primes p and l. As a consequence of Theorems 1.2 and 1.3 in [26], we obtain

Corollary 2.2. *For the fields $\mathbb{Q}(\sqrt{pl})$, 4-rank 0, 1, and 2 appear with natural density $\frac{13}{64}$, $\frac{97}{128}$, $\frac{5}{128}$ respectively in X. For the fields $\mathbb{Q}(\sqrt{-pl})$, 4-rank 0, 1, and 2 appear with natural density $\frac{37}{64}$, $\frac{13}{32}$, and $\frac{1}{64}$ respectively in Y.*

The rough idea behind Theorem 2.1 and Corollary 2.2 is to use the matrices of local Hilbert symbols to get a correspondence bewteen 4-rank values and characterizations of the primes p and l by positive definite binary quadratic forms. This characterization then determines the splitting of p and l in a certain normal extension of $\mathbb{Q}$. Associating Artin symbols to p and l, we then use the Cébotarev Density theorem.

3. Further Research

3.1. **4-rank densities.** These matrices of local Hilbert symbols are analogous to Rédei matrices [41] which were used in the 1930's to study the structure of ideal class groups. In [34], this analogy is discussed along with density results of Gerth [15]. In the appendix of [34], we give a product formula for a local Hilbert symbol. Do Gerth's methods [15] coupled with this product formula yield, for any quadratic number field, asymptotic formulas for 4-rank densities of tame kernels?

3.2. **Higher 2-power ranks.** Is it possible to classify higher 2-power ranks of tame kernels of quadratic number fields in terms of positive definite binary quadratic forms? Do density results exist for higher 2-power ranks? Little is known about 8-ranks of tame kernels. Recent results in [18], [39], and [48] still need to be studied in order to provide a more unified approach.

3.3. **Question of Erdös.** During a conference in honor of D.H Lemher [16], Ron Graham posed the following question of Erdös: Are there infinitely many n such that the middle binomial coefficient $\binom{2n}{n}$ is relatively prime to 105? Lucas knew [23] that for a prime p, $(\binom{2n}{n},\ p) = 1$ if and only if every coefficient in the base p expansion of n is $< \frac{p}{2}$. This implies that there are infinitely many n such that $(\binom{2n}{n},\ p) = 1$ for a given prime p. Erdös, Graham, Ruzsa, and Straus [12] proved that for any two primes p and q, there exist infinitely many n for which $(\binom{2n}{n},\ pq) = 1$. By Lucas' theorem, Erdös' question can be rephrased: Are there infinitely many n that have the digits 0, 1 or 0, 1, 2 or 0, 1, 2, 3 when written in bases 3, 5, or 7 respectively? A list of known n's is given by sequence $\#A030979$ [42].

3.4. **t-cores.** A **partition** of a positive integer n is a non-increasing sequence of positive integers whose sum is n. The number of such partitions is denoted by $p(n)$. If $\Lambda = \lambda_1 \geq \lambda_2 \geq \ldots \lambda_s$ is a partition of n, then the **Ferrers-Young diagram** of Λ is the s-row collection of nodes:

$$\begin{array}{lll} \bullet\ \bullet\ \ldots\ \bullet\ \bullet & \lambda_1 & \text{nodes} \\ \bullet\ \bullet\ \ldots\ \bullet & \lambda_2 & \text{nodes} \\ \vdots & & \\ \bullet\ \ldots\ \bullet & \lambda_s & \text{nodes} \end{array}$$

Label the nodes as if it were a martix. Let ${\lambda_j}'$ denote the number of nodes in column j. Define the **hook number** $H(i,j)$ of the (i,j) node to be $H(i,j) := \lambda_i + {\lambda_j}' - j - i + 1$. If t is a positive integer, then a partition

of n is called a **t-core** of n if none of the hook numbers of its associated Ferrers-Young diagram are multiples of t. Let $C_t(n)$ denote the number of t-core partitions of n. In [32], Ono and Sze made the following remarkable discovery: If $8n+5$ is square-free, then $C_4(n) = \frac{1}{2}h(-32n-20)$ where $h(N)$ is the order of the class group of discriminant N binary quadratic forms. There are two proofs of this theorem. One proof uses the generating function for $C_4(n)$ [14] and properties of class numbers. The second proof relies on an explicit map from the set of 4-core partitions of n to the class group of binary quadratic forms of discriminant $-32n-20$. Does such an explicit map exist between other t-cores and class numbers? Between t-cores and orders of K-groups?

3.5. **Partition congruences.** There has been recent exciting work [1], [2], [31] on congruence properties of the partition function $p(n)$. There are still many interesting open questions concerning the distribution of $p(n)$ modulo integers M, see [3] or [8]. The "folklore conjecture" [35] states that the values of $p(n)$ are distributed evenly modulo 2. Of the first 10000 values of $p(n)$, 4996 are even and 5004 are odd. The pattern seems to continue with 2 replaced by 3. Namely, the values of $p(n)$ seem to be evenly distributed modulo 3. Currently, there is no known explanation for this behavoir. In fact it is not known whether there are infinitely many n for which $p(n) \equiv 0 \bmod 3$.

3.6. **Sign Ambiguities.** Gauss, Jacobi, Stern, E. Lehmer, Whiteman, and others have obtained congruences for binomial coefficients in terms of parameters coming from representations of primes by quadratic forms. In [17], many other beautiful binomial coefficient congruences are proved. In certain cases, the key step is the resolution of a sign ambiguity. These sign ambiguities are counterexamples to Hasse's conjecture that all multiplicative relations between Gauss sums follow from the Davenport-Hasse product formula and the norm relation for Gauss sums. Very few ([28], [29], [30], [50]) sign ambiguities have been given. Recently, Brian Murray [27] has proved a remarkable product formula which yields an infinite class of new sign ambiguities. Can these new resolutions of sign ambiguities be used to obtain new congruences for binomial coefficients?

Random Walks

- **Mixing time and long paths in graphs**, preprint, 2001

  We prove that regular graphs with large degree and small mixing time contain long paths and other graphs. We apply the results to size Ramsey numbers, self-avoiding walks in graphs, and present efficient algorithm for finding long paths in graphs as above.

  Download .dvi file or .ps file of the paper.

  The extended abstract of the paper has appeared in the Proc. SODA'2002. Download .dvi file, .ps file or .pdf file of the extended abstract.

- (with *A. Zuk*) **On Kazhdan Constants and Mixing of Random Walks**, *International Mathematical Research Notes*, 2002, No. 36, 1891-1905.

  Let *G* be a group with Kazhdan's property (T), and let *S* be a *transitive* generating set (there exists a subgroup *H* of *Aut(G)* which acts transitively on *S*.) In this paper we relate two definitions of

the Kazhdan constant and the eigenvalue gap in this case. Applications to various random walks on groups, and the product replacement random algorithm, are also presented.

Download .dvi file, .ps file or .pdf file.

- (with *Alex Astashkevich*) **Random walks on nilpotent groups**, preprint, 2001

  We obtain sharp bounds on mixing time of random walks on nilpotent groups, with Hall bases as generating sets.

  Download .dvi file, .ps file or .pdf file.

- (with *Nathan Lulov*) **Rapidly mixing random walks and bounds on characters of the symmetric group**, *Journal of Algebraic Combinatorics*, vol. 16, 2002, 151-163.

  We investigate mixing of random walks on *S_n* and *A_n* generated by permutations of a given cycle structure. In our approach we follow methods developed by Diaconis, by using characters of the symmetric group and combinatorics of Young tableaux. We conclude with conjectures and open problems.

  Download .dvi file, .ps file, or .pdf file.

- (with *Don Coppersmith*) **Random walk on upper triangular matrices mixes rapidly**, *Probability Theory and Related Fields*, vol. 117 (2000), 407-417.

  We present an upper bound *O(n^2)* for the mixing time of a simple random walk on upper triangular matrices. We show that this bound is sharp up to a constant, and find tight bounds on the eigenvalue gap. We conclude by applying our results to indicate that the asymmetric exclusion process on a circle indeed mixes more rapidly than the corresponding symmetric process.

  Download .dvi file, .ps file or .pdf file.

- (with *Feng Chen, László Lovász*) **Lifting Markov Chains to Speed up Mixing**, *Proceedings of STOC'99*, 275-281.

  There are several examples where the mixing time of a Markov chain can be reduced substantially, often to about its square root, by ``lifting", i.e., by splitting each state into several states. In several examples of random walks on groups, the lifted chain not only mixes better, but is easier to analyze.

  We characterize the best mixing time achievable through lifting in terms of multicommodity flows. We show that the reduction to square root is best possible. If the lifted chain is time-reversible, then the gain is smaller, at most a factor of *log (1/p)*, where *p* is the smallest stationary probability of any state. We give an example showing that a gain of a factor of *log (1/p) log log (1/p)* is possible.

The Product Replacement Algorithm

- (with *Alex Gamburd*) **Expansion of product replacement graphs**, preprint, 2001, to appear in *Combinatorica*.

We establish a connection between the expansion coefficient of the product replacement graph of a group *G*, and the minimal expansion coefficient of a Cayley graph of *G*. This gives a new explanation of the outstanding performance of the product replacement algorithm and supports the speculation that all product replacement graphs are expanders.

Download .dvi file or .ps file of the paper.

The extended abstract of the paper has appeared in the Proc. SODA'2002. Download .dvi file, .ps file or .pdf file of the extended abstract. Note that the proceedings version does not contain the Appendix.

- **The product replacement algorithm is polynomial**, Proc. FOCS'2000, 476-485.

The main result of this paper is a polynomial upper bound for the cost of the algorithm, provided *k* is large enough. This is the first such result, improving (sub)-exponential bounds by Diaconis and Saloff-Coste, etc.

Download .dvi file or .ps file of the extended abstract.

- (with *Alex Lubotzky*) **The product replacement algorithm and Kazhdan's property (T)**, *Journal of AMS*, vol. 52 (2000), no. 12, 5525-5561.

The ``product replacement algorithm'' is a commonly used heuristic to generate random group elements in a finite group *G*, by running a random walk on generating *k*-tuples of *G*. While experiments showed outstanding performance, the theoretical explanation remained mysterious. In this paper we propose a new approach to study of the algorithm, by using Kazhdan's property (T) from representation theory of Lie groups.

Download .dvi file, .ps file, or .pdf file.

- (with *Gene Cooperman*) **The product replacement graph on generating triples of permutations**, preprint, 2000

We prove that the *product replacement graph* on generating 3-tuples of *A_n* is connected for *n* <

12. We employ an efficient heuristic based on the ``large connected component'' concept and use of symmetry to prune the search. The heuristic works for any group. Our tests were confined to *A_n* due to the interest in Wiegold's Conjecture, usually stated in terms of *T*-systems. Our results confirm Wiegold's Conjecture in some special cases and are related to the recent conjecture of Diaconis and Graham. The work was motivated by the study of the product replacement algorithm.

Download .dvi file or .ps file.

- **What do we know about the product replacement algorithm?**, *Groups and Computation III* (W. Kantor, A. Seress, eds.), de Gruyter, Berlin, 2001, 301-347.

  We give an extensive review of the theoretical results related to the product replacement algorithm. Both positive and negative results are described. The review is based on a large amount of work done by the author, including joint results with Babai, Bratus, Cooperman, Lubotzky and Zuk (see on this web page).

  See also .dvi file, .ps file, or .pdf file of the MathSciNet review.

- (with *László Babai*) **Strong bias of group generators: an obstacle to the "product replacement algorithm"**, to appear in *Journal of Algorithms*, 2001. An extended abstract of this paper has appeared in *Proc. SODA'00*, 627-635.

  Let *G* be a finite group. Efficient generation of *nearly uniformly distributed* random elements in *G*, starting from a given set of generators of *G*, is a central problem in computational group theory. In this paper we demonstrate a weakness in the popular "product replacement algorithm," widely used for this purpose. Roughly, we show that components of the uniform generating *k*-tuples have a bias in the distribution, detectable by a short straight-line program.

  Download .dvi file or .ps file of the full paper.
  Download .dvi file, .ps file, or .pdf file of the extended abstract.

- **On the graph of generating sets of a simple group**, preprint, 1999.

We prove that the *product replacement graph* on generating *k*-tuples of a simple group contains a large connected component. This is related to the recent conjecture of Diaconis and Graham. As an application, we also prove that the output of the product replacement algorithm in this case does not have a strong bias.

Download .dvi file or .ps file.

- (with *Sergey Bratus*) **On sampling generating sets of finite groups and product replacement algorithm**, in *ISSAC'99* Conference Proceedings, 91-96

  This is an extended abstract of the two separate papers on the generating *k*-subsets of a finite group. We elaborate on the number of such subsets and present an efficient and very economic algorithm in case of nilpotent groups. We also prove rapid mixing of the product replacement algorithm in case when group is abelian.

  Download .dvi file, .ps file or .pdf file.

Other Group Algorithms

- **Testing commutativity of a group and the power of randomization**, preprint, 2000

  Let *G* be a group generated by *k* elements, with group operations (multiplication, inversion, comparison with identity) performed by a black box. We prove that one can test whether *G* is abelian at a cost of *O(k)* group operations. On the other hand, we show that deterministic approach requires *Omega(k^2)* group operations.

  Download .dvi file or .ps file.

- (with *Sergey Bratus*) **On sampling generating sets of finite groups**, preprint, 1999.

  Let *G* be a finite group. For a given *k*, what is the probability that a group is generated by *k* random group element? How small can be this probability and how one can uniformly sample these generating *k*-tuples of elements? In this paper we answer these questions for nilpotent and solvable groups. Applications to product replacement algorithms and random random walks are discussed.

Download .dvi file or .ps file.

- (with *Sergey Bratus*) **Fast constructive recognition of a black box group isomorphic to S_n using Goldbach conjecture**, *J. of Symbolic Computation*, vol. 29, 2000, 33-57.

  We present a Las Vegas algorithm for verification whether a given group defined as a black box group (we can multiply elements, take inverses, and compare them with identity) is isomorphic to a given symmetric group. Surprisingly, the algorithm relies on the Goldbach conjecture and its various extensions. In the appendix to the article we use analytic number theory and probabilistic approach to support the conjectures.

  Download .dvi file (no pictures), .ps file, or .pdf file

- **When and how *n* choose *k***, *AMS DIMACS series*, vol. 43, 1998, 191-238.

  We present several combinatorial and probabilistic algorithms for generating random k-subsets of n-sets, k-subspaces of a n-dimensional space, random nonsingular matrices, etc.

Tilings

- (with *Michael Korn*) **Tilings of rectangles with T-tetrominoes**, preprint, 2003, 20 pp.

  We prove that any two tilings of a rectangular region by T-tetrominoes are connected by moves involving only 2 and 4 tiles. We also show that the number of such tilings is an evaluation of the Tutte polynomial. The results are extended to more general class of regions.

  Download .ps file or .pdf file of the paper.

- **Tile Invariants: New Horizons**, *Theoretical Computer Science*, vol. 303, 2003, 303-331 (special issue on tilings).

  Let T be a finite set of tiles. The group of invariants $G(T)$, introduced by the author, is a group of linear relations between the number of copies of the tiles in tilings of the same region. We survey known results about $G(T)$, the height function approach, the local move property, various applications and special cases.

  Download .ps file of the paper (800K), or .dvi file (no pictures).

- (with *Cris Moore*) **Ribbon tile invariants from signed area**, *J. Comb. Th., Ser. A*, Vol. 98, 2002, 1-16.

  Ribbon tiles are polyominoes consisting of *n* squares laid out in a path, each step of which goes north or east. Tile invariants were first introduced in **Pak**, *"Ribbon tile invariants"* (see below), where a full basis of invariants of ribbon tiles was conjectured. Here we present a complete proof of the conjecture, which works by associating ribbon tiles with a certain polygon in the complex plane, and deriving invariants from the signed area of this polygon.

  Download .ps file of the paper.

- **Ribbon tile invariants**, *Trans. A.M.S.*, vol. 352, 2000, 5525-5561.

  Consider a set of *ribbon tiles* which are polyominoes with *n* squares obtained by *up* and *right* rook moves. We describe all the linear relations for the number of times each such tile can appear in a tiling of any given row convex region. We also investigate the connection with signed tilings and give applications of tileability.

  Download .dvi file or .ps file (no pictures). About 20 pages of pictures are available in this .ps file (450Kb.) The full paper (with pictures) is available to download in .pdf file (670Kb.)

  Compare reviews in Zbl. Math. and Math. Reviews. See also a .ps file of an extended abstract (10 pages), which appeared in *FPSAC'98* Conference Proceedings.

- (with *Roman Muchnik*) **On tilings by ribbon tetrominoes**, *J. Comb. Th., Ser. A*, vol. 88, 1999, 188-193.

  We resolve a problem posed in the previous paper by extending the set of regions to all simply connected regions in the case $n=4$. Conway-Lagarias type technique is employed.

  Download .dvi file, .ps file or .pdf file.

Enumerative Combinatorics

- (with *Mike Korn*) **Combinatorial evaluations of the Tutte polynomial**, preprint, 2003

  We give a number of new combinatorial interpretations of values of the Tutte polynomial of planar graphs, in terms of two different graph colorings, claw coverings, and, for particular graphs on a square grid, in terms of Wang tilings and T-tetromino tilings. These results are extended to surfaces of higher genus and give interpretations of the Bollobas-Riordan polynomial. Most proofs are bijective.

  We present two versions of the paper which differ only in the pictures. The first, *colored version* is for viewing on a monitor and printing on a colored printer. The second, *monochromatic version*, is optimized for printing on a monochromatic printer.

  Download .ps file or .pdf file of the colored version.
  Download .ps file or .pdf file of the monochromatic version.

- (with *Sergi Elizalde*) **Bijections for refined restricted permutations**, preprint, 2002

  We present a bijection between 321- and 132-avoiding permutations that preserves the number of fixed points and the number of excedances. This gives a simple combinatorial proof of recent results of Robertson, Saracino and Zeilberger [RSZ], and the first author [E]. We also show that our bijection preserves additional statistics, which extends the previous results.

- **On sampling integer points in polyhedra**, in *Foundations of Computational Mathematics: Proceedings of Smalefest 2000* (F. Cucker and J. M. Rojas, Editors), World Scientific, Singapore, 2002

  We investigate the problem of sampling integer points in rational polyhedra provided an oracle for counting these integer points. When the dimension is bounded, this assumption is justified in view of a recent algorithm due to Barvinok. We show that in full generality the exactly uniform sampling is possible, when the oracle is called polynomial number of times. Further, when Barvinok's algorithm is used, poly-log number of calls suffices.

  Download .dvi file or .ps file.

- **Four questions on Birkhoff polytope**, *Annals of Combinatorics*, vol. 4, 2000, 83-90.

  The questions are: what is the volume of Birkhoff polytope, how fast simplex method works, how fast vertex nearest neighbor random walk mixes, and what about mixing on other 0-1 polytopes?

Download .dvi file, .ps file, or .pdf file.

- **On the number of faces of certain transportation polytopes**, *European J. Combinatorics*, vol. 21 (2000), 689-694.

  Define transportation polytope *T(n,m)* to be a polytope of nonnegative *n x m* matrices with row sums equal to *m* and column sums equal to *n*. We present an efficient algorithm for computing the numbers of the *k*-dimensional faces for the transportation polytope *T(n,n+1)*. The construction relies on the new recurrence relation for which is of independent interest.

  Download .dvi file, .ps file, or .pdf file.

- (with *Alex Postnikov*) **Transversal Matroids and Strata on a Grassmannian**, *Funct. Anal. Appl.*, vol. 29, 1995, 140-143.

  We discuss combinatorial and topological properties of strata on grassmanian which correspond to transversal matroids. Applications to differential equations are also given.

Representation Theory of S_n and Combinatorics of Young Tableaux

- **Periodic permutations and the Robinson-Schensted correspondence**, preprint (2003), 13 pp.

  We introduce a group of periodic permutations, a new version of the infinite symmetric group. We then generalize and study the Robinson--Schensted correspondence for such permutations.

  Download .ps file or .pdf file.

- (with *Ernesto Vallejo*) **Combinatorics and geometry of Littlewood-Richardson cones**, preprint (2003) 15 pp., to appear in *Europ. J. Combinatorics*.

  We present several direct bijections between different combinatorial interpretations of the Littlewood-Richardson coefficients. The bijections are defined by explicit linear maps which

have other applications.

Download .dvi file, .ps file or .pdf file.

- **Hook Length Formula and Geometric Combinatorics**, *Séminaire Lotharingien de Combinatoire*, vol. 46 (2001), article B46f, 13 pp.

  We present a transparent proof of the classical hook length formula. The formula is reduced to an equality between the number of integer point in certain polytopes. The latter is established by an explicit continuous volume-preserving piecewise linear map.

  Download .ps file or .pdf file. Click here for a journal version.

- (with *J-C Novelli, A.V. Stoyanovsky*) **A direct bijective proof of the hook-length formula**, *Discrete Mathematics and Theoretical Computer Science*, vol. 1, 1997, 53-67.

  We give simple bijective proof of the hook-length formula. This is an extended version of the note **Short Bijective Proof of the Hook-length Formula**, *Funct. Anal. Appl.*, vol. 26, 1992 (with *A.V. Stoyanovsky*.)

  Download .ps file. Click here for a journal version. See also here for a nice web version of the idea. Click here for another one. You can also check the Third Edition of Don Knuth's *"The Art of Computer Programming"*, Vol. 3, 1998, for a 2-page overview of the algorithm. Yet another 2-page overview is in Bruce Sagan's *"Group Representations and Symmetric Functions"*, MSRI Lecture Notes, 1997 (available here)

  Here is what Christian Krattenthaler writes in the Math. Reviews, 99h:05123 :
  "This is probably the most important recent contribution to bijective combinatorics."

  We present a new approach to the RSK correspondence via oscillating tableaux. Generalization of RSK, continuous analog, and closed connection with (S_p x S_q)-modules are discussed.

Download .dvi file or .ps file of the *extended abstract*.

- (with *Alex Postnikov*) **Enumeration of trees and one amazing Representation of S_n**, Proc. FPSAC'96 Conf., Minneapolis, MN

  We present several remarkable properties of the one representation of S_n, obtained by an action on parking functions. Of particular importance are multiplicities of the irreducible representations corresponding to hook shapes which correspond to certain k-trees.

  Download .dvi file or .ps file of the *extended abstract*.

- (with *Alex Postnikov*) **Resolutions for S_n-modules Corresponding to Skew Hooks, and Combinatorial Applications**, *Funct. Anal. Appl.*, vol. 28, 1994, 132-134.

  We construct a new resolution for a special type of S_n-modules. The resolution arises from inversion polynomial and generalizes a known combinatorial identity. In the limiting case we obtain new and classical partition identities.

- (with *Alexandre A. Kirillov*) **Covariants of the Symmetric Group and its analogues in Weil algebras**, *Funct. Anal. Appl.*, vol. 24, 1990, 172-176.

  A classical hook-content formula appears as a Poincare series for the multiplicities of the irreducible *S_n*-module in symmetric algebra. We obtain a *super-analog* of this formula by taking Weil algebra instead of the symmetric algebra.

Probability on Finite and Infinite Groups

- (with *Rados Radoicic*) **Hamiltonian paths in Cayley graphs**, preprint, 2002.

  We prove that every finite group G has a generating set of size at most *log_2 |G|*, such that the corresponding Cayley graph contains a Hamiltonian path. We also present an explicit construction of *3*-regular Hamiltonian expanders.

Download .dvi file, .ps file, or .pdf file of the paper.

- (with *Christopher Malon*) **Percolation on Finite Cayley Graphs**, preprint, 2002. Extended abstract of the earlier version of the paper has appeared in Proc. RANDOM'02.

  In this paper, we study percolation on finite Cayley graphs. A conjecture of Benjamini says that the critical percolation *p_c* of such a graph can be bounded away from one, for any Cayley graph satisfying a certain diameter condition. We prove Benjamini's conjecture for some special classes of groups. We also establish a reduction theorem, which allows us to build Cayley graphs for large groups without increasing *p_c*.

  Download .dvi file, .ps file, or .pdf file of the paper.

- (with *Bob Guralnick*) **On a question of B.H. Neumann**, *Proc. A.M.S.*, vol. 131, 2003, 2021-2025.

  The automorphism group of a free group *Aut(F_k)* acts on the set of generating *k*-tuples *(g_1,..., g_k)* of a group *G*. Higman showed that when *k=2*, the union of conjugacy classes of the commutators [*g_1*,*g_2*] and [*g_2*,*g_1*] is an orbit invariant. We give a negative answer to a question of B.H. Neumann, as to whether there is a generalization of Higman's result for *k > 2*.

  Download .dvi file, .ps file, or .pdf file of the paper.

- (with *Tatiana Smirnova-Nagnibeda*) **Uniqueness of percolation on nonamenable Cayley graphs**, *Comptes Rendus Acad. Sci. Paris, Ser. I Math*, vol. 330 (2000), no. 6, 495-500.

  For every nonamenable group, a finite system of generators is constructed such that the Bernoulli bond percolation on the corresponding Cayley graph exhibits the double phase transition phenomenon, i.e., nonempty nonuniqueness phase.

  Download .dvi file or .ps file.

- **On probability of generating a finite group**, preprint, 1999.

Let *G* be a finite group, and let *p(G,k)* be the probability that *k* random group elements generate *G*. Denote by *v(G)* the smallest *k* such that *p(G,k)>1/e*. In this paper we analyze the quantity *v(G)* for different classes of groups. We prove that *v(G)< r(G)+1* when *G* is *nilpotent*, and *r(G)* is the minimal number of generators of *G*. When *G* is *solvable* we show that *v(G) < 3.25 r(G) + 10^7*. We also show that *v(G) < C log log |G|*, where *G* is a direct product of simple nonabelian groups and *C* is a universal constant. Applications to the "product replacement algorithm" are also discussed.

Download .dvi file or .ps file.

- (with *Roman Muchnik*) **On growth of Grigorchuk groups**, *International Journal of Algebra and Computation*, vol. 11 (2001), 1-17.

  We present an analytic technique for estimating the growth for groups of intermediate growth. We apply our technique to Grigorchuk groups, which are the only known examples of such groups. Our estimates generalize and improve various bounds by Grigorchuk, Bartholdi and others.

  Download .dvi file or .ps file.

- (with *Roman Muchnik*) **Percolation on Grigorchuk groups**, *Comm. Algebra*, vol. 29 (2001), 661-671.

  Let *p_c(G)* be the critical probability of the site percolation on the Cayley graph of group *G*. Benjamini and Schramm conjectured that *p_c<1*, given the group is infinite and not a finite extension of *Z*. The conjecture was proved earlier for groups of polynomial and exponential growth and remains open for groups of intermediate growth. In this note we prove the conjecture for a special class of *Grigorchuk groups*, which contains all known examples of groups of intermediate growth.

Partial Order Programming

(Technical Report CSD-870067, December 1987)

D. Stott Parker

We introduce a programming paradigm in which statements are constraints over partial orders. A *partial order programming problem* has the form

```
minimize        u

subject to      u1 >= v1
                u2 >= v2
                ...
```

where u is the goal, and u1 >= v1, ... is a collection of constraints called the program. A solution of the problem is a minimal value for u determined by values for u1,v1, etc. satisfying the constraints. The domain of values here is a partial order, a domain D with

ordering relation >=. The partial order programming paradigm has interesting properties:

1. It generalizes mathematical programming, dynamic programming, and computer programming paradigms (logic, functional, and others) cleanly, and offers a foundation both for studying and combining paradigms.
2. It takes thorough advantage of known results for continuous funtionals on complete partial orders, when the constraints involve expressions using only continuous and monotone operators. These programs have an elegant semantics coinciding with recent results on the relaxation solution method for constraint problems.
3. It presents a framework that may be effective in modeling of complex systems, and in knowledge representation for cognitive computation problems.

- Parker.Partial.Order.Programming.ps.Z

Greedy Optimization

Greed and Majorization

(Technical Report CSD-960003, November 1994; issued March 1996; revised and expanded August 1997)

D. Stott Parker, Prasad Ram

Modern analyses of greedy-solvable problems (in terms of matroids, greedoids, submodularity, etc.) have grown in sophistication to the point that uninitiated readers can come away with a sense of confusion and disbelief. Despite the sophistication of these analyses and the great importance of greedy algorithms, currently there appears to be no truly satisfactory resolution of *what* a greedy algorithm is, or *when* and *why* greedy algorithms work. The pervasiveness of greedy algorithms is due to their simplicity, so it is disturbing that an arcane theory would be required to explain them.

Our contribution here is a new theory, giving a simple linear algebraic framework of greed. First, we introduce a generalized **majorization** ordering on numeric sequences, and identify conditions for functions on sequences to preserve this ordering. Generalized majorization is not a total order, but a preorder. It is naturally viewed as an `exchange' ordering where the exchanges are specific linear transformations. Second, we show that greedy-solvable problems can be formalized as optimization problems in which the objective is monotone with respect to this exchange ordering. We outline greedy algorithms for such problems, including those that exploit additional properties of the objective, such as convexity. Examples from the literature illustrate how diverse well-known applications of greed can be expressed.

Huffman Codes and Convex Optimization

The construction of Huffman codes is a submodular (`convex') optimization problem over a lattice of binary trees

(Technical Report CSD-960038, October 1996; revised and expanded September 1997)

D. Stott Parker, Prasad Ram

We show that the space of all binary Huffman codes for a finite alphabet defines a *lattice*, ordered by the imbalance of the code trees. Representing code trees as path-length sequences, we show that the imbalance ordering is closely related to a majorization ordering on real-valued sequences that correspond to discrete probability density functions. Furthermore, this tree imbalance is a partial ordering that is consistent with the total orderings given by either the external path length (sum of tree path lengths), or the entropy determined by the tree structure. On the imbalance lattice, we show the weighted path-length of a tree (the usual objective function for Huffman coding) is a *submodular* function, as is the corresponding function on the majorization lattice. Submodular functions are discrete analogues of convex functions. These results give perspective on Huffman coding, and suggest new approaches to coding as optimization over a lattice.

Reconstruction of Majorization

A Linear Algebraic Reconstruction of Majorization

(Technical Report CSD-970036, September 1997)

D. Stott Parker, Prasad Ram

Majorization is an important partial order on multisets. Since its development at the turn

of the twentieth century by economists formalizing the notion of `exchange' among distributions, it has found applications ranging from stochastic scheduling to singular value theory.

In this paper we reconstruct majorization as a partial order on vectors (ordered sequences) using linear algebra. We do this in two different ways, one following a recent extension of majorization to permit partial ordering among the indices of the sequences, and the other following a model of majorization as `exchangeability'. Majorization with respect to a partial order is shown to be a special case of majorization as exchangeability. In this special case, the resulting majorization order always defines a distributive lattice that is isomorphic to the standard real vector lattice.

In classical majorization theory, the semigroup of doubly-stochastic matrices plays a crucial role, both in the definition of majorization and in the modeling of exchange. We generalize majorization to permit any matrix semigroup of exchanges. Various semigroups of stochastic matrices make particularly interesting kinds of exchanges, and simultaneously define useful notions of majorization.

Finally, we investigate notions of convexity. When the functions in question are differentiable, we show that both Schur convexity and submodularity can be reexpressed naturally in this linear algebraic formulation.

Conjectures on the Size of Constellations Constructed from Direct Sums of PSK Kernels

Matthew G. Parker**

Department of Informatics, University of Bergen, N-5020 Bergen, Norway,
matthew@ii.uib.no

Abstract. A general equation is given for the size of complex constellations constructed from the direct sum of PSK-like constellation primitives. The equation uses a generating function whose numerator is a power of a 'coordination polynomial'. Conjectures are also given as to the form and value of these coordination polynomials for various PSK. The study has relevance to error-coding, polynomial residue number theory, and the analysis of random walks.

1 Introduction

Communications systems often transmit data by modulating using Binary or Quaternary Phase Shift Keyed (BPSK or QPSK) or Quadrature Amplitude Modulated (QAM) constellations in the complex plane. But larger constellations can be more bandwidth-efficient and lead to efficient hardware implementation of complex arithmetic and algorithms [1, 2]. This paper considers the problem of finding the size of constellations constructed from direct sums of {PSK plus the origin}, referred to here as 'PSK⊕' constellations. These constellations form lattices for 1,2,3, or 6 PSK primitives, but for any other PSK⊕ there will be residue 'folding' making the determination of constellation size more complicated. This problem can be recast, for mPSK⊕, as finding an expression for the number of non-identical polynomial residues resulting from the reduction, mod $\Phi_m(x)$, of polynomials in x of Coefficient Weight $\leq n$, (for some positive integer, n), and degree $< m$, where $\Phi_m(x)$ is the m^{th} cyclotomic polynomial in x. Although residue folding is, for many applications, undesirable, it is hoped that an algebraic understanding of PSK⊕ will help in the construction of constellations more suited to communications systems which use PSK⊕ as building blocks. Also, from an algebraic point of view, it is useful to be able to enumerate the residues of polynomials, mod $\Phi_m(x)$. The theorem and conjectures to be presented here are based on computational results. During the course of the work integer sequences, relating to the 8PSK⊕ and 16PSK⊕ constellations, were entered into Sloane's On-Line Encyclopedia of Integer Sequences [3] and were found to refer, in particular, to the paper by Conway and Sloane on Low Dimensional Lattices [4] which, in turn, references work by O'Keefe [5] and others [6].

** This work was funded by NFR Project Number 119390/431

Their results have applications to crystallography, and use generating functions which require the specification of a 'Coordination Sequence'. This paper conjectures a general solution to a related problem, although a general form for the Coordination Sequence (Polynomial) has yet to be found. The results could be used to help extend the scope of error coding strategies such as [7, 8], and may also be useful for the development of 'Random Walk' statistics.

2 Statement of the Problem

Define mPSK+ as the set of $m+1$ points in the complex plane given by,

$$m\text{PSK+} = \{0, 1, w, w^2, \ldots, w^{m-1}\}$$

where $w = e^{\frac{2\pi i}{m}}$, and $i^2 = -1$. Define mPSK$\oplus n$ as the direct sum of n copies of mPSK+, given by,

$$m\text{PSK} \oplus n = \sum_{k=0}^{n-1} \{0, 1, w, w^2, \ldots, w^{m-1}\}$$

We wish to find a formula for d_n as n varies over the positive integers, where d_n is the number of non-identical points in mPSK$\oplus n$, given by,

$$d_n = |\sum_{k=0}^{n-1} \{0, 1, w, w^2, \ldots, w^{m-1}\}|$$

For instance, let $m = 4$. The kernel constellation is $\{0, 1, w, w^2, w^3\}$, where $w = e^{\frac{2\pi i}{4}}$, and,

$$d_2 = |\sum_{k=0}^{1} \{0, 1, w, w^2, w^3\}| = |\{0, \pm 1, \pm w, \pm 1 \pm w, \pm 1 \mp w, \pm 2, \pm 2w\}| = 13$$

As another example, for $m = 6$ and $n = 2$,

$$d_2 = |\{0, \pm 1, \pm w, \pm w^2, \pm 2, \pm 2w, \pm 2w^2, \pm 1 \pm w, \pm 1 \mp w^2, \pm w \mp w^2\}| = 19$$

An algebraic description of the same problem is as follows.

Definition 1 *The 'Coefficient Weight', (cw), of a polynomial, $f(x)$, is the sum of it's coefficient values. In other words $cw(f(x)) = f(1)$.*

Let $g(x) = \sum_i g_i x^i$. Let,

$$\mathbf{G_{m,n}} = \{g(x) \mid 0 \leq \deg(g(x)) < m, g_i \geq 0 \ \ \forall i, 0 \leq \mathrm{cw}(g(x)) \leq n\}$$

where $\deg(a(x))$ is the degree of $a(x)$. Let $x = e^{\frac{2\pi i}{m}}$, where $i^2 = -1$. Then,

$$m\text{PSK} \oplus n = \{h(x) \mid h(x) = \langle g(x) \rangle_{\Phi_m(x)}, \forall g(x) \in \mathbf{G_{m,n}}\}$$

where $\langle a \rangle_b$ is the residue of a mod b, and $\Phi_m(x)$ is the m^{th} cyclotomic polynomial. Therefore,

$$d_n = |m\text{PSK} \oplus n|$$

as before.

3 Computational Results

Tables 1 and 2 show some computed values of d_n for various n and m. The number of Euclidean distances, D, refers to the size of the set of values for the absolute (straight-line) distance from each point in mPSK$\oplus n$ to the origin. The figures for D are not discussed further in this paper, but are included here for the reader's interest.

4 Some Conjectures

We shall form a generating function for the sequences, d_n, where d_n is different for every m. Thus define $d_m(x) = \sum_{n=0}^{\infty} d_n x^n$. The following conjecture satisfies all numerical results quoted above,

Conjecture 1

$$d_m(x) = \frac{c_h(x)^{\frac{m}{h}}}{(1-x)^{\phi(m)+1}}$$

where ϕ is Euler's Totient Function, h is the square free part of m, and $c_h(x)$ is referred to as the h^{th} coordination polynomial. $c_h(x)$ is palindromic and $\deg(c_h(x)) = \phi(h)$.

The above conjecture omits to specify exactly the form of $c_h(x)$. This is an area of further research. However the following theorem determines $c_h(x)$ where h is a prime, and two following conjectures satisfy the computational results for $h = 2p$, p an odd prime, and $h = 15$, respectively,

Theorem 1

$$c_p(x) = \Phi_p(x), \qquad p \text{ prime}$$

Theorem 1 was conjectured by the author based on numerical computation. A proof was found by T.Kløve and it is given in Appendix A.

Conjecture 2

$$c_{2p}(x) = \sum_{k=0}^{\frac{p-3}{2}} x^k + x^{p-1-k} \sum_{i=0}^{k} \binom{p}{i} + x^{\frac{p-1}{2}} \sum_{i=0}^{\frac{p-1}{2}} \binom{p}{i}, \qquad p \text{ an odd prime}$$

Conjecture 3

$$c_{15}(x) = (1+x^8) + 7(x+x^7) + 28(x^2+x^6) + 79(x^3+x^5) + 130x^4$$

The following observation was also made,

Conjecture 4

$$m \mid \left(\frac{m^{n+1}-1}{m-1} - d_n \right)$$

From the computational results values of $c_h(x)$ have also been partially ascertained for various h as shown in Table 3.

All preceding coordination polynomials were computed from the d_n sequences using the following strategy. For instance, for $m = 6$ the d_n sequence is computed to be 1,7,19,37,61,91,127,169,..... Thus $d_6(x) = 1+7x+19x^2+37x^3+61x^4+91x^5+127x^6+169x^7+\ldots$. Note that $\phi(6)+1 = 3$ so, from Conjecture 1, we multiply $d_6(x)$ (truncated to degree 7) by $(1-x)^3$ to get $c'_6(x) = e(x) + x^2 + 4x + 1$, where $e(x)$ is some error term due to having truncated $d_6(x)$ to degree 7. In this case $e(x) = -217x^8 + 380x^9 - 169x^{10}$, which is evidently an error term so $c_6(x) = x^2 + 4x + 1$. The same strategy can be used to compute $c_h(x)$ for all d_n sequences in the table, and hence arrive at the preceding Conjectures 2 - 3 on the form of $c_h(x)$.

Table 3. Incomplete Coordination Polynomials for Various Composite h

h	$c_h(x)$
21	$1 + 9x + 45x^2 + 158x^3 + 432x^4 + 909x^5 + \ldots$?
30	$1 + 22x + 208x^2 + 874x^3 + 1480x^4 + \ldots$?
33	$1 + 13x + 91x^2 + 444x^3 + 1677x^4 + \ldots$?
35	$1 + 22x + 208x^2 + 874x^3 + 1480x^4 + \ldots$?

5 Triangle Patterns

An examination of number triangles may give a clue as to how to extend the previous conjectures on coordination polynomials to the more general case. On page 14 of [4] it was observed that the coordination polynomials for the dual lattice, A_d^*, satisfy the following 'coordinator' triangle.

```
                                1
                              1   1
                            1   4   1
                          1   5   5   1
                        1   6  16   6   1
                      1   7  22  22   7   1
                    1   8  29  64  29   8   1
                  1   9  37  93  93  37   9   1
                1   10  46 130 256 130  46  10   1
              1   11  56 176 386 386 176  56  11   1
            1   12  67 232 562 1024 562 232  67  12   1
```

The p^{th} line of the above triangle, p prime, also provides the coordination polynomials, $c_{2p}(x)$, for Conjectures 1 and 2 of this paper.

In the same way we can construct a partial triangle for the $c_{3p}(x)$ case, using our previous computational results. Thus,

```
                                1
                              1   4   1
                            1   5   ?   5   1
                          1   6  21   ?  21   6   1
                        1   7  28  79 130  79  28   7   1
                      1   8  36 114 282   ? 282 114  36   8   1
                    1   9  45 158 432 909   ? 909 432 158  45   9   1
                  1  10  55 212 635 1499   ?   ?   ? 1499 635 212  55  10   1
                1  11  66 277 902 2346   ?   ?   ?   ?   ? 2346 902 277  66  11   1
              1  12  78 354 1245 3525   ?   ?   ?   ?   ?   ?   ? 3525 1245 354  78  12   1
            1  13  91 444 1677 5124   ?   ?   ?   ?   ?   ?   ?   ?   ? 5124 1677 444  91  13   1
```

where each entry apart from those of the middle three columns seems to be the sum of the three entries immediately above, e.g. $158 = 8 + 36 + 114$. **Note that the only triangle entries directly computed from computational results are the sequences, 1,4,1, and 1,7,28,79,130,79,28,7,1, and 1,9,45,158,432,909, and 1,13,91,444,1677. All other numbers in the above triangle are nominally filled in to fit the 'sum of three' conjecture.** The $c_{3p}(x)$ coordination polynomial can be read from the p^{th} line of the previous triangle for p prime. For instance, $c_{15}(x) = (1 + x^8) + 7(x + x^7) + 28(x^2 + x^6) + 79(x^3 + x^5) + 130x^4$. Although we do not currently have an equation for $c_{3p}(x)$ it is worth noting that the following triangle is similar to the previous triangle,

										1								
									1	4	1							
								1	5	15	5	1						
							1	6	21	52	21	6	1					
						1	7	28	79	175	79	28	7	1				
					1	8	36	114	282	576	282	114	36	8	1			
				1	9	45	158	432	972	1869	972	432	158	45	9	1		
			1	10	55	212	635	1562	3273	6000	3273	1562	635	212	55	10	1	
		1	11	66	277	902	2409	5470	10385	19107	10385	5470	2346	902	277	66	11	1
	1	12	78	354	1245	3588	8781	18714	35412	60460	35412	18714	8781	3588	1245	354	78	12	1
1	13	91	444	1677	5187	13614	31083	62907	114586	190333	114586	62907	31083	13614	5187	1677	444	91	13	1

and satisfies the equation,

$$P_r(x) = \sum_{k=0}^{r-1} (3x)^k (1 + x + x^2)^{r-k-1}$$

for each line of the triangle, r, thus providing a clue as to the true form of $c_{3p}(x)$.

Appendix B sketches out an alternative strategy for the rapid computation of the coefficients, d_n, of $d_m(x)$ for general m, and is a good starting place for further research. It is hoped that the strategy of Appendix B may lead to a proof of the remaining conjectures, in particular Conjecture 1, and may also lead to a theorem for the construction of $c_h(x)$ in the general case.

6 Conclusion

This paper has presented computational results relating to the size of constellations formed from direct sums of PSK-type constellations. A theorem and a number of conjectures have been offered, comprising formulae for the rapid computation of sizes of such 'direct-sum' constellations. These formulae have application to error-control coding, random-walk statistics, algebraic number representations, and (polynomial) residue number theory. It remains to verify the conjectures.

7 Appendix A- Proof of Theorem 1 by T.Kløve

Let $p_r(n)$ denote the number of ordered partitions of n into r parts, that is

$$p_r(n) = |\{(a_1, a_2, \ldots, a_r) \in N^r \mid a_1 + a_2 + \ldots + a_r = n\}|$$

where $N = \{0, 1, 2, \ldots\}$. If,

$$n = a_1 + a_2 + \ldots + a_{r-1} + a_r$$

and $a_i \geq 1$ for $i = 1, 2, \ldots, r-1$, then

$$n - (r-1) = (a_1 - 1) + (a_2 - 1) + \ldots + (a_{r-1} - 1) + a_r$$

and vice versa. Hence the number of ordered partitions of n into r parts such that the first $r-1$ parts are positive is $p_r(n-(r-1))$.

Lemma 1 *We have*

$$\sum_{n=0}^{\infty} p_r(n)x^n = \frac{1}{(1-x)^r} \qquad \textit{and} \qquad \sum_{n=r-1}^{\infty} p_r(n-(r-1))x^n = \frac{x^{r-1}}{(1-x)^r}$$

Proof of Lemma 1: These are standard results from the theory of partitions:

$$\sum_{n=0}^{\infty} p_r(n)x^n = (1+x+x^2+x^3+\ldots)^r = \frac{1}{(1-x)^r}$$

and

$\sum_{n=r-1}^{\infty} p_r(n-(r-1))x^n = x^{r-1}\sum_{n=r-1}^{\infty} p_r(n-(r-1))x^{n-(r-1)} = \frac{x^{r-1}}{(1-x)^r}$. ∎

Lemma 2 *Let m be an odd prime. Then $d_n = p_{m+1}(n) - p_{m+1}(n-m)$.*

Proof of Lemma 2: d_n counts the number of distinct sums

$$a_1 w + a_2 w^2 + \ldots + a_m w^m + a_{m+1} \cdot 0 \tag{1}$$

where $a_i \geq 0$ for $i = 1, 2, \ldots, m+1$ and $a_1 + a_2 + \ldots + a_{m+1} = n$. Noting that $w + w^2 + \ldots w^m = 0$ we get d_n by counting all sums (1), this number is $p_{m+1}(n)$, and subtracting the number of sums where $a_i \geq 1$ for $i = 1, 2, \ldots, m$, this number is $p_{m+1}(n-m)$ (as explained above). ∎

Theorem 1 now follows from the two lemmas:

$\sum_{n=0}^{\infty} d_n x^n = \sum_{n=0}^{\infty} p_{m+1}(n)x^n - \sum_{n=0}^{\infty} p_{m+1}(n-m)x^n = \frac{1-x^m}{(1-x)^{m+1}} = \frac{\Phi_m(x)}{(1-x)^m}$

since $\Phi_m(x) = x^m + x^{m-1} + \ldots + 1$. ∎

8 Appendix B - A General Strategy for Computing the Size of PSK⊕ Constellations

Here a technique is proposed for the fast computation of the coefficients of $d_m(x)$ in the general case. Hopefully this may lead to a general proof of the conjectures of this paper, and a fast way to construct $c_h(x)$ in the general case, at least for m up to some large value. The technique will be illustrated by looking at the case where $m = 6$. Note that $\Phi_6(x) = x^2 - x + 1$. The steps of the technique are the following subsection headings.

8.1 Find all Forbidden Binary Patterns

$\Phi_6(x)$ implies the following polynomial equivalences:

$$x^2 + 1 = x \qquad \text{pattern is } 101000$$

$$x^3 + 1 = 0 \qquad \text{pattern is } 100100$$

These are the two **binary** patterns (polynomials) which are 'forbidden' for $m = 6$. The forbidden polynomials are the set of polynomials which are equivalent, mod $\Phi_m(x)$, to polynomials of lower hamming weight. Note that, for example, x^2-x+1 is not included as a 'forbidden' polynomial as it includes the polynomial $x^2 + 1$ as a sub-polynomial. In general, for $m = 2p$, p prime, there are only two forbidden polynomials, namely, $x^{p-1} + x^{p-3} + x^{p-5} + \ldots + x^2 + 1$, and, x^p+1. More generally, for large, composite m, there may be non-binary forbidden polynomials.

8.2 Enumerate all Length m Binary Words Which Avoid the Forbidden Patterns

For $m = 6$, and for Hamming Weights (hw) 0-6 we have the following cyclically distinct **binary** strings which avoid the forbidden patterns or any cyclic shift of the forbidden patterns.

hw = 0 000000
hw = 1 100000
hw = 2 110000
hw = 3 none
hw = 4 none
hw = 5 none
hw = 6 none

Each string of non-zero Hamming Weight has cyclic shift order 6. We will refer to the set of length m strings which avoid the forbidden patterns as the 'foundation' polynomials. These 'foundation' polynomials form the set **E**. For $m = 6$ $|\mathbf{E}| = 3$. We will define there to be $e_{\mathrm{hw},m}$ cyclically distinct length m binary words in **E**, $0 \leq \mathrm{hw} \leq m$. For $m = 6$, $e_{0,6} = 1$, $e_{1,6} = 1$, $e_{2,6} = 1$, $e_{3,6} = 0$, $e_{4,6} = 0$, $e_{5,6} = 0$, $e_{6,6} = 0$. Note that $e_{0,m} = 1$ $\forall m$.

8.3 Use Each Member of E as a 'Foundation' for Building All Length m Inequivalent Polynomials of Coefficient Weight n, mod $\Phi_m(x)$

The '1' positions of the 'foundation' polynomials of **E** mark the positions where we are allowed to add 'coefficient weight' to construct our inequivalent polynomials. It therefore follows that the number of inequivalent polynomials, d_n, satisfies,

$$d_n = 1 + m \sum_{k=1}^{n} \sum_{\mathrm{hw}=1}^{m} \binom{k-1}{k-\mathrm{hw}} e_{\mathrm{hw},m} \tag{2}$$

For $m = 6$,

$d_0 = 1$
$d_1 = 1 + 6 = 7$
$d_2 = 1 + 6 + 6(1 + 1) = 19$
$d_3 = 1 + 6 + 6(1 + 1) + 6(1 + 2 + 0) = 37$
$d_4 = 1 + 6 + 6(1 + 1) + 6(1 + 2 + 0) + 6(1 + 3 + 0 + 0) = 61$
$d_5 = 1 + 6 + 6(1 + 1) + 6(1 + 2 + 0) + 6(1 + 3 + 0 + 0) + 6(1 + 4 + 0 + 0 + 0) = 91$
$\ldots$ etc

These numbers agree with those of Table 1. The number of r-way ordered partitions adding to n is $p_r(n)$, and

$$p_r(n) = \binom{n + r - 1}{n}$$

Therefore we can rewrite (2) in terms of partitions as,

$$d_n = 1 + m \sum_{k=1}^{n} \sum_{\mathrm{hw}=1}^{m} p_{\mathrm{hw}}(k - \mathrm{hw}) e_{\mathrm{hw},m} \tag{3}$$

8.4 Comments on the Technique

The technique assumes that all polynomials in **E** have cyclic order m. It seems likely that this is true in general as d_n appears to satisfy $m|(d_n - 1)$ for all cases computed in Tables 1 and 2. A proof of Conjecture 1, and a proof of the general form of $c_h(x)$ may well follow if one can do the following for a given m,

1. Derive an efficient method to compute the 'forbidden' polynomials.
2. Derive an efficient method to compute the elements $e_{\mathrm{hw},m}$ of **E** from the forbidden polynomials.

For large m (e.g. perhaps $m = 105$?) there may be non-binary forbidden polynomials for which the above technique must be modified as follows: Consider, as an example, a 'hypothetical' forbidden polynomial, $F(x)$, of the following form:

$$F(x) = x^5 + 3x^2 + x + 2$$

Then it has an associated binary forbidden polynomial, $f(x)$, where,

$$f(x) = x^5 + x^2 + x + 1$$

We wish to disallow all polynomials built from the foundation $F(x)$ not $f(x)$. Let the cyclic order (over m) of $F(x)$ and $f(x)$ be v. Then we should include γ_n polynomials in our count for d_n, where

$$\gamma_n = v(\sum_{k=1}^{n} p_4(k - 4) - \sum_{k=1}^{n-3} p_4(k - 4)) = v \sum_{k=n-2}^{n} p_4(k - 4)$$

where the '3' in the summation limit of the previous equation is the coefficient weight (cw) of $F(x)$ minus the hamming weight of $F(x)$. In general, for a given forbidden polynomial $F(x)$ we include γ_n in our count for d_n where γ_n satisfies,

$$\gamma_n = v \sum_{k=n+\mathrm{hw}(F(x))-\mathrm{cw}(F(x))+1}^{n} p_{\mathrm{hw}(F(x))}(k - \mathrm{hw}(F(x)))$$

In the case where the forbidden polynomial is a binary polynomial $\mathrm{hw}(F(x)) = \mathrm{cw}(F(x))$ and γ_n for $F(x)$ is 0, as expected. Things will be further complicated if the cyclic order of $F(x)$ is lower than that of $f(x)$.

9 Acknowledgements

The author thanks S.J.Shepherd and D.A.Gillies for helpful discussions, and D.A.Gillies for writing software which independently confirmed results for the $m = 8$ case, and provided extra data for this case.

Abstract. A recursive construction is provided for sequence sets which possess good Hamming Distance and low Peak-to-Average Power Ratio (PAR) under any Local Unitary Unimodular Transform. We identify a subset of these sequences that map to binary indicators for linear and nonlinear Factor Graphs, after application of subspace Walsh-Hadamard Transforms. Finally we investigate the quantum PAR_l measure of 'Linear Entanglement' (LE) under any Local Unitary Transform, where optimum LE implies optimum weight hierarchy of an associated linear code.

1 Introduction

Golay Complementary sequences of length 2^n form sequences with Peak-to-Average Power Ratio (PAR) ≤ 2 under the one-dimensional continuous Discrete Fourier Transform (DFT_1^∞) [9]. The upper PAR bound of 2 follows by forming these Complementary Sequences using Rudin-Shapiro construction [25, 26]. This set is the union of certain quadratic cosets of Reed-Muller (RM) $(1, n)$ [5]. Moreover the quadratic coset representatives can be viewed as 'line graphs' in Algebraic Normal Form (ANF) [21]. As these sequences are a subset of $\text{RM}(2, n)$, the Hamming Distance, D, between sequences in the set satisfies $D \geq 2^{n-2}$. The problem of finding error-correcting codes where each codeword also has low PAR has application to Orthogonal Frequency Division Multiplexing (OFDM) communications systems [11]. However the fundamental codeset identified by Davis and Jedwab [5] (DJ sequences) suffers from vanishing rate as n increases, and much higher rates are possible and desirable, where $\text{PAR} \leq O(n)$ [27, 22]. A generalisation of Rudin-Shapiro construction to other starting seeds [16, 17]. allows inclusion of more low PAR quadratic cosets of $\text{RM}(1, n)$ in the code, thereby improving code rate somewhat. Higher degree cosets...etc can also be added, increasing code rate at price of distance, D, which decreases. However these rate improvements are marginal. In this paper we present a construction for much larger codesets of sequences with $\text{PAR} \leq 2^t$, comprising ANFs up to degree u, where $u \leq t$ for $t > 1$, and $u = 2$ for $t = 1$ [19]. These codesets have $\text{PAR} \leq 2^t$ under **all** Linear Unimodular Unitary Transforms (LUUTs), including one and multi-dimensional continuous DFTs. As LUUTs include the Walsh-Hadamard

Transform (WHT) then our construction gives large codesets of Almost-Bent functions [3, 23]. The functions are cryptographically even stronger, as the binary sequences are distant from linear sequences over all alphabets, not just over Z_2. We then describe a mapping of a subset of the bipolar sequences, generated using our construction, to Factor Graphs [12]. By applying tensor products of Hadamard and Identity kernels to our bipolar sequence we transform to a Factor Graph in a Normal Realisation [7] representing a linear or nonlinear error-correcting code. This transformation provides spectral characterisation for Factor Graphs (and Quantum Factor Graphs [15]). Finally we present PAR_l, which is a partial measure of quantum entanglement and measures PAR under **all** Linear Unitary Transforms (LUTs) [17, 18]. We also define 'Linear Entanglement' (LE), and 'Stubborness of Entanglement' (SE), which is a series of parameters related to PAR_l over all sequence subspaces. At least in the bipartite quadratic case, a length 2^n bipolar sequence with optimal LE and SE represents a $[n, k, d]$ binary linear code with optimal weight hierarchy. We conjecture that optimally entangled subsystems represent optimal linear and nonlinear codes - and vice versa. A similar relationship between secrecy and entanglement has recently been highlighted by [4].

2 A Construction For Low PAR Error-Correcting Codes

Joint work with C.Tellambura [19]
PAR is a spectral measure. We must therefore define the transforms over which the spectrum is computed:

2.1 Definitions

Definition 1 $\boldsymbol{L_n}$ *is the infinite set of length* 2^n *complex linear unimodular sequences,* $\boldsymbol{l} = (l_0, l_1, \ldots, l_{2^n-1})$*, where* $|l_i| = |l_j|$*,* $\forall i, j$*,* $\sum_{i=0}^{2^n-1} |l_i|^2 = 1$*, and,*

$$\boldsymbol{l} = \{2^{\frac{-n}{2}}(a_0, b_0) \otimes (a_1, b_1) \otimes \ldots \otimes (a_{n-1}, b_{n-1})\}$$

where $\otimes$ *means 'tensor product'.*

Definition 2 *A* $2^n \times 2^n$ *Linear Unimodular Unitary Transform (LUUT) matrix* $\mathbf{L}$ *has rows taken from* $\boldsymbol{L_n}$ *such that* $\mathbf{L}\mathbf{L}^\dagger = \mathbf{I_{2^n}}$*, where* $\dagger$ *means conjugate transpose, and* $\mathbf{I_{2^n}}$ *is the* $2^n \times 2^n$ *identity matrix.*

Definition 3 $\boldsymbol{G_n}$ *is the infinite set of length* 2^n *complex linear sequences,* $\boldsymbol{l} = (l_0, l_1, \ldots, l_{2^n-1})$*, where* $\sum_{i=0}^{2^n-1} |l_i|^2 = 1$ *and,*

$$\boldsymbol{l} = \{2^{\frac{-n}{2}}(a_0, b_0) \otimes (a_1, b_1) \otimes \ldots \otimes (a_{n-1}, b_{n-1})\}$$

Note that $\boldsymbol{G_n} \supset \boldsymbol{L_n}$*.*

Definition 4 *A* $2^n \times 2^n$ *Linear Unitary Transform (LUT) matrix* $\mathbf{G}$ *has rows taken from* $\boldsymbol{G_n}$ *such that* $\mathbf{G}\mathbf{G}^\dagger = \mathbf{I_{2^n}}$*. LUUTs are a special case of LUT.*

Let s_i be an element of a length 2^n vector, $\boldsymbol{s}$. PAR($\boldsymbol{s}$) is computed by measuring maximum possible correlation of $\boldsymbol{s}$ with **any** length 2^n 'linear' unimodular sequence, $\boldsymbol{l} \in \boldsymbol{L_n}$:

Definition 5 $PAR(\boldsymbol{s}) = 2^n max_{\boldsymbol{l}}(|\boldsymbol{s} \cdot \boldsymbol{l}|^2)$
where $\boldsymbol{l} \in \boldsymbol{L_n}$ and $\cdot$ means 'inner product' [17].

Let $\boldsymbol{x} = \{x_0, x_1, \ldots, x_{n-1}\}$. Then $p(\boldsymbol{x})$: $Z_2^n \rightarrow Z_2$ has a bipolar representation, $\boldsymbol{s} = (-1)^{p(\boldsymbol{x})} = (s_0, s_1, \ldots, s_{2^n-1})$, where $s_i = (-1)^{p(x_0=i_0, x_1=i_1, \ldots, x_{n-1}=i_{n-1})}$, and $i = \sum_{k=0}^{n-1} i_k 2^k$ is a radix-2 decomposition of i.

2.2 Construction

This paper focuses on a special case of a more general construction. Here, all x_i are two-state binary variables, and the fundamental recursion is based on Walsh-Hadamard Transform (WHT) kernels. The more general construction is presented in [19]. We now present the construction:

$$\begin{array}{l} p(\boldsymbol{x}) = \sum_{j=0}^{L-2} \sum_{l=0}^{t-1} x_{\pi(tj+l)} f_{l,j}(x_{\pi(t(j+1))}, x_{\pi(t(j+1)+1)}, \ldots, x_{\pi(t(j+2)-1)}) \\ + \sum_{j=0}^{L-1} g_j(x_{\pi(tj)}, x_{\pi(tj+1)}, \ldots, x_{\pi(tj+t-1)}) \end{array} \quad (1)$$

where $n = Lt$, π permutes Z_n, and where $f_{l,j} : Z_2^t \rightarrow Z_2$ is such that $f_{\gamma_j} = (f_{0,j}, f_{1,j}, \ldots, f_{t-1,j})$ is an invertible boolean function (permutation polynomial) from $Z_2^t \rightarrow Z_2^t$, governed by the permutation, $i' = \gamma_j(i)$, where $i' = \sum_{l=0}^{t-1} i'_l 2^l$ is a radix-2 decomposition, $i'_l = f_{l,j}(i_0, i_1, \ldots, i_{t-1})$, and each γ_j permutes Z_t. To avoid unnecessary duplications, we exclude the f_{γ_j} where one or more $f_{l,j}$ has a '+1' constant offset, and also the cases where all $f_{l,j}$ are monomials, except when f_{γ_j} is the identity function.

Theorem 1 *[19] The length $N = 2^n$ bipolar sequence $\boldsymbol{s} = (-1)^{\boldsymbol{p}}$ satisfies $PAR(s) \leq 2^t$ under all LUUTs, where $\boldsymbol{p}$ is generated using construction (1).*

Proof. (sketch) Let m factor fully as $m = \prod_{i=0}^{F-1} p_i$, p_i not necessarily distinct. A length m vector, $\boldsymbol{l}$, is defined linear if it satisfies $\boldsymbol{l} = \bigotimes_{i=0}^{F-1} \boldsymbol{v_i}$ where length($\boldsymbol{v_i}$) = p_i, and $\sum_{j=0}^{m-1} |l_j|^2 = 1$. Let $\boldsymbol{E_j}$ and $\boldsymbol{A_j}$, $1 \leq j \leq L$, be a series of $N \times N$ and $N \times N^j$ complex matrices, respectively, where $\boldsymbol{A_1} = \boldsymbol{E_1}$ is unitary. Let the rows of $\boldsymbol{A_{j-1}}$, $(\boldsymbol{a_{0,j-1}}, \boldsymbol{a_{1,j-1}}, \ldots, \boldsymbol{a_{N-1,j-1}})$, form a complementary set of N sequences under any $N^{j-1} \times N^{j-1}$ unitary transform with linear unimodular rows. Let $\boldsymbol{l}$ and $\boldsymbol{l_j}$ be normalised linear rows of length N^{j-1} and N, respectively. Let $\boldsymbol{r} = \boldsymbol{A_{j-1}} \boldsymbol{l}$. Let γ permute Z_N. Construct the $N \times N^j$ matrix, $\boldsymbol{A_j}$, such that $\boldsymbol{a_{i,j}} = ((\boldsymbol{a_{\gamma(0),j-1}} | \boldsymbol{a_{\gamma(1),j-1}} | \ldots, | \boldsymbol{a_{\gamma(N-1),j-1}}) \odot (\boldsymbol{e_{i,j}} \otimes \boldsymbol{1}))$ where $\boldsymbol{x} \odot \boldsymbol{y} = (x_0 y_0, x_1 y_1, \ldots, x_{N^j-1} y_{N^j-1})$, $\boldsymbol{1}$ is the length N^{j-1} all-ones vector, $\boldsymbol{e_{i,j}}$ is the ith row of $\boldsymbol{E_j}$, and $'|'$ means concatenation. The rows of $\boldsymbol{A_j}$ form a complementary N-set under any unitary transform if $\boldsymbol{r'} = \boldsymbol{A_j}(\boldsymbol{l_j} \otimes \boldsymbol{l})$ satisfies, $\sum_{k=0}^{N-1} |r'_i|^2 = 1$. This follows if $\sum_{i=0}^{N-1} |\sum_{k=0}^{N-1} (r_{\gamma(k)} e_{i,k} l_k)|^2 = 1$, for $r_k, e_{i,k}$ and l_k elements of

$\boldsymbol{r}$,$\boldsymbol{e_{i,j}}$ and $\boldsymbol{l_j}$, respectively. This is true if $\boldsymbol{E_j}$ is unitary, and if $\boldsymbol{e_{i,j}} \odot \boldsymbol{l_j}$ is unimodular, which follows if $\boldsymbol{e_{i,j}}$ and $\boldsymbol{l_j}$ are unimodular. Construction (1) occurs when successive $\boldsymbol{A_j}$ are recursively generated, where all $\boldsymbol{E_i}$ are $2^t \times 2^t$ WHTs. The γ permutation essentially maps to f_γ, and concatenation is widened to a more general permutation, π, over all linear variables. ∎

Theorem 2 *For a fixed t, let $\boldsymbol{P}$ be the codeset of length 2^n binary sequences of degree μ or less, generated using (1). Then,*

$$\begin{aligned} \frac{|\boldsymbol{P}|}{2^{n+1}} &\leq \frac{(\frac{\Gamma}{t!})^{\frac{n}{t}-1} n! (2^{2^t-t-1})^{\frac{n}{t}}}{2t!}, & \mu = 2 \\ &\leq \frac{((2^t-1)!)^{\frac{n}{t}-1} n! (2^{2^t-t-1})^{\frac{n}{t}}}{2t!}, & \mu \geq 2 \end{aligned} \tag{2}$$

where $\Gamma = \prod_{i=0}^{t-1}(2^t - 2^i) = |GL(t,2)|$. (GL is the General Linear Group). (Only for $t = 1$ is the upper bound exact).

Proof. By counting arguments we can show that, for $\mu = 2$,

$$\frac{|\boldsymbol{P}|}{2^{n+1}} \leq \frac{\prod_{l=1}^{t} \binom{\frac{ln}{t}}{\frac{n}{t}}}{t!} \times \frac{(\frac{n}{t})!^t}{2} \times (\frac{\Gamma}{t!})^{\frac{n}{t}-1} \times (2^{(t/2)})^{\frac{n}{t}}$$

For $\mu \geq 2$, we replace $\frac{\Gamma}{t!}$ with $\frac{(2^t)!}{2^t}$, which is the number of permutations excluding those with a constant offset, '+1'. The Theorem follows. ∎

In Section 2.4 we show how to generate all degree-one permutation polynomials, via an isomorphism to the General Linear Group, where the number of degree-one permutation polynomials is Γ.

2.3 Examples

The $2^n \times 2^n$ Walsh-Hadamard (WHT) and Negahadamard (NHT) Transform matrices are $\bigotimes_{i=0}^{n-1} \boldsymbol{H}$, and $\bigotimes_{i=0}^{n-1} \boldsymbol{N}$, respectively, where $\boldsymbol{H} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$ and $\boldsymbol{N} = \left(\begin{smallmatrix} 1 & i \\ 1 & -i \end{smallmatrix}\right)$, and $i^2 = -1$. DFT_1^∞ is the set of $2^n \times 2^n$ matrices, the union of whose rows form a subset of $\boldsymbol{L_n}$ such that each row satisfies $a_i = 1$, $b_i = \omega^{ik}$ for some fixed k, and ω is a complex root of unity (see Definition 1). These three transforms are used as 'spot-checks' in the examples to validate the PAR upper-bound.

Example 1 Let γ_j be the identity permutation $\forall j$. Then,
$f_{l,j}(x_{\pi(t(j+1))}, x_{\pi(t(j+1)+1)}, \ldots, x_{\pi(t(j+2)-1)}) = x_{\pi(t(j+1)+l)}$, and (1) becomes,

$$p(\boldsymbol{x}) = \sum_{j=0}^{L-2} \sum_{l=0}^{t-1} x_{\pi(tj+l)} x_{\pi(t(j+1)+l)} + \sum_{j=0}^{L-1} g_j(x_{\pi(tj}, x_{\pi(tj+1)}, \ldots, x_{\pi(tj+t-1)}) \tag{3}$$

When $\deg(g_j) < 2$, $\forall j$, it is well-known that $\boldsymbol{s} = (-1)^{p(\boldsymbol{x})}$ is Bent (PAR = 1 under the WHT) for L even [14] and (perhaps not known) that $\boldsymbol{s}$ has PAR $= 2^t$

under the WHT for L odd. In general, for any g_j, s has PAR $\leq 2^t$ under all LUUTs. For example, if $L = 4$ and,

$$p(\boldsymbol{x}) = x_0x_3 + x_1x_4 + x_2x_5 + x_3x_6 + x_4x_7 + x_5x_8 + x_6x_9 + x_7x_{10} + x_8x_{11}$$

then $\boldsymbol{s} = (-1)^{p(\boldsymbol{x})}$ has PAR = 1.0 under the WHT, PAR = 1.0 under the NHT, and PAR = 7.09 under DFT_1^∞. Similarly, let $g_0(x_0, x_1, x_2) = x_1x_2$, $g_1(x_3, x_4, x_5) = x_3x_4x_5$, and $g_2(x_6, x_7, x_8) = 0$. Then $\boldsymbol{s'} = (-1)^{p(\boldsymbol{x})+g_0+g_1+g_2}$ has PAR = 4.0 under the WHT, PAR = 2.0 under the NHT, and PAR = 7.54 under DFT_1^∞. In all cases, PAR ≤ 8.0 under any LUUT.

Example 2, PAR $\leq$ 2.0 Let $t = 1$. Then we have one possible permutation polynomial, namely, $f_\gamma = x$, (we exclude $f_\gamma = x + 1$). From (1) we obtain,

$$p(\boldsymbol{x}) = \textstyle\sum_{j=0}^{L-2} x_{\pi(j)}x_{\pi(j+1)} + c_jx_j + d, \qquad c_j, d \in Z_2 \tag{4}$$

This is exactly the DJ set of binary quadratic cosets of RM$(1, n)$, where $n = L$ [5]. This set has PAR ≤ 2.0 under DFT_1^∞ [5]. Such sequences are Bent for n even [14, 23] and, in [16, 17] it was shown that such a set has PAR = 2.0 under the WHT for n odd, and also, under the NHT, has PAR = 1.0 for $n \neq 2 \bmod 3$ (NegaBent), and PAR = 2.0 for $n = 2 \bmod 3$. More generally the DJ set has PAR ≤ 2.0 under any LUUT [17], and this agrees with Theorem 1. For example, let $p(\boldsymbol{x}) = x_0x_4 + x_4x_1 + x_1x_2 + x_2x_3 + x_1 + 1$. Then $\boldsymbol{s} = (-1)^{p(\boldsymbol{x})}$ has PAR = 2.0 under the WHT, PAR = 2.0 under the NHT, and PAR = 2.0 under DFT_1^∞. The DJ set, being cosets of $R(2, n)$, forms a codeset with Hamming Distance, $D >= 2^{n-2}$. The rate of the DJ codeset follows $\frac{(\frac{n!}{2})2^{n+1}}{2^{2^n}}$ as n increases. This is their primary drawback as the code rate vanishes rapidly as n increases.

Example 3, PAR $\leq$ 4.0 [5, 22, 17, 23] have all proposed techniques for the inclusion of further quadratic cosets, so as to improve rate at the price of increased PAR. We here propose an improved rate code (although still vanishing), where PAR ≤ 4.0. To achieve this we set $t = 2$ in (1). There are $\frac{(2^t)!}{2^t t!} = 3$ valid permutation polynomials, $f_\gamma = (f_0, f_1)$. These polynomials map from $Z_2^2 \to Z_2^2$, and are taken from the set,

$$f_\gamma(x_0, x_1) \in \{(x_0, x_1), (x_0 + x_1, x_1), (x_0, x_0 + x_1)\}$$

Substituting for $f_{l,j}$ and g_j in (1) gives a large set of polynomials with PAR≤ 4.0 under all LUUTs. We now list, for this construction, the $p(\boldsymbol{x})$ arising from the the 3 invertible polynomial functions, f_γ, for one 'section' of the polynomial, i.e. for $L = 2$, where we fix π to the identity permutation.

$$\begin{aligned}
p(\boldsymbol{x}) &= x_0x_2 + x_1x_3 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1, 4)\\
p(\boldsymbol{x}) &= x_0(x_2 + x_3) + x_1x_3 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1, 4)\\
p(\boldsymbol{x}) &= x_0x_2 + x_1(x_2 + x_3) + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1, 4)
\end{aligned}$$

where $c_0, c_1 \in Z_2$. The quadratic part of each of these 3 functions is isomorphic to a distinct invertible boolean $t \times t$ matrix, where $t = 2$ (Section 2.4), as the

permutation polynomials form a group which is isomorphic to the General Linear Group, $\mathrm{GL}(t,2)$, where $|\mathrm{GL}(t,2)| = \prod_{i=0}^{t-1}(2^t - 2^i)$ [13]. Two of the 3 quadratic functions are inequivalent under permutation of the four variable indices, e.g.,

$$p(\boldsymbol{x}) = x_0x_2 + x_1x_3 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)$$
$$p(\boldsymbol{x}) = x_0(x_2 + x_3) + x_1x_3 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)$$

An upper bound on $|\boldsymbol{P}|$ is given by Theorem 2, (2). Substituting $t = 2$ into (2),

$$\frac{|\boldsymbol{P}|}{2^{n+1}} < n!2^{\frac{n-4}{2}}3^{\frac{n}{2}-1} \tag{5}$$

An exact enumeration and construction for this set remains open, due to extra 'hidden' symmetries. Computationally we are able to calculate the exact number of quadratic coset leaders for $n = 4, 6, 8, 10$, and these are compared to the upper bound of (5) in Table 1. They are also compared to the number of quadratic coset leaders, $(= \frac{n!}{2})$ in the binary DJ codeset (Example 2). By assigning $t = 2$

Table 1. The Number of Quadratic Coset Leaders for Construction (1) when $t = 2$

n	4	6	8	10
Theorem 2, (5),(2), $\lvert\boldsymbol{P}\rvert/2^{n+1}$	72	12960	4354560	2351462400
Exact Computation	36	9240	4086096	2317593600
$\frac{\text{DJ Code}}{2^{n+1}}$	12	360	20160	1814400
$\log_2(\lvert\boldsymbol{P}\rvert/2^{n+1})$	6.2	13.7	22.1	31.1
$\log_2$(Number of quadratics)	6	15	28	45

we have a construction for a much larger codeset than the DJ codeset and with the same Hamming Distance, $D = 2^{n-2}$, but the price paid is that the PAR is now upper-bounded by 4.0 instead of 2.0. For example, let,
$p(\boldsymbol{x}) = x_0x_2 + x_1x_2 + x_1x_6 + x_2x_5 + x_6x_3 + x_6x_5 + x_5x_4 + x_3x_7 + x_0x_1 + x_5x_3 + x_7 + x_1$
Then $\boldsymbol{s} = (-1)^{\boldsymbol{P}}$ has PAR = 1.0 under the WHT, PAR = 2.0 under the NHT, and PAR = 3.43 under DFT_1^∞.

Example 4, PAR $\leq$ 8.0 Set $t = 3$ in (1). There are now $\frac{(2^t)!}{2^t t!} = 840$ valid permutation polynomials, $f_\gamma = (f_0, f_1, f_2)$. These polynomials map from $Z_2^3 \to Z_2^3$. Moreover, $(2^3-1)(2^3-2)(2^3-2^2)/t! = \frac{168}{6} = 28$ of the polynomials are degree-one permutations leading to quadratic forms, $p(\boldsymbol{x})$, and can be represented by the following 7 permutation polynomials.

$f_\gamma(x_0, x_1, x_2) \in \{$
$(x_0, x_1, x_2), (x_0 + x_2, x_1, x_2), (x_0 + x_2, x_1 + x_2, x_2), (x_0 + x_1 + x_2, x_1, x_2),$
$(x_0 + x_1, x_1 + x_2, x_2), (x_0 + x_1 + x_2, x_1 + x_2, x_2), (x_0 + x_2, x_1 + x_0, x_2 + x_0 + x_1)\}$

Substituting for $f_{l,j}$ and g_j in (1) gives a large set of polynomials with PAR$\leq$ 8.0 under all LUUTs. We now list, for this construction, all quadratic $p(\boldsymbol{x})$ arising

from the 7 inequivalent degree-one permutation polynomials, f_γ, for one 'section' of the polynomial, i.e. for $L = 2$, where π is fixed as the identity permutation.

$$
\begin{aligned}
p(\boldsymbol{x}) &= x_0x_3 + x_1x_4 + x_2x_5 + g(\boldsymbol{x}) \\
p(\boldsymbol{x}) &= x_0x_3 + x_0x_5 + x_1x_4 + x_2x_5 + g(\boldsymbol{x}) \\
p(\boldsymbol{x}) &= x_0x_3 + x_0x_5 + x_1x_4 + x_1x_5 + x_2x_5 + g(\boldsymbol{x}) \\
p(\boldsymbol{x}) &= x_0x_3 + x_0x_4 + x_0x_5 + x_1x_4 + x_2x_5 + g(\boldsymbol{x}) \\
p(\boldsymbol{x}) &= x_0x_3 + x_0x_4 + x_1x_4 + x_1x_5 + x_2x_5 + g(\boldsymbol{x}) \\
p(\boldsymbol{x}) &= x_0x_3 + x_0x_4 + x_0x_5 + x_1x_4 + x_1x_5 + x_2x_5 + g(\boldsymbol{x}) \\
p(\boldsymbol{x}) &= x_0x_3 + x_0x_5 + x_1x_3 + x_1x_4 + x_2x_3 + x_2x_4 + x_2x_5 + g(\boldsymbol{x})
\end{aligned}
$$

where $g(\boldsymbol{x}) = c_0x_0x_1 + c_1x_0x_2 + c_2x_1x_2 + c_3x_0x_1x_2 + c_4x_3x_4 + c_5x_3x_5 + c_6x_4x_5 + c_7x_3x_4x_5 + \mathrm{RM}(1,6)$, and $c_0, c_1, \ldots, c_7 \in Z_2$. An upper bound to $|\boldsymbol{P}|$ can be computed from Theorem 2, (2), and the upper bound is compared to the total number of quadratics in n binary variables in Table 2. As with $t = 2$, an

Table 2. The Number of Quadratic Coset Leaders for Construction (1) when $t = 3$

n	6	9	12	15
Theorem 2, (2), $\log_2(\lvert\boldsymbol{P}\rvert/2^{n+1})$	16.7	33.5	51.7	70.9
$\log_2$(Number of quadratics)	15	36	66	105

exact enumeration and construction for this set remains open, due to extra 'hidden' symmetries. By assigning $t = 3$ we have a construction for a codeset with Hamming Distance, $D \geq 2^{n-2}$ and PAR ≤ 8.0 under all LUUTs.

For $t = 3$ we can also include cubic forms in Construction (1). There are $\frac{5040-168}{6} = 812$ degree 2 permutation polynomials, $f_\gamma = (f_0, f_1, f_2)$, that map from $Z_2^3 \rightarrow Z_2^3$, and lead to cubic forms, $p(\boldsymbol{x})$. This set can be represented by 147 degree 2 permutation polynomials which are inequivalent under variable permutation, and these are listed at [20]. (Along with the 7 inequivalent degree 1 permutation polynomials, this makes a total of 154 inequivalent permutation polynomials for $t = 3$ [10, 28]). Substituting for $f_{l,j}$ and g_j in (1) gives a large set of polynomials with PAR$\leq$ 8.0 under all LUUTs, and Hamming Distance, $D \geq 2^{n-3}$. An upper bound to $|\boldsymbol{P}|$ can be computed from Theorem 2, (2), and the upper bound is compared to the total number of quadratics and cubics in n binary variables in Table 3. Here is an example from this codeset, where ijk, uv

Table 3. The Number of Cubic and Quadratic Coset Leaders for Construction (1) when $t = 3$

n	6	9	12	15
Theorem 2, (2), $\log_2(\lvert\boldsymbol{P}\rvert/2^{n+1})$	23.6	46.3	70.4	95.5
$\log_2$(Number of quadratics and cubics)	35	120	286	560

is short for $x_i x_j x_k + x_u x_v$. Let,

$$p(\boldsymbol{x}) = 034, 035, 045, 135, 145, 234, 235, 245, 367, 368, 378, 567, 568, 69A, 79A, 7AB,$$
$$89A, 345, 9AB, 03, 05, 14, 24, 25, 36, 38, 47, 58, 69, 6A, 6B, 7A, 7B, 89, 8B, 67, 78, AB$$

then $\boldsymbol{s} = (-1)^{p(\boldsymbol{x})}$ has PAR = 4.0 under the WHT, PAR = 6.625 under the NHT, and PAR = 7.66 under DFT_1^∞. In all cases, PAR ≤ 8.0.

2.4 A Matrix Construction for all Quadratic Codes from (1)

Each degree-one permutation polynomial, f_γ from $Z_2^t \rightarrow Z_2^t$ can be viewed as a $t \times t$ binary adjacency matrix. Let $x = \{x_0, x_1, \ldots, x_{t-1}\}$. We can write,

$$M \Leftrightarrow f_\gamma(x) = (f_0(x), f_1(x), \ldots, f_{t-1}(x)), \qquad M = \{m_{i,l}\}, \deg(f_l(\boldsymbol{x})) = 1, \text{ and}$$
$$m_{i,l} = 1 \qquad \text{if } x_i \in f_l(x) \qquad m_{i,l} = 0 \qquad \text{otherwise}$$

The mapping is an isomorphism from the degree-one permutation polynomials to the General Linear Group, $G = \mathrm{GL}(t, 2)$, of all binary $t \times t$ invertible matrices [13]. To construct all quadratic sequences, $p(\boldsymbol{x})$, for a given n and t we need to construct all degree one permutation polynomials, f_γ. These can, in turn be constructed by generating all members of $G = \mathrm{GL}(t, 2)$, and this is accomplished as follows [1, 2].

Definition 6 *A binary $t \times t$ 'transvection' matrix, X_{ab}, satisfies,*

$$X_{ab} = \{u_{i,j}\}, \text{ where}$$
$$u_{i,j} = 1, \quad i = j, \text{ and } i = a, j = b \qquad u_{i,j} = 0, \quad \text{otherwise}$$

Definition 7 *The Borel subgroup of G over Z_2 is the $t \times t$ upper-triangular binary matrices, B.*

Definition 8 *The Weyl subgroup of G is the $t \times t$ permutation matrices, W.*

Assign a fixed ordering, O, to the $\frac{\binom{t}{2}}{2}$ matrices, X_{ab}, $a < b$. Let $w \in W$ be a permutation of Z_t and its associated $t \times t$ permutation matrix. For each w, form the matrix product, X_w, comprising all X_{ab} which satisfy $a < b = w(a) > w(b)$, where the X_{ab} in X are ordered according to O.

Theorem 3 *[1, 2]*

$$G = X'_w W B \tag{6}$$

where X'_w is any sub-product of X_w that maintains the ordering of the X_{ab} matrices in X_w. This is the 'Bruhat' decomposition.

All quadratic constructions using (1) can be constructed using Theorem 3., where $|\boldsymbol{G}| = \Gamma = \prod_{i=0}^{t-1}(2^t - 2^i)$.

3 Graphical Representations

Joint work with V.Rijmen [18]

We now identify a subset of the length 2^n sequence constructions of (1), where $(-1)^{p(\boldsymbol{x})}$ exhibits a bipolar $\leftrightarrow$ binary equivalence under transform by a tensor product of combinations of $\boldsymbol{H}$ and $\boldsymbol{I}$ 2×2 matrices. The resultant length 2^n binary sequences can be interpreted as indicators for binary linear or nonlinear $[n, k, d]$ error-correcting codes. In such cases, $p(\boldsymbol{x})$ is closely related to a Normal Realisation for the Factor Graph of the associated $[n, k, d]$ code [7]. Let $\boldsymbol{s} = (-1)^{p(\boldsymbol{x})}$.

Definition 9 *"H acting on i" means the action of the $2^n \times 2^n$ transform, $\mathbf{I} \otimes \ldots \otimes \mathbf{I} \otimes \mathbf{H} \otimes \mathbf{I} \otimes \ldots \otimes \mathbf{I}$ on $\boldsymbol{s}$, where $\mathbf{H}$ is preceded by i $\mathbf{I}$ matrices, and followed by $n - i - 1$ $\mathbf{I}$ matrices. We write this as $H(i)$, or $H(i)[\boldsymbol{s}]$.*

Definition 10 *Let $\mathbf{T_C}$, $\mathbf{T_{C^\perp}}$ be integer sets chosen so that $\mathbf{T_C} \cap \mathbf{T_{C^\perp}} = \emptyset$, and $\mathbf{T_C} \cup \mathbf{T_{C^\perp}} = \{0, 1, \ldots, n-1\}$. This is a bipartite splitting of $\{0, 1, \ldots, n-1\}$. Let us also partition the variable set $\mathbf{x}$ as $\mathbf{x} = \mathbf{x_C} \cup \mathbf{x_{C^\perp}}$, where $\mathbf{x_C} = \{x_i | i \in \mathbf{T_C}\}$, and $\mathbf{x_{C^\perp}} = \{x_i | i \in \mathbf{T_{C^\perp}}\}$.*

Definition 11 *$\kappa_{\mathbf{p}}$ is the set of all $s(\mathbf{x})$ of the form $s(\mathbf{x}) = (-1)^{p(\mathbf{x})}$, where $p(\mathbf{x}) = \sum_k q_k(\mathbf{x_C}) r_k(\mathbf{x_{C^\perp}})$, where $\deg(q_k(\mathbf{x_C})) = 1$ $\forall k$, and where $x_i \in p(\mathbf{x})$, $\forall$ $i \in \{0, 1, \ldots, n-1\}$. We refer to $\kappa_{\mathbf{p}}$ as the set of 'half-linear bipartite bipolar' states. $\ell_{\mathbf{p}}$ is the subset of $\kappa_{\mathbf{p}}$ where $\deg(r_k(\mathbf{x_C})) = 1$ $\forall k$.*

Theorem 4 *[18] Let $m(\mathbf{x})$ be a binary ANF. If $s(\mathbf{x}) \in \kappa_{\mathbf{p}}$, then the action of $\prod_{i \in \mathbf{T_C}} H(i)$ on $s(\mathbf{x})$ gives $s'(\mathbf{x}) = m(\mathbf{x})$. If $s(\mathbf{x}) \in \ell_{\mathbf{p}}$, then the action of $\prod_{i \in \mathbf{T_{C^\perp}}} H(i)$ on $s(\mathbf{x})$ gives $s''(\mathbf{x}) = m(\mathbf{x})$. $s'(\mathbf{x})$ ($s''(\mathbf{x})$) is the binary indicator for a binary linear or nonlinear $[n, n - |\mathbf{T}|, d]$ error correcting code, $\mathbf{C}$.*

Theorem 4 is particularly relevant when $p(\boldsymbol{x})$ is constructed using (1), as the 'strongest' members of $\kappa_{\mathbf{p}}$ are generated as a subclass of the construction if $\deg(g_j) < 2$, $\forall j$. (By considering matrices other than $\boldsymbol{H}$ it is conjectured that it is always possible to convert a bipolar sequence, $\boldsymbol{s} = (-1)^{\boldsymbol{p}}$, constructed using (1) to a binary form, even when $\deg(g_j) \geq 2$). If $\boldsymbol{s}$ can be transformed to a binary linear indicator, $\boldsymbol{s'}$, using only tensor products of $\boldsymbol{H}$ and $\boldsymbol{I}$, then we say that $\boldsymbol{s}$ is 'HI-equivalent to' $\boldsymbol{s'}$.

Theorem 5 *[18] The set $\ell_{\mathbf{p}}$ is HI-equivalent to the set of $[n, k, d]$ binary linear codes.*

3.1 Examples

Example A Let $t = 2$, $L = 3$. Then (1) can generate,

$$p(\boldsymbol{x}) = x_0x_2 + x_1x_3 + x_2x_4 + x_3x_5 + x_2x_5$$

Let $\mathbf{T_C} = \{0, 1, 4, 5\}$ and $\mathbf{T_{C^\perp}} = \{2, 3\}$. Applying $H(0)H(1)H(4)H(5)$ (in any order) to $\boldsymbol{s} = (-1)^{p(\boldsymbol{x})}$ gives the binary sequence, $\boldsymbol{s'} = m(x) = (x_0 + x_2 + 1)(x_1 +$

$x_3+1)(x_2+x_4+1)(x_2+x_3+x_5+1)$, which is the indicator for a $[6,2,2]$ binary linear code, $\mathbf{C}$. Graphical representations for $\boldsymbol{s}$ and $\boldsymbol{s'}$ are shown in Fig 1, where the graph for $\boldsymbol{s'}$ is a Normal Realisation of a Factor Graph [7]. If, instead, we apply $H(2)H(3)$ (in any order) to $\boldsymbol{s} = (-1)^{p(\boldsymbol{x})}$, we get the binary sequence, $\boldsymbol{s''} = m(x) = (x_0+x_2+x_4+x_5+1)(x_1+x_3+x_5+1)$, which is the indicator for a $[6,4,2]$ binary linear code, $\mathbf{C}^{\perp}$, the dual of $\mathbf{C}$. Applying $H(0)H(1)H(4)H(5)$ to $\boldsymbol{s'}$, followed by $H(2)H(3)$, gives $\boldsymbol{s''}$. This is the same as applying the WHT to $\boldsymbol{s'}$, and it is known that binary indicators of a linear code code, $\mathbf{C}$, and its dual, $\mathbf{C}^{\perp}$, are related by the WHT [14].

Example B Let $t = 3$, $L = 3$. Then (1) can generate,

$$p(\boldsymbol{x}) = 034, 035, 045, 134, 135, 145, 234, 235, 245, 03, 05, 14, 15, 36, 47, 58$$

Let $\mathbf{T_C} = \{0,1,2,6,7,8\}$ and $\mathbf{T}_{\mathbf{C}^{\perp}} = \{3,4,5\}$. Applying $H(0), H(1), H(2), H(6), H(7), H(8)$ (in any order) to $\boldsymbol{s} = (-1)^{p(\boldsymbol{x})}$ gives,

$$\begin{aligned}&\boldsymbol{s'} = m(x) = \\ &(x_0 + x_3x_4 + x_3x_5 + x_4x_5 + x_3 + x_5 + 1)(x_1 + x_3x_4 + x_3x_5 + x_4x_5 + x_4 + x_5 + 1) \\ &\times(x_2 + x_3x_4 + x_3x_5 + x_4x_5 + 1)(x_3 + x_6 + 1)(x_4 + x_7 + 1)(x_5 + x_7 + 1)\end{aligned}$$

which is the indicator for a $[9,3,3]$ binary nonlinear code, $\mathbf{C}$. Graphical representations for $\boldsymbol{s}$ and $\boldsymbol{s'}$ are shown in Fig 1, where the graph for $\boldsymbol{s'}$ is a Normal Realisation of a **nonlinear** Factor Graph. In this case application of $H(3)H(4)H(5)$ does not produce the dual code, $\mathbf{C}^{\perp}$, but the nonlinear dual could be obtained by nonlocal transform over x_3, x_4, x_5.

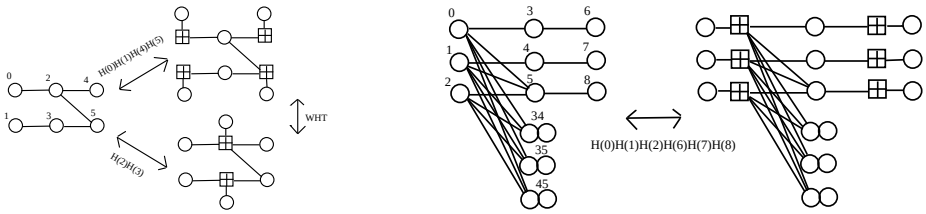

Fig. 1. Bipolar ↔ Factor Graph HI-Equivalence for Examples A and B

Example C The nonlinear $[16,8,6]$ Nordstrom-Robinson binary code is HI-equivalent to a half-linear bipolar bipartite sequence, $(-1)^{p(\boldsymbol{x})}$, where $p(\boldsymbol{x})$ can be constructed using (1), and has ANF comprising 96 cubic and 40 quadratic terms, and where $|T_C| = |T_{C^{\perp}}| = 8$. The quadratic part of $p(\boldsymbol{x})$ is HI-equivalent to a binary linear $[16,8,4]$ code, so we can view the 96 cubic terms of $p(\boldsymbol{x})$ as further 'doping' to increase Hamming Distance, d, from 4 to 6.

3.2 Comments

This section has identified an important subset of $\kappa_{\mathbf{p}}$ as a subset of the construction of (1), where a member of $\kappa_{\mathbf{p}}$ can be transformed to a binary sequence

under selective action of $\boldsymbol{H}$. Conversely, this gives us a way of analysing a Factor Graph, by transforming it back into bipolar sequence form. A natural question to ask is which length 2^n bipolar sequences are transform-equivalent to the best $[n, k, d]$ linear and nonlinear codes? We offer offer the following conjecture,

Conjecture 1 *Optimal linear or nonlinear codes can be constructed from (1) if $L = 2$, and $(-1)^{g_j}$ is, itself, HI-equivalent to an optimal linear or nonlinear code, $\forall j$. But what f_{γ_j} should be chosen?*

In the next section we pose the related question: Which quantum n-qubit states have optimal Linear Entanglement?

4 PAR_l and Quantum 'Linear' Entanglement (LE)

Joint work with V.Rijmen [18]

In previous sections our PAR metric has been measured relative to all LUUTs. Quantum systems require that we compute our PAR metric (now called PAR_l) relative to all LUTs, of which LUUTs are a subset. It is argued in [18] that PAR_l and Linear Entanglement (LE) are good partial measures of quantum entanglement. [1] Let $\boldsymbol{s}$ be a length 2^n bipolar sequence. In the context of quantum systems we interpret (after appropriate normalisation) this sequence as a probability density function of an n-qubit quantum state. Let s_i be an element of $\boldsymbol{s}$. Then $|s_i|^2$ is the probability of measuring the quantum system in state i. We must normalise so that $\sum_{i=0}^{2^n-1} |s_i|^2 = 1$, although normalisation constants are usually omitted in this paper. An n-qubit state, $\boldsymbol{s}$, contains entanglement if $\boldsymbol{s}$ is not a member of $\boldsymbol{G_n}$. The definition of PAR_l is then identical to Definition 5 except that, now, $|l_i|$ does not have to equal $|l_j|$, i.e. $\boldsymbol{l}$ is not necessarily unimodular.

Definition 12 $PAR_l(\boldsymbol{s}) = 2^n max_{\boldsymbol{l}}(|\boldsymbol{s} \cdot \boldsymbol{l}|^2))$

where $\boldsymbol{l}$ is any normalised linear sequence from the set, $\boldsymbol{G_n}$, and $\cdot$ means 'inner product' [17, 18].

Linear Entanglement (LE) is then defined as,

Definition 13 $LE(\boldsymbol{s}) = n - \log_2(PAR_l(\boldsymbol{s}))$

Entanglement and LE are invariant under transformation of $\boldsymbol{s}$ by any LUT. Therefore PAR_l is Local Unitary (LU)-invariant, and two states, $\boldsymbol{s}$ and $\boldsymbol{s'}$, related by a transform from LUT, are LU-equivalent. Code duality under the WHT and the HI-equivalence between $\boldsymbol{s}$ and $\boldsymbol{s'}$, as discussed in Section 3, are special cases of LU-equivalence. One can also view entanglement invariance as a generalisation of code duality.

[1] Quantum information theorists often consider 'mixed-state' entanglement, where entanglement with the environment is unavoidable [24, 8]. This is similar to the analysis of classical communications codes in the context of a corrupting channel. In this paper we only consider a closed (pure) quantum system with no environmental entanglements [6].

4.1 PAR_l for States from $\ell_{\mathbf{p}}$

Theorem 6 *[18] If $\boldsymbol{s} \in \ell_{\mathbf{p}}$, then $\boldsymbol{s}$ is LU equivalent to the indicator for an $[n, k, d]$ binary linear code, and,*

$$PAR_l(\boldsymbol{s}) \geq 2^r, \quad \text{where } r = max(k, n-k)$$

Theorem 6 implies that states, $\boldsymbol{s}$, from $\ell_{\mathbf{p}}$ have a minimum lower bound on PAR_l (upper bound on LE) when the associated $[n, k, d]$ code, $\mathbf{C}$, satisfies $k = \lfloor \frac{n}{2} \rfloor$, with $\mathrm{PAR}_l \geq 2^{\lceil \frac{n}{2} \rceil}$. Here is a stronger result.

Theorem 7 *[18] In (1), let $t = 1$ and $f_{\gamma j}$ be the identity permutation $\forall j$. Using (1), we can generate $s(\mathbf{x}) = (-1)^{p(\boldsymbol{x})}$ for $p(\boldsymbol{x})$ constructed using (4). Then $PAR_l(\boldsymbol{s}) = 2^{\lceil \frac{n}{2} \rceil}$.*

Definition 14 $\quad PA(\boldsymbol{s}) = 2^n max_i(|s_i|^2)$

We now compute PA for any HI transform of a member of $\ell_{\mathbf{p}}$. Let $\mathbf{s} \in \ell_{\mathbf{p}}$. Recalling Definition 10, let $k = |\mathbf{T}_{\mathbf{C}^\perp}|$, $k^\perp = |\mathbf{T}_{\mathbf{C}}|$, and $k + k^\perp = n$. Without loss of generality we renumber integer sets $\mathbf{T}_{\mathbf{C}^\perp}$ and $\mathbf{T}_{\mathbf{C}}$ so that $\mathbf{T}_{\mathbf{C}^\perp} = \{0, 1, \ldots, k-1\}$ and $\mathbf{T}_{\mathbf{C}} = \{k, k+1, \ldots, n-1\}$. Let $\mathbf{t}_{\mathbf{C}^\perp} \subset \mathbf{T}_{\mathbf{C}^\perp}$ and $\mathbf{t}_{\mathbf{C}} \subset \mathbf{T}_{\mathbf{C}}$, where $h = |\mathbf{t}_{\mathbf{C}^\perp}|$ and $h^\perp = |\mathbf{t}_{\mathbf{C}}|$. Let $\mathbf{x}_{\mathbf{t}^\perp} = \{x_i | i \in \mathbf{t}_{\mathbf{C}^\perp}\}$, $\mathbf{x}_{\mathbf{t}} = \{x_i | i \in \mathbf{t}_{\mathbf{C}}\}$, and $\mathbf{x}_* = \mathbf{x}_{\mathbf{t}^\perp} \cup \mathbf{x}_{\mathbf{t}}$. Define $\mathbf{M}$ to be a $k \times k^\perp$ binary matrix where $M_{i,j-k} = 1$ iff $x_i x_j \in p(\mathbf{x})$, and $M_{i,j-k} = 0$ otherwise. Thus $p(\mathbf{x}) = \sum_{i \in \mathbf{T}_{\mathbf{C}^\perp}} x_i (\sum_{j \in \mathbf{T}_{\mathbf{C}}} M_{i,j-k} x_j)$. Let $\mathbf{M}_{\mathbf{t}}$ be a submatrix of $\mathbf{M}$, which comprises only the rows and columns of $\mathbf{M}$ specified by $\mathbf{t}_{\mathbf{C}^\perp}$ and $\mathbf{t}_{\mathbf{C}}$. Let χ_t be the rank of $\mathbf{M}_{\mathbf{t}}$.

Theorem 8 *[18] Let $\boldsymbol{s'}$ be the result of $\prod_{i \in \mathbf{t}_{\mathbf{C}^\perp} \cup \mathbf{t}_{\mathbf{C}}} H(i)$ on $\boldsymbol{s} \in \ell_{\mathbf{p}}$. Then,*

$$PA(\boldsymbol{s'}) = 2^{h + h^\perp - 2\chi_t}$$

Corollary 1 *As $0 \leq \chi_t \leq min(h, h^\perp)$, it follows that, for $\boldsymbol{s} \in \ell_{\mathbf{p}}$, $PA(\boldsymbol{s'}) \geq 2^{|h - h^\perp|}$*

In general, PAR_l must consider $\mathrm{PA}(\boldsymbol{s})$ under all LUTs. $\mathrm{PA}(\boldsymbol{s})$ for $\boldsymbol{s} \in \ell_{\mathbf{p}}$ is easily computed. Let the 'HI multispectra' be the union of the power spectra of $\boldsymbol{s}$ under the action of $\prod_{i \in \boldsymbol{T}} H(i)$, for all possible subsets, $\boldsymbol{T}$, of $\{0, 1, \ldots, n-1\}$.

Theorem 9 *[18] PAR_l of $\boldsymbol{s} \in \ell_{\mathbf{p}}$ is found in the HI multispectra of $\boldsymbol{s}$.*

Theorem 9 means that, for $\boldsymbol{s} \in \boldsymbol{\ell_p}$, we only need compute the 2^n HI transforms to compute PAR_l. If $\mathrm{PA}(\boldsymbol{s})$ is optimally low over the HI multispectra, then $\boldsymbol{s'} = m(\boldsymbol{x})$ is an optimal binary linear code when $\boldsymbol{T} = \boldsymbol{T_C}$ or $\boldsymbol{T} = \boldsymbol{T_{C^\perp}}$.

Definition 15 *The Weight Hierarchy of a linear code* $\mathbf{C}$*, is a series of parameters,* d_j*,* $0 \leq j \leq k$*, representing the smallest blocklength of a linear sub-code of* $\mathbf{C}$ *of dimension* j*, where* $d_k = n$*,* $d_1 = d$*, and* $d_0 = 0$*.*

Theorem 10 *[18] Let* $\boldsymbol{s_c}$ *be the indicator of an* $[n, k, d]$ *binary linear code,* $\mathbf{C}$*. Let* $\mathbf{Q} \subset \{0, 1, \ldots, n-1\}$*. Let,*

$$m_{\mathbf{Q}} = \frac{|\mathbf{Q}| + \log_2(\mu) - n + k}{2}, \quad \text{where } \mu = PA(\boldsymbol{s'_c}) \tag{7}$$

and $\boldsymbol{s'_c} = \prod_{t \in \mathbf{Q}} H(t)[\boldsymbol{s_c}]$*. Then the Weight Hierarchy of* $\mathbf{C}$ *is found from the HI multispectra of* $\boldsymbol{s_c}$*, where* $d_j = min_{\mathbf{Q}|m_Q=j}(|\mathbf{Q}|)$

Quantum measurement projects a system to a subsystem. This allows us to equate a series of quantum measurements with a series of subcodes of $\boldsymbol{C}$. Let the entanglement order of a system be the size (in qubits) of the largest entangled subsystem of the system. A most-destructive series of j single-qubit measurements over some set of possible measurements on $\boldsymbol{s}$ produces a final state $\boldsymbol{s'}$ such that entanglement order($\boldsymbol{s}$) − entanglement order($\boldsymbol{s'}$) is maximised.

Definition 16 *Stubborness of Entanglement (SE) is a series of parameters,* β_j*,* $0 \leq j \leq k'$*, representing smallest possible entanglement order,* β_j*, after* $k' - j$ *most-destructive measurements of an* n*-qubit system, where* $\beta_{k'} = n$*,* $\beta_0 = 0$*.*

Theorem 11 *[18] Let* $\boldsymbol{s} \in \ell_{\mathbf{p}}$ *where* $\boldsymbol{s}$ *is LU equivalent to an optimal or near-optimal binary linear code of dimension* $\leq \frac{n}{2}$*. Then Stubborness of Entanglement is equal to the Weight Hierarchy of the code.*

Corollary 2 *Quantum states from* $\ell_{\mathbf{p}}$ *which have optimum LE and optimum SE are LU-equivalent to binary linear codes with optimum Weight Hierarchy.*

The results of this section suggests the following modification of Conjecture 1.

Conjecture 2 *States with optimal LE can be constructed from (1) if* $L = 2$*, and* $(-1)^{g_j}$ *also has optimal LE,* $\forall j$*. But what* f_{γ_j} *should be chosen?*

5 Discussion and Open Problems

We have highlighted the importance PAR plays (explicitly or implicitly) in current research. We emphasis four areas:
a) Low PAR error-correcting codes for OFDM and CDMA.
b) Highly nonlinear, distinguishable sequence sets for cryptography.
c) Graphical construction primitives for Factor Graphs which represent good error-correcting codes.
d) Classification and quantification of quantum entanglement.
We finish with a list of a few open problems.

- Construction (1) only provides an exact, implementable encoder if the two following sub-problems can be solved:

- Provide algorithms to generate all permutation polynomials, f_γ, of degree $\mu - 1$. $\mu = 0$ is trivial. Section 2.4 provides an answer for $\mu = 1$. But, for $\mu > 1$ the situation is unclear.
- Given an algorithm to generate all permutation polynomials, then construction (1) only generates distinct $p(\boldsymbol{x})$ for $t = 1$. For $t > 1$, the permutation, π, induces extra symmetries which cause many $p(\boldsymbol{x})$ to be generated more than once. This situation is reflected in (2), which is a strict upper bound for $t > 1$. It remains an open problem to provide an algorithm for $t > 1$ which ensures the generated $p(\boldsymbol{x})$ are distinct and form the whole code. Such an algorithm would replace of (2) with an exact expression.

– Construct decoders for the above codes.
– It is considered that successful iteration on a Factor Graph requires few short graph cycles. This is ensured if the graph has a large girth. How does one construct Factor Graphs with low PAR_l and large girth?
– Provide a construction for optimally large sets, $\boldsymbol{P}$, of pure quantum states such that each state satisfies a low upper bound on PAR_l, and where any two members of $\boldsymbol{P}$ are optimally distinguishable. This problem is 'simply' the LUT extension of the problem of low PAR error-correcting codes for OFDM and cryptography.

A Construction for Binary Sequence Sets with Low Peak-to-Average Power Ratio

Matthew G. Parker*and Chintha Tellambura†

21st February 2003

Abstract

A recursive construction is provided for sequence sets which possess good Hamming Distance and low Peak-to-Average Power Ratio (PAR) with respect to **any** Local Unitary Unimodular Transform (including all one and multi-dimensional Discrete Fourier Transforms).

1 Introduction

Pairs of Golay Complementary Sequences (CS) have the property that the sidelobes of the Aperiodic Autocorrelation of each sequence in the pair sum to zero [7]. Consequently they have found application in the areas of Telecommunications and Physics for such tasks as channel-sounding, spread-spectrum, and synchronization. It follows that the Peak-to-Average Power Ratio (PAR) with respect to the one-dimensional continuous Discrete Fourier Transform (DFT_1^∞) of each sequence in the pair satisfies PAR ≤ 2. For lengths 2^n one can generate CS pairs using Golay-Rudin-Shapiro (RuS) construction [28, 29]. However it has not yet been proved that all length 2^n CS can be constructed using RuS as $n \to \infty$. Davis and Jedwab have shown that the RuS set comprise a union of certain binary quadratic cosets of Reed-Muller (RM) $(1, n)$ when expressed in Algebraic Normal Form (ANF)[4]. Moreover, as these sequences are a subset of RM$(2, n)$, then the Hamming Distance, D, between sequences in the set satisfies $D \geq 2^{n-2}$. Although the properties of RuS and CS pairs have been known for many years, the description of [4] brought together and formalised much of this work in the context of Reed-Muller codes. This was in response to the pressing demand of Orthogonal Frequency Division Multiplexing (OFDM) communications systems for error-correcting codes where each codeword also has low PAR with respect to (wrt) DFT_1^∞. The low PAR is required to alleviate the linearity requirements of the amplifier at the transmitter. The question of error-correcting codes with low PAR wrt DFT_1^∞ was highlighted by [10], prompting a great deal of research culminating in the fundamental codeset of Davis and Jedwab (DJ set), as outlined in the papers of [4, 23] (equation (6) of this paper), which exploit the properties of RuS. However, a communications engineer will probably point out that the major weakness of the DJ set for OFDM is that its code rate only remains acceptably high for up to about 32 frequency carriers, the

rate vanishing as $n \to \infty$, and most current OFDM systems require anywhere from 256 to 8192 frequency carriers. Therefore, in practise, most engineers will implement some form of clipping or Selected-Mapping in order to reduce spectral peaks (PAR) at the OFDM transmitter. In other words, instead of constructing and sending a sequence, the transmitter will generate an arbitrary sequence or sequences, test their PARs, then either clip their peaks before transmission or choose to send the sequence with lowest PAR. Constructive techniques can avoid all this testing, but a major requirement for any constructive coding technique is that its rate remains acceptably high for large numbers of carriers. Higher rates are certainly possible and desirable for PAR $\leq O(n)$ and D large [24]. A generalisation of RuS construction to other starting seeds [16, 17] allows inclusion of more low PAR quadratic cosets of RM$(1, n)$ in the code, thereby improving code rate somewhat. Higher degree cosets can also be added, marginally increasing code rate at price of distance, D, which decreases. However the rate remains unacceptably low for more than about 32 carriers.

This paper provides new answers to this problem by defining constructive techniques for low PAR error-correcting codes of blocklength > 32 with acceptable rate. For instance, we can (almost) construct a rate $\frac{1}{3}$ code of length 64 with distance 16 and PAR ≤ 4.0, a rate $\frac{2}{3}$ code of length 64, distance 4, and PAR ≤ 8.0, and a rate $\frac{1}{2}$ code of length 256, distance 4, and PAR ≤ 16.0. We emphasise 'almost' because, although we most certainly identify and algebraically describe very large codesets with low PAR, our constructions are not strictly implementable yet, due to certain edge symmetries (coding collisions) which compromise invertibility of the encoding. It remains an open challenge to eliminate these coding collisions, and part of the aim of this paper is to present and motivate this challenge in a clear way.

It turns out that our construction also requires the ability to generate all distinct permutation polynomials from $Z_2^t \to Z_2^t$ of algebraic degree $\leq d$ for some d, $1 \leq d < t$. To the best knowledge of the authors, such an algorithm only exists in the literature for the case $d = 1$ (namely "Bruhat Decomposition", or as encountered when generating all possible binary linear error-correcting codes of maximum rank and length) and, for $d = 1$, there are $\prod_{i=0}^{t-1}(2^t - 2^i)$ such polynomials. This paper provides strong motivation to develop further algorithms for the cases $1 < d < t$, along with the enumeration of the size of such sets as t varies.

Another aim of this paper is to advertise the fact that RuS sequences, and their generalisation as described in this paper, have a much stronger property than just a low PAR upper bound wrt the DFT_1^∞. [13, 16, 17, 25] have all pointed out the Bent/Almost Bent properties of the RuS set, and [16, 17] and this paper proves that the RuS set, and their generalisations satisfy PAR $\leq 2^t$ wrt <u>all</u> possible Linear Unitary Unimodular Transforms (LUUTs), including DFT_1^∞ and Walsh-Hadamard Transform (WHT). We will define LUUTs in the sequel. Consequently, the RuS construction and its generalisation have relevance also to Multi-Code CDMA [16, 17, 25], Weight Hierarchy and Quantum Entanglement [18, 19], and Cryptography [27].

To summarise, the main new contributions of this paper are as follows:

- A proposal to measure PAR wrt the infinite set of Linear Unimodular Unitary Transforms (LUUTs), whose rows comprise all possible linear unimodular sequences. This set includes DFT_1^∞, the Walsh-Hadamard Transform (WHT), and many other transforms.
- A construction (Constructions 1 - 3) for large sets of sequences with tight constant upper bound on PAR and good distance properties, where PAR is computed wrt the

infinite set of LUUTs.

Although we acknowledge that our constructions are implicitly covered in the literature by Golay [6, 7], Turyn [34], and others [33, 5], wrt DFT_1^∞, no mention in the literature is given of low PAR constructions wrt to the much larger set of LUUTs and, apart from the special case considered by Davis and Jedwab [4] wrt DFT_1^∞, and the case of low PAR wrt the WHT [3, 25], no attempt has been made to express these constructions in concise Algebraic Normal Form (ANF) or to consider the construction of such sequences, or to consider the Hamming Distance between members of the sequence set.

Our Construction as a Generalisation of Golay-Rudin-Shapiro Construction:
Golay-Rudin-Shapiro (RuS) sequences are a special case of Golay Complementary Pairs as first introduced by Marcel Golay [6, 22]. RuS sequence construction [7, 28, 29] exploits the recursion,

$$\begin{aligned} \mathbf{a}' &= \mathbf{a}|\mathbf{b} \\ \mathbf{b}' &= \mathbf{a}|\overline{\mathbf{b}} \end{aligned} \tag{1}$$

where $\mathbf{a}$ and $\mathbf{b}$ are both bipolar sequences of length N, $\mathbf{a}'$ and $\mathbf{b}'$ are both sequences of length $2N$, '|' means concatenation, and $\overline{\mathbf{b}}$ means the multiplication of elements of $\mathbf{b}$ by -1. The key observation that motivates the constructions of this paper is that we can write (1) as,

$$(\mathbf{a}', \mathbf{b}')^T = \mathbf{E} \odot \begin{pmatrix} \mathbf{a} & \mathbf{b} \\ \mathbf{a} & \mathbf{b} \end{pmatrix}$$

where $\mathbf{E} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$, and '$\odot$' means point-multiplication of matrix elements. For instance, if $a = (1, 1)$ and $b = (1, -1)$, then $a' = (1, 1, 1, -1)$ and $b' = (1, 1, -1, 1)$.

This paper shows that RuS sequences satisfy PAR ≤ 2.0 wrt all LUUTs precisely because $\mathbf{E}$ is an orthogonal 2×2 matrix. The RuS generalisation of this paper uses sequence recursion where successive $\mathbf{E}$ matrices are arbitrary $R \times R$ Hadamard matrices, such that the generated sequences have PAR $\leq R$. For a given canonical representation of a Hadamard matrix, $\mathbf{E}$, an arbitrary row/column permutation of $\mathbf{E}$ is specified by γ, for row permutation, and θ, for column permutation. In this paper we emphasise the case where $\mathbf{E}$ is the Walsh-Hadamard Transform (WHT) matrix, although the basic construction still works when $\mathbf{E}$ is a more general Hadamard matrix. Given that $\mathbf{E}$ is a WHT, the sequence construction is then primarily specified by the permutations γ_j and θ_j, at each stage of the recursion. As stated earlier, much of the difficulty relating to the construction of this paper arises from an attempt to classify, enumerate, and generate these permutations according to their algebraic degree, as these degrees determine the overall ANF degree of the constructed sequence, which in turn determines the (Reed-Muller) Hamming Distance of the code. This paper therefore gives a strong justification for future research into classification and enumeration of permutation polynomials according to maximum polynomial degree.

Construction 1 provides a way of generating low PAR error-correcting codes of any length, r^n, and over any alphabet. As a special case, Construction 2 generates binary codesets of length 2^n and PAR $\leq 2^t$, comprising ANFs up to degree μ, where $\mu \leq 2t - 2$ for $t > 1$, and $\mu = 2$ for $t = 1$. These codesets have PAR $\leq 2^t$ wrt **all** LUUTs, including one and multi-dimensional continuous DFTs [16, 17]. As LUUTs include WHTs, then our construction gives large codesets of (Near)-Bent functions [15, 3, 26]. These binary sequences are not just (Near)-Bent but are also distant from linear sequences over all (unimodular) alphabets, not just over Z_2 - a particularly strong cryptographic attribute. Construction 2 of this paper can be viewed as a recursive generalisation of a **two-sided** Maiorana-McFarland construction where our sequence set has low PAR wrt **all** LUUTs, not just WHT. We also provide an explicit generation method for the complete quadratic subset of Construction 2

using Bruhat decomposition [2, 1]. In [25], Paterson increases code rate, at the price of increased PAR wrt the WHT, by replacing the inherent one-to-one permutation of Maiorana-McFarland construction with a many-to-one map. Construction 3 of this paper similarly generalises Construction 2 by replacing the constituent permutations with many-to-one and/or one-to-many maps. Throughout this paper, we assume our sequences are of length r^n for some integers, r, n, although we emphasise the case where $r = 2$.

2 Linear Sequences, Linear Unimodular Unitary Transforms (LUUTs) and Peak-to-Average Power Ratio (PAR)

PAR is a spectral measure. We must therefore first define the transforms over which the spectrum is to be computed. We call these transforms *LUUTs* (defined below), and LUUTs have linear rows, so we first define linearity:

Definition 1. *Let* $\mathbf{l} = (l_0, l_1, \ldots, l_{r^n-1})$ *be a length* r^n *complex sequence.* $\mathbf{l}$ *is defined to be* unimodular *if* $|l_i| = |l_j|, \forall i, j$, unitary *if* $\sum_{i=0}^{r^n-1} |l_i|^2 = 1$, *and* r-linear *if,*

$$\begin{array}{ll} \mathbf{l} = & (a_{0,0}, a_{0,1}, \ldots, a_{0,r-1}) \otimes (a_{1,0}, a_{1,1}, \ldots, a_{1,r-1}) \otimes \ldots (a_{n-1,0}, a_{n-1,1}, \ldots, a_{n-1,r-1}) \\ = & \bigotimes_{i=0}^{n-1} (a_{i,0}, a_{i,1}, \ldots, a_{i,r-1}) \end{array}$$

where $\otimes$ *is the 'left tensor product', such that* $\mathbf{A} \otimes (B_0, B_1, \ldots) = (B_0\mathbf{A}, B_1\mathbf{A}, \ldots)$. *For length* r^n *sequences where* r *is prime,* r*-linear is called* linear.

For example,

$l = \frac{1}{\sqrt{2}}(1, 0, 0, 1)$ is a unitary sequence,
$l = \frac{1}{2}(1, 1, 1, -1)$ is a unimodular unitary sequence,
$l = \frac{1}{2}(1, -1, 1, -1) = \frac{1}{\sqrt{2}}(1, -1) \otimes \frac{1}{\sqrt{2}}(1, 1)$ is a linear, unimodular, unitary sequence

Definition 2. $\mathbf{L_{r,n}}$ *is the infinite set of length* r^n *complex* r*-linear, unitary, unimodular sequences.*

Definition 3. *A* $r^n \times r^n$ *matrix,* $\mathbf{U}$, *is* unitary *if* $\mathbf{U}\mathbf{U}^\dagger = \mathbf{I_{r^n}}$, *where* $\dagger$ *means conjugate transpose, and* $\mathbf{I_{r^n}}$ *is the* $r^n \times r^n$ *identity matrix.*

Definition 4. *A* $r^n \times r^n$ r-Linear Unimodular Unitary Transform *(*r*-LUUT) matrix* $\mathbf{L}$ *has rows taken from* $\mathbf{L_{r,n}}$ *such that* $\mathbf{L}\mathbf{L}^\dagger = \mathbf{I_{r^n}}$. *When* r *is prime,* $r^n \times r^n$ r*-LUUTs are called* LUUTs. *Note that the set of* $r^n \times r^n$ q*-LUUTs is a subset of the set of* $r^n \times r^n$ r*-LUUTs iff* $q|r$.

Example LUUTs for $r = 2$**:** The $2^n \times 2^n$ Walsh-Hadamard (WHT) and Negahadamard (NHT) matrices are LUUTs defined by $\bigotimes_{i=0}^{n-1} \mathbf{H}$, and $\bigotimes_{i=0}^{n-1} \mathbf{N}$, respectively, where $\mathbf{H} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$, $\mathbf{N} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & i \\ 1 & -i \end{pmatrix}$, and $i^2 = -1$. For instance, for $n = 2$, the WHT is the LUUT whose rows have the following tensor decomposition:

$$\frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \otimes \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} (1,1) & \otimes & (1,1) \\ (1,-1) & \otimes & (1,1) \\ (1,1) & \otimes & (1,-1) \\ (1,-1) & \otimes & (1,-1) \end{pmatrix}$$

Similarly, for $n = 2$, the NHT is the LUUT whose rows have the following tensor decomposition:

$$\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & i \\ 1 & -i \end{pmatrix} \otimes \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & i \\ 1 & -i \end{pmatrix} = \frac{1}{2}\begin{pmatrix} 1 & i & i & -1 \\ 1 & -i & i & 1 \\ 1 & i & -i & 1 \\ 1 & -i & -i & -1 \end{pmatrix} = \frac{1}{2}\begin{pmatrix} (1,i) & \otimes & (1,i) \\ (1,-i) & \otimes & (1,i) \\ (1,i) & \otimes & (1,-i) \\ (1,-i) & \otimes & (1,-i) \end{pmatrix}$$

where $i^4 = 1$.

Definition 5. *We define* DFT_1^∞ *for length* 2^n *vectors to be an infinite subset of* $2^n \times 2^n$ *LUUTs, the union of whose rows form a subset of* $\mathbf{L_{2,n}}$ *such that each row factors, as in Definition 1, into a tensor product of length-two vectors* $(a_{i,0}, a_{i,1})$ *which, in turn, must satisfy* $a_{i,0} = \frac{1}{\sqrt{2}}$, $a_{i,1} = \frac{\omega^{ik}}{\sqrt{2}}$ *for some fixed integer* k*, where* ω *is any complex root of unity.*

For instance, for $n = 2$, DFT_1^∞ includes the LUUT which is the 4-point one-dimensional Cyclic DFT whose rows have a tensor decomposition as follows:

$$\frac{1}{2}\begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & i & -1 & -i \\ 1 & -1 & 1 & -1 \\ 1 & -i & -1 & i \end{pmatrix} = \frac{1}{2}\begin{pmatrix} (1,1) & \otimes & (1,1) \\ (1,i) & \otimes & (1,-1) \\ (1,-1) & \otimes & (1,1) \\ (1,-i) & \otimes & (1,-1) \end{pmatrix}$$

where $i^2 = -1$.

DFT_1^∞ also includes the LUUT which is the 4-point one-dimensional NegaCyclic DFT whose rows have a tensor decomposition as follows:

$$\frac{1}{2}\begin{pmatrix} 1 & \omega & \omega^2 & \omega^3 \\ 1 & \omega^3 & \omega^6 & \omega \\ 1 & \omega^5 & \omega^2 & \omega^7 \\ 1 & \omega^7 & \omega^6 & \omega^5 \end{pmatrix} = \frac{1}{2}\begin{pmatrix} (1,\omega) & \otimes & (1,\omega^2) \\ (1,\omega^3) & \otimes & (1,\omega^6) \\ (1,\omega^5) & \otimes & (1,\omega^2) \\ (1,\omega^7) & \otimes & (1,\omega^6) \end{pmatrix}$$

where $\omega^4 = -1$.

By taking more and more 4×4 LUUTs of this form, we more closely approximate DFT_1^∞ for the case $r = 2, n = 2$. It is also helpful to notice that <u>all</u> rows of DFT_1^∞ occur as a subset of the rows of certain LUUTs formed from tensor products of 2×2 LUUTs. For instance, for $n = 2$, the rows of the 4×4 Cyclic DFT are contained in two rows of each of $\mathbf{H} \otimes \mathbf{H}$ and $\mathbf{N} \otimes \mathbf{H}$. Similarly, the rows of the 4×4 NegaCyclic DFT are contained in two rows of each of $\mathbf{W_1} \otimes \mathbf{N}$ and $\mathbf{W_3} \otimes \mathbf{N}$, where $\mathbf{W_1} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & \omega \\ 1 & -\omega \end{pmatrix}$, $\mathbf{W_3} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & \omega^3 \\ 1 & -\omega^3 \end{pmatrix}$.

Having defined linear unimodular sequences, we are in a position to define PAR with respect to $\mathbf{L_{r,n}}$:

Definition 6. *Let* s_i *be the* i*th element of a length* r^n *vector,* $\mathbf{s}$*. Then* r*-PAR*$(\mathbf{s})$ *is computed by measuring the maximum possible correlation squared of* $\mathbf{s}$ *with* **any** *length* r^n r*-linear unimodular sequence,* $\mathbf{l} \in \mathbf{L_{r,n}}$*:*

$$r\text{-}PAR(\mathbf{s}) = r^n max_{\mathbf{l} \in \mathbf{L_{r,n}}}(|\mathbf{s} \cdot \mathbf{l}|^2) = r^n max_{\mathbf{l} \in \mathbf{L_{r,n}}}(|\sum_{i=0}^{r^n-1} s_i l_i^*|^2)$$

where $\cdot$ *means 'inner product', and* * *means complex conjugate. Similarly,*

$$PA(\mathbf{s}) = r^n max_{\mathbf{l}}(|\mathbf{s} \cdot \mathbf{l}|^2)$$

$\mathbf{l}$ *taken over all rows of a* **fixed, specified** *subset of* $r^n \times r^n$ *unitary transforms,* $\mathbf{U}$

For a length r^n *sequence, the values of* r*-PAR and PA range from* 1.0 *(for an ideal spectrally flat sequence) to* r^n *(for a spectral* δ*-function). When* r *is prime,* r*-PAR is termed PAR.*

We can compute r-PAR of $\mathbf{s}$ by examining the transform spectra of $\mathbf{s}$ wrt **all** r-LUUTs (more practically we can approximate this continuous spectrum by applying a large enough subset of well-chosen r-LUUTs).

Example: Let $\mathbf{s} = 2^{\frac{-3}{2}}(1,1,1,-1,1,-1,1,-1)$. Then $\mathrm{PA}(\mathbf{s})$ wrt the LUUT, $\mathbf{H} \otimes \mathbf{H} \otimes \mathbf{N}$, is obtained by first computing the matrix-vector product:

$$\begin{aligned}\mathbf{S} = (\mathbf{H} \otimes \mathbf{H} \otimes \mathbf{N})\mathbf{s} \quad &= 2^{\frac{-3}{2}} \begin{pmatrix} 1 & 1 & 1 & 1 & i & i & i & i \\ 1 & -1 & 1 & -1 & i & -i & i & -i \\ 1 & 1 & -1 & -1 & i & i & -i & -i \\ 1 & -1 & -1 & 1 & i & -i & -i & i \\ 1 & 1 & 1 & 1 & -i & -i & -i & -i \\ 1 & -1 & 1 & -1 & -i & i & -i & i \\ 1 & 1 & -1 & -1 & -i & -i & i & i \\ 1 & -1 & -1 & 1 & -i & i & i & -i \end{pmatrix} 2^{\frac{-3}{2}} \begin{pmatrix} 1 \\ 1 \\ 1 \\ -1 \\ 1 \\ -1 \\ 1 \\ -1 \end{pmatrix} \\ &= 2^{-3} \begin{pmatrix} 2 \\ 2+4i \\ 2 \\ -2 \\ 2 \\ 2-4i \\ 2 \\ -2 \end{pmatrix}\end{aligned}$$

The largest magnitude value in $\mathbf{S}$ is $2^{-3}(2 \pm 4i)$. It follows that $\mathrm{PA}(\mathbf{s}) = 2^3(2^{-6}(2^2 + 4^2)) = 2.5$ wrt $\mathbf{H} \otimes \mathbf{H} \otimes \mathbf{N}$. This also means that $\mathrm{PAR}(\mathbf{s})$ is lower bounded by 2.5.

2.1 Complementary Sequence Sets (CS Sets)

A Complementary Sequence Set (*CS set*) of R unitary sequences of length R' conventionally has the complementary property that the sum of the one-dimensional Aperiodic Autocorrelations of each sequence in the set results in the δ function of magnitude R (zero sidelobe energy) [7, 33]. Equivalently this means that the sum of the R DFT_1^∞ power spectra of the sequences at each spectral index is $\frac{R}{R'}$, i.e. the DFT_1^∞ power spectral sum of the sequences is completely flat at all spectral indices. This implies that each of the R sequences has $\mathrm{PA} \leq R$ wrt the DFT_1^∞. We now modify the CS definition as follows,

Definition 7. *We define the* Complementary Set *(*CS Set*) to mean a set of sequences which is complementary wrt any specified set of unitary transforms, $\{\mathcal{T}\}$, such that the sum of the power spectra of the set of R sequences of length R', wrt any member of the set, $\mathcal{T}$, sum to $\frac{R}{R'}$ at each spectral index [16, 21]. Therefore, for $\mathbf{s}$ a member of the CS set, PAR$(\mathbf{s}) \leq R$.*

We formalise this as follows:

Definition 8. *The rows of an $R \times R'$ matrix, $\mathbf{A}$, form a complementary set of R sequences wrt the set of $R' \times R'$ unitary transform matrices, $\mathcal{T}$, iff, for every $\mathcal{U} \in \mathcal{T}$, $\mathbf{b_i} = \frac{R'}{R}\mathbf{A}\mathbf{u_i^T}$ is unitary, where $\mathbf{u_i}$ is the ith row of $\mathcal{U}$, and the rows of $\mathbf{A}$ are unitary.*

Lemma 1 provides an initial starting CS set for the example of the next section and the subsequent constructions:

Lemma 1. *Let $\mathbf{A}$ be a $R \times R$ unitary matrix. Then the rows of $\mathbf{A}$ form a* CS set *of R sequences wrt all $R \times R$ unitary matrices.*

Proof. Let $\mathbf{B}$ be an $R \times R$ matrix with rows, $\mathbf{b_i}$, where the $\mathbf{b_i}$ are constructed as in Definition 8. Then $\mathbf{B} = \mathbf{A}\mathcal{U}^\mathbf{T}$. Similarly $\mathbf{B}^\dagger = \mathcal{U}^*\mathbf{A}^\dagger$, where $*$ means conjugate. Then $\mathbf{B}\mathbf{B}^\dagger = \mathbf{A}\mathcal{U}^\mathbf{T}\mathcal{U}^*\mathbf{A}^\dagger = \mathbf{I_R}$, where $\mathbf{I_R}$ is the $R \times R$ identity matrix. Therefore $\mathbf{B}$ is unitary which means all $\mathbf{b_i}$ are unitary, and Lemma 1 follows from Definition 8. □

3 Construction Example

Before presenting the formal constructions of this paper, we first provide an example which highlights the main points of the constructions. For clarity of exposition we usually omit the normalisation constant for each matrix or sequence which would ensure the unitarity of the matrix or sequence. For instance, $\mathbf{A}$ below should be multiplied by $\frac{1}{2}$. We also provide and utilise ANFs, $p(x_0, x_1, \ldots, x_{n-1})$, for the binary sequence exponent of the bipolar sequences constructed, where the ith element, p_i of the length 2^n binary sequence, p, is given by $p(x_0 = i_0, x_1 = i_1, \ldots, x_{n-1} = i_{n-1})$, where $(i_0, i_1, \ldots, i_{n-1})$ is the 2-adic expansion of i. For instance, the function $p = x_0 + x_1$ has a truth table

x_0	x_1	p
0	0	0
1	0	1
0	1	1
1	1	0

which can be used to represent the sequence $(-1)^p = (-1)^{0110} = 1, -1, -1, 1$.

The construction strategy is as follows:

3.0.1 Choose Unitary Matrix

Choose, for example, the unitary matrix

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix} = \begin{pmatrix} (-1)^0 \\ (-1)^{x_0} \\ (-1)^{x_1} \\ (-1)^{x_0+x_1} \end{pmatrix}$$

By Lemma 1 the four rows of $\mathbf{A}$ form a CS set wrt any 4×4 unitary matrix, i.e. any 4×4 4-LUUT. We can perform a number of operations on $\mathbf{A}$ to generate a length 16 bipolar sequence with 4-PAR ≤ 4.00 wrt any 4-LUUT (which includes any 2-LUUT).

3.0.2 Concatenate Rows:

Concatenating rows of $\mathbf{A}$ gives the length 16 sequence,

$$\mathbf{s} = 1 \quad 1 \quad 1 \quad 1 \quad 1 \quad -1 \quad 1 \quad -1 \quad 1 \quad 1 \quad -1 \quad -1 \quad 1 \quad -1 \quad -1 \quad 1 \quad = (-1)^{x_0x_2+x_1x_3}$$

This sequence has 4-PAR$(\mathbf{s}) \leq 4.0$ wrt all 4-LUUTs including all 2-LUUTs. As will be shown, the upper bound is 4.0 because $\mathbf{A}$ is a 4×4 unitary matrix whose four rows form a CS set wrt all 4-LUUTs, which includes all 2-LUUTs. The transform set includes all 2-LUUTs because 2 divides 4. For example, $\mathbf{s}$ has PAs of 3.12, 1.00, and 4.00 wrt DFT_1^∞, WHT, and NHT, respectively. (Note that PA wrt DFT_1^∞ is computed approximately by taking the PA wrt enough 16×16 LUUTs of the form discussed in Definition 5. In other words we 'oversample' the one-dimensional DFT to sufficient precision).

3.0.3 Permute Rows and/or Columns Prior to Concatenation:

Choose any row/column permutation of $\mathbf{A}$ prior to concatenation. For example, choose the concatenation: Row 1 | Row 3 | Row 2 | Row 0, giving,

$$\begin{aligned} \mathbf{s} &= 1 \quad -1 \quad 1 \quad -1 \quad 1 \quad -1 \quad -1 \quad 1 \quad 1 \quad 1 \quad -1 \quad -1 \quad 1 \quad 1 \quad 1 \quad 1 \\ &= (-1)^{x_0x_3+x_1x_2+x_1x_3+x_0} \end{aligned}$$

This sequence also has 4-PAR$(\mathbf{s}) \leq 4.0$ wrt all 4-LUUTs, including all 2-LUUTs. For example, $\mathbf{s}$ has PAs of 1.95, 1.00, and 1.00 under DFT_1^∞, WHT, and NHT, respectively.

As another example, consider the column permutation: Col 3,Col 0,Col 2,Col 1, followed by the row permutation and concatenation: Row 2 | Row 3 | Row 0 | Row 1, giving,

$$\begin{aligned}\mathbf{s} &= -1 \quad 1 \quad -1 \quad 1 \quad 1 \quad 1 \quad -1 \quad -1 \quad 1 \quad 1 \quad 1 \quad 1 \quad -1 \quad 1 \quad 1 \quad -1 \\ &= (-1)^{x_0x_2+x_0x_3+x_1x_2+x_0+x_2+x_3+1}\end{aligned}$$

This sequence also has PAR$(\mathbf{s}) \leq 4.0$ wrt all 4-LUUTs, including all 2-LUUTs. For example, $\mathbf{s}$ has PAs of 1.999, 1.00, and 1.00 wrt DFT_1^∞, WHT, and NHT, respectively. (Note that for 4×4 matrices, a combined row and column permutation is equivalent to a row (or column) permutation. This is not generally the case for square matrix dimension > 4).

3.0.4 Generate Cosets

Let $\mathbf{g}$ be any length-4 bipolar vector. Let us express $\mathbf{A}$ as

$$\mathbf{A} = \begin{pmatrix} \mathbf{a_0} \\ \mathbf{a_1} \\ \mathbf{a_2} \\ \mathbf{a_3} \end{pmatrix}$$

where the a_i are length-4 bipolar vectors.

Let $\mathbf{A^g}$ be any matrix of the form,

$$\mathbf{A^g} = \begin{pmatrix} \mathbf{a_0} \odot \mathbf{g} \\ \mathbf{a_1} \odot \mathbf{g} \\ \mathbf{a_2} \odot \mathbf{g} \\ \mathbf{a_3} \odot \mathbf{g} \end{pmatrix}$$

where $\mathbf{a} \odot \mathbf{g} = (a_0g_0, a_1g_1, \ldots, a_3g_3)$, For instance, let $\mathbf{g} = (1, 1, 1, -1)$. Then,

$$\mathbf{A^g} = \begin{pmatrix} 1 & 1 & 1 & -1 \\ 1 & -1 & 1 & 1 \\ 1 & 1 & -1 & 1 \\ 1 & -1 & -1 & -1 \end{pmatrix}$$

Then concatenation of any row/column permutation of $\mathbf{A^g}$ also has 4-PAR ≤ 4.0 wrt all 4-LUUTs, which includes all 2-LUUTs. As an example, consider the column permutation of $\mathbf{A^g}$: Col 0,Col 3,Col 2,Col 1, followed by the row permutation and concatenation: Row 1 | Row 3 | Row 0 | Row 2, giving,

$$\begin{aligned}\mathbf{s} &= 1 \quad 1 \quad 1 \quad -1 \quad 1 \quad -1 \quad -1 \quad -1 \quad 1 \quad -1 \quad 1 \quad 1 \quad 1 \quad 1 \quad -1 \quad 1 \\ &= (-1)^{x_0x_1+x_0x_2+x_0x_3+x_1x_2}\end{aligned}$$

This sequence has 4-PAR$(\mathbf{s}) \leq 4.0$ wrt all 4-LUUTs, including 2-LUUTs. For example, $\mathbf{s}$ has PAs of 2.97, 1.00, and 2.00 wrt DFT_1^∞, WHT, and NHT, respectively.

3.0.5 Symmetric Permutation:

Definition 9. *Let π be any permutation of Z_n. Then π_r is defined to be any* r-symmetric permutation *of Z_{r^n}, where $\pi_r(i) = \sum_{k=0}^{n-1} i_{\pi(k)} r^k$, and i has a radix-r decomposition as $\sum_{k=0}^{n-1} i_k r^k$, $i_k \in Z_r$, $\forall k$. We can then write the r-symmetric permutation of $\mathbf{s}$ as,*

$$\pi_r(\mathbf{s}) = (s_{\pi_r(0)}, s_{\pi_r(1)}, \ldots, s_{\pi_r(r^n-1)})$$

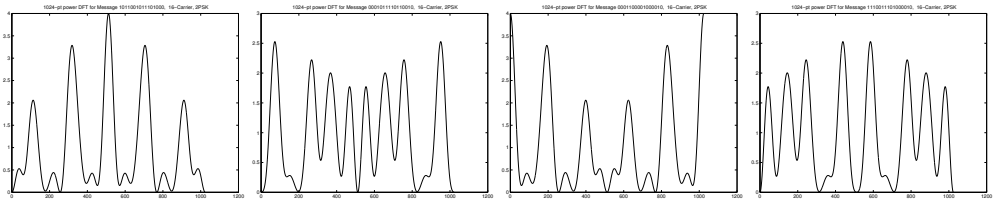

Figure 1: Power Spectrums for Size-4 Complementary Set, $\{\mathbf{s_0}, \mathbf{s_1}, \mathbf{s_2}, \mathbf{s_3}\}$, wrt DFT_1^∞ (x-axis is spectral index, y-axis is power value)

If $\mathbf{s}$ has 4-PAR ≤ 4.0 wrt all 4-LUUTs, then $\pi_2(\mathbf{s})$ has PAR ≤ 4.0 wrt all 2-LUUTs. (Note that because π_2 is a radix-2 permutation, the PAR upper bound no longer covers all 4-LUUTs). For instance, we have just stated that
$\mathbf{s} = 1, 1, 1, -1, 1, -1, -1, -1, 1, -1, 1, 1, 1, 1, -1, 1$ has 4-PAR ≤ 4.0 wrt all 4-LUUTs. Let $\pi = (0)(1, 2, 3)$ be a permutation of Z_4. Then π_2 permutes the indices of $\mathbf{s}$ according to $(0)(1)(2, 4, 8)(3, 5, 9)(6, 12, 10)(7, 13, 11)(14)(15)$ to give,

$$\begin{aligned}\mathbf{s} &= 1 \quad 1 \quad 1 \quad -1 \quad 1 \quad -1 \quad 1 \quad 1 \quad 1 \quad -1 \quad 1 \quad 1 \quad -1 \quad -1 \quad -1 \quad 1 \\ &= (-1)^{x_0x_1+x_0x_2+x_0x_3+x_2x_3}\end{aligned}$$

This sequence has $\mathrm{PAR}(\mathbf{s}) \leq 4.0$ wrt all 2-LUUTs. For example, $\mathbf{s}$ has PAs of 2.56, 1.00, and 2.00 wrt DFT_1^∞, WHT, and NHT, respectively.

3.0.6 Form Complementary Sequence (CS) Set:

Let $\mathbf{E}$ be another 4×4 unitary matrix (it could be the same as $\mathbf{A}$). For example,

$$\mathbf{E} = \begin{pmatrix} 1 & 1 & 1 & -1 \\ 1 & 1 & -1 & 1 \\ 1 & -1 & 1 & 1 \\ -1 & 1 & 1 & 1 \end{pmatrix}$$

where the element at row i and column j is $e_{i,j}$. For any row and/or column permutation of $\mathbf{A}$ (or $\mathbf{A^g}$) we can form four length-16 CS. For instance, from subsection 3.0.4, let our constructed sequence be,
$\mathbf{s} = \mathbf{a_0^g}|\mathbf{a_1^g}|\mathbf{a_2^g}|\mathbf{a_3^g} = 1, 1, 1, -1, 1, -1, -1, -1, 1, -1, 1, 1, 1, 1, -1, 1$, where
$\mathbf{a_0^g} = 1, 1, 1, -1$, $\mathbf{a_1^g} = 1, -1, -1, -1$, $\mathbf{a_2^g} = 1, -1, 1, 1$, $\mathbf{a_3^g} = 1, 1, -1, 1$. Then our size-4 CS set is:

$$\begin{array}{lcccccccccccccccc}
\mathbf{s_0} = e_{0,0}\mathbf{a_0^g}|e_{0,1}\mathbf{a_1^g}|e_{0,2}\mathbf{a_2^g}|e_{0,3}\mathbf{a_3^g} = & + & + & + & - & + & - & - & - & + & - & + & + & - & - & + & - \\
\mathbf{s_1} = e_{1,0}\mathbf{a_0^g}|e_{1,1}\mathbf{a_1^g}|e_{1,2}\mathbf{a_2^g}|e_{1,3}\mathbf{a_3^g} = & + & + & + & - & + & - & - & - & - & + & - & - & + & + & - & + \\
\mathbf{s_2} = e_{2,0}\mathbf{a_0^g}|e_{2,1}\mathbf{a_1^g}|e_{2,2}\mathbf{a_2^g}|e_{2,3}\mathbf{a_3^g} = & + & + & + & - & - & + & + & + & + & - & + & + & + & + & - & + \\
\mathbf{s_3} = e_{3,0}\mathbf{a_0^g}|e_{3,1}\mathbf{a_1^g}|e_{3,2}\mathbf{a_2^g}|e_{3,3}\mathbf{a_3^g} = & - & - & - & + & + & - & - & - & + & - & + & + & + & + & - & +
\end{array}$$

where '$+$' is 1 and '$-$' is -1.

Then $|\mathbf{s_0} \cdot \mathbf{l}|^2 + |\mathbf{s_1} \cdot \mathbf{l}|^2 + |\mathbf{s_2} \cdot \mathbf{l}|^2 + |\mathbf{s_3} \cdot \mathbf{l}|^2 = 4.0$ for $\mathbf{l}$ 4-linear. In other words, the four sequences, $\mathbf{s_i}$, form a size-4 CS set wrt any 4-LUUT, which includes any 2-LUUT, as the sum of their power spectrums wrt any 4-LUUT is a constant at every point. Therefore each sequence satisfies 4-$\mathrm{PAR}(\mathbf{s_i}) \leq 4.0$ wrt any 4-LUUT, which includes any 2-LUUT. The power spectrums wrt DFT_1^∞ for each sequence of the above CS set are shown in Fig 1, and the spectrums sum to 4.0 at each spectral index. The power spectrums wrt the 16-point

WHT for each of the four sequences are as follows:

Sequence	Power Spectrum															
$\mathbf{s_0}$	0	4	0	0	4	0	0	0	0	0	4	0	0	0	0	4
$\mathbf{s_1}$	0	0	4	0	0	0	0	4	0	4	0	0	4	0	0	0
$\mathbf{s_2}$	4	0	0	0	0	4	0	0	0	0	0	4	0	0	4	0
$\mathbf{s_3}$	0	0	0	4	0	0	4	0	4	0	0	0	0	4	0	0

The power spectrums wrt the 16-point NHT for each of the four sequences are as follows:

Sequence	Power Spectrum															
$\mathbf{s_0}$	2	0	2	0	0	2	0	2	2	0	2	0	0	2	0	2
$\mathbf{s_1}$	2	0	2	0	0	2	0	2	2	0	2	0	0	2	0	2
$\mathbf{s_2}$	0	2	0	2	2	0	2	0	0	2	0	2	2	0	2	0
$\mathbf{s_3}$	0	2	0	2	2	0	2	0	0	2	0	2	2	0	2	0

In all cases the power spectrums sum to 4.0 at each point. Furthermore, the sequences, $\pi_2(\mathbf{s_i})$ also form a size-4 CS set wrt any 2-LUUT, for any π_2.

3.0.7 Iterate Construction:

Let us now assign

$$\mathbf{A}' = \begin{pmatrix} \mathbf{s_0} \\ \mathbf{s_1} \\ \mathbf{s_2} \\ \mathbf{s_3} \end{pmatrix} = \begin{pmatrix} e_{0,0}\mathbf{a}_0^{\mathbf{g}} & e_{0,1}\mathbf{a}_1^{\mathbf{g}} & e_{0,2}\mathbf{a}_2^{\mathbf{g}} & e_{0,3}\mathbf{a}_3^{\mathbf{g}} \\ e_{1,0}\mathbf{a}_0^{\mathbf{g}} & e_{1,1}\mathbf{a}_1^{\mathbf{g}} & e_{1,2}\mathbf{a}_2^{\mathbf{g}} & e_{1,3}\mathbf{a}_3^{\mathbf{g}} \\ e_{2,0}\mathbf{a}_0^{\mathbf{g}} & e_{2,1}\mathbf{a}_1^{\mathbf{g}} & e_{2,2}\mathbf{a}_2^{\mathbf{g}} & e_{2,3}\mathbf{a}_3^{\mathbf{g}} \\ e_{3,0}\mathbf{a}_0^{\mathbf{g}} & e_{3,1}\mathbf{a}_1^{\mathbf{g}} & e_{3,2}\mathbf{a}_2^{\mathbf{g}} & e_{3,3}\mathbf{a}_3^{\mathbf{g}} \end{pmatrix}$$

for any size-4 CS set of length 16 sequences, $\mathbf{s_i}$, as constructed using the previous subsections. Let $\mathbf{E}'$ be any 4×4 unitary matrix. For instance,

$$\mathbf{E}' = \begin{pmatrix} 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & 1 & 1 & 1 \\ 1 & -1 & -1 & 1 \end{pmatrix}$$

$\mathbf{A}'$ takes the place of the $\mathbf{A}$ matrix discussed previously. We again perform row permutation or column-segment permutation of $\mathbf{A}'$, with optional coset offset and symmetric permutation to construct sequences of length 64 with 4-PAR ≤ 4.0 wrt any 4-LUUT. (Note that we refer to column-segment permutation because we only permute the 4 segments of each row of $\mathbf{A}'$). $\mathbf{E}'$ now takes the place of the $\mathbf{E}$ matrix discussed previously, allowing us to construct size-4 CS sets of length 64 whose power spectrums sum to a constant wrt any 4-LUUT. For example, we can concatenate the sequences $\mathbf{s_i}$, constructed in subsection 3.0.6, to get the length 64 sequence,

$$\begin{aligned} &+++-+---+-++--+-+++-+----+--++-++++--++++-++++-+---++---+-++++-+ \\ &= (-1)^{x_0x_1+x_0x_2+x_0x_3+x_1x_2+x_2x_3+x_2x_5+x_3x_4+x_4x_5} \end{aligned}$$

where '$+$' and '$-$' are short for 1 and -1, respectively. This sequence has 4-PAR$(\mathbf{s}) \leq 4.0$ wrt all 4-LUUTs, including all 2-LUUTs. For example, $\mathbf{s}$ has PAs of 3.01, 1.00, and 1.00 wrt DFT_1^∞, WHT, and NHT, respectively. Using $\mathbf{E}'$ we can construct the size-4 CS set,

$$\begin{array}{l} +++-+---+-++--+-+++-+----+--++-++++--++++-++++-+---++---+-++++-+ \\ +++-+---+-++--+-+--+-+--+-++++-+--++-+-++--++++-++++-++++-++--+--+++-+----+- \\ +++-+---+-++--+-+++-+-+---+--++-++++-++--+-++++--++++-++++-+---++---+-++++-+ \\ +++-+---+-++--+-+--+-+----+--++-++++--++++-++++-+---++---+-++++-+ \end{array}$$

which is a set of 4 length-64 sequences whose power spectrums sum to a constant wrt any 4-LUUT, which includes any 2-LUUT.

We can iterate the contruction as many times as we like to produce sequences of length 2^{2L} for some positive integer L, where each sequence has 4-PAR ≤ 4.0 wrt any 4-LUUT. (If there is symmetric permutation by π_2 then each sequence generally only has PAR ≤ 4.0 wrt any 2-LUUT, not any 4-LUUT).

3.0.8 Summary of Example Construction

We summarise the construction operations as follows:

- 1. Choose a 4×4 unitary matrix, $\mathbf{A}$.
- 2. Permute rows and/or columns of $\mathbf{A}$.
- 3. Select length-4 sequence, $\mathbf{g}$, to act as coset offset for $\mathbf{A}$.
- 4. Choose 4×4 unitary matrix, $\mathbf{E}$.
- 5. Concatenate the rows of (permuted coset of) $\mathbf{A}$ and multiply each row-segment by the appropriate entry in $\mathbf{E}$, for each row of $\mathbf{E}$, to form a size-4 CS set of length 16 sequences with 4-PAR ≤ 4.0 wrt any 4-LUUT. Define this 4-set as a 4×16 matrix, $\mathbf{A}'$.
- 6. Iterate the construction L times by looping back to step 2, where $\mathbf{A}$, $\mathbf{E}$ and $\mathbf{g}$ are replaced by $\mathbf{A}'$, a new 4×4 unitary matrix, $\mathbf{E}'$, and a new length-4 unitary vector, $\mathbf{g}'$, respectively.
- 7. Finally, symmetrically permute each sequence in the size-4 CS set, using the same permutation, π_2, for each sequence, and define this set as a 4×4^L matrix, each row of which has PAR ≤ 4.0 wrt any 2-LUUT, and such that the four rows form a size-4 CS set.

Our construction can be fully specified by the sequence of 4×4 unitary matrices, $\mathbf{E_j}$, where $\mathbf{A} = \mathbf{A_0} = \mathbf{E_0}$, by the row/column permutations over Z_4 at each iteration, the coset offset at each iteration, the number of iterations of the construction, and the final symmetric permutation over $Z_{2^{2L}}$. Using this construction we can generate a vast number of sequences with low PAR wrt any 2-LUUT. However, the difficulty with the construction arises because the above constructive operations are not disjoint (orthogonal), so it is problematic to count the complete sequence set, and to design hardware/software to implement the construction without gneerating a (small) fraction of the sequences more than once. We tackle the quadratic case in subsection 4.4.

In subsection 4 we formalise the construction and generalise to r-PAR $\leq R$, for any R by using $R \times R$ matrices, $\mathbf{E_j}$, to recursively construct matrices, $\mathbf{A_j}$. Instead of applying the row/column permutations and coset offset to the $\mathbf{A_j}$ matrices, we shall, equivalently, apply these operations to the $\mathbf{E_j}$ matrices.

4 Constructions

4.1 Construction 1

Let $N = r^n$, $R = r^t$. Let $\mathbf{E_j}$ and $\mathbf{A_j}$, $0 \le j < L$, be a sequence of $R \times R$ and $R \times R^{j+1}$ complex matrices, respectively, $\mathbf{E_j}$ a unitary, unimodular matrix with rows $\mathbf{e_{i,j}}$, $\mathbf{A_j}$ with unitary, unimodular rows, $\mathbf{a_{i,j}}$. Let γ_j and θ_j permute Z_R, and $\mathbf{E'_j}$, with rows $\mathbf{e'_{i,j}}$, be the row/column permutation of $\mathbf{E_j}$, specified by γ_j and θ_j, respectively. Let $\mathbf{A_0} = \mathbf{E'_0}$. Then $\mathbf{A_j}$ is formed as,

$$\mathbf{a_{i,j}} = (\mathbf{a_{0,j-1}}|\mathbf{a_{1,j-1}}|\dots|\mathbf{a_{R-1,j-1}}) \odot (\mathbf{1} \otimes \mathbf{e'_{i,j}}) \tag{2}$$

where $\mathbf{x} \odot \mathbf{y} = (x_0 y_0, x_1 y_1, \dots, x_{R^j-1} y_{R^j-1})$, $\mathbf{1}$ is the length R^j all-ones vector, $'|'$ means concatenation, and $\mathbf{e'_{i,j}}$ is the ith row of $\mathbf{E'_j}$.

Theorem 1. *Let $\mathbf{s}$ be a length $N = R^L$ row of $\mathbf{A_{L-1}}$. Then $\pi_r(\mathbf{s})$ satisfies r-PAR$(\pi_r(\mathbf{s})) \le R$ wrt all $N \times N$ r-LUUTs, where π_r is any r-symmetric permutation of $\mathbf{s}$.*

Proof. Assume the rows of $\mathbf{A_{j-1}}$ form a size-R CS set wrt any r-LUUT. Let $\mathbf{l_j}$ and $\mathbf{l}$ be unitary unimodular r-linear rows of length R^{j+1} and R, respectively. Let $\mathbf{b} = R^{j-1}\mathbf{A_{j-1}}\mathbf{l}^{\mathbf{T}}_{\mathbf{j-1}}$. Then, by Definition 8, $\mathbf{b}$ is unitary. By Definitions 2,4,8, the rows of $\mathbf{A_j}$ must form a size-R CS set wrt any r-LUUT if $\mathbf{b'} = R^j \mathbf{A_j}(\mathbf{l_{j-1}} \otimes \mathbf{l})^T$ is unitary $\forall \mathbf{l_{j-1}}, \mathbf{l}$. This follows because $b'_i = \sum_{k=0}^{R-1}(\mathbf{a_{k,j-1}}\mathbf{l}^{\mathbf{T}}_{\mathbf{j-1}})(e'_{i,j,k}l_k) = \sum_{k=0}^{R-1} b_k e'_{i,j,k} l_k$ for $b'_k, b_k, e'_{i,j,k}$ and l_k the kth elements of $\mathbf{b'}$, $\mathbf{b}$,$\mathbf{e'_{i,j}}$ and $\mathbf{l}$, respectively. To make $\mathbf{b'}$ unitary, we require $P = R\sum_{i=0}^{R-1}|b'_i|^2 = R\sum_{i=0}^{R-1}|\sum_{k=0}^{R-1}(b_k e'_{i,k} l_k)|^2 = 1$. Let $\mathbf{z} = \sqrt{R}(b_0 l_0, b_1 l_1, \dots, b_{R-1} l_{R-1})^T$, and $\mathbf{Z} = \mathbf{E'_j z}$. Then $P = 1$ if $\mathbf{Z}$ is unitary, which follows by Parseval's Theorem if $\mathbf{E'_j}$ is a unitary matrix, and if $\mathbf{z}$ is unitary. $\mathbf{E'_j z}$ is a unitary matrix and $\mathbf{z}$ is unitary because $\mathbf{b}$ is unitary and $\mathbf{l}$ is unitary unimodular. It follows that the rows of $\mathbf{A_j}$ form a size-R CS set if the rows of $\mathbf{A_{j-1}}$ form a size-R CS set. The induction is completed by noting that the rows of $\mathbf{A_0} = \mathbf{E'_0}$ form a size-R CS set. Finally, any r-symmetric permutation of $\mathbf{s}$ is allowed because $\mathbf{l}$ and $\mathbf{l_j}$ are both r-linear. □

Note that, if $\mathbf{l_j}$ is not unimodular then Theorem 1 does not, in general, hold.

It is interesting to observe that the Hadamard matrix construction of [14] is related to the constructions of this paper. Using the terminology of [14], their construction is,

$$\mathbf{H} = \begin{pmatrix} c_{11} + \mathbf{B_1} & c_{12} + \mathbf{B_2} & \dots & c_{1m} + \mathbf{B_m} \\ c_{21} + \mathbf{B_1} & c_{22} + \mathbf{B_2} & \dots & c_{2m} + \mathbf{B_m} \\ \dots & \dots & \dots & \dots \\ c_{m1} + \mathbf{B_1} & c_{m2} + \mathbf{B_2} & \dots & c_{mm} + \mathbf{B_m} \end{pmatrix}$$

where $\mathbf{C} = [c_{ij}]$, the $\mathbf{B_i}$ are $T \times T$ Hadamard matrices, and their alphabet comprises $\{0, 1\}$ instead of $\{1, -1\}$, and they use '+', mod 2, instead of $\times$. One can relate this construction to the first iteration of Construction 1 of our paper by equating our $\mathbf{E}$ matrix with their $\mathbf{C}$ matrix, assigning $T = m = R$, and by assigning $\mathbf{B_{i+1}}$ to be derived from $\mathbf{B_i}$ where every column of $\mathbf{B_i}$ is cyclically shifted round by one position. Then we pick out every Rth row of $\mathbf{H}$ to form a CS set of R sequences of length R^2, where every sequence has PAR $\le R$ wrt all LUUTs. There are R such sets. It would be interesting to develop a classification of Hadamard matrices according to the worst-case PAR of the rows of the matrix.

PAR ≤ 8.0

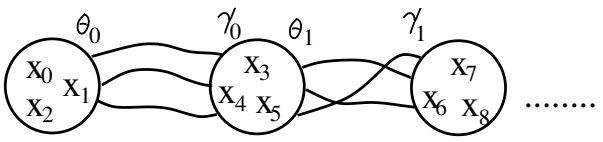

Figure 2: Construction 2 for $t = 3$

4.2 Construction 2 (special case of Construction 1)

Consider Construction 1. Let $r = 2$ and all $\mathbf{E_j}$ be $2^t \times 2^t$ WHTs. Let $\mathbf{x} = \{x_0, x_1, \ldots, x_{n-1}\}$ be n binary variables. Then $\mathbf{s} = 2^{\frac{-n}{2}}(-1)^{\mathbf{P(x)}}$, where,

$$p(\mathbf{x}) = \sum_{j=0}^{L-2} \theta_j(\mathbf{x_j})\gamma_j(\mathbf{x_{j+1}}) + \sum_{j=0}^{L-1} g_j(\mathbf{x_j}) \tag{3}$$

where θ_j and γ_j are any permutations: $Z_2^t \rightarrow Z_2^t$,
$\mathbf{x_j} = \{x_{\pi(tj)}, x_{\pi(tj+1)}, \ldots, x_{\pi(t(j+1)-1)}\}$, $n = Lt$, π permutes Z_n, and g_j is any function from $Z_2^t \rightarrow Z_2$.

To clarify (3) note that, $\forall j$, we can define $\rho(\mathbf{x_j}, \mathbf{x_{j+1}}) = \theta_j(\mathbf{x_j})\gamma_j(\mathbf{x_{j+1}})$ such that ρ can be expanded as the function $\rho : Z_2^{2t} \rightarrow Z_2$, $\rho(\mathbf{x_j}, \mathbf{x_{j+1}}) = \theta_{0,j}(\mathbf{x_j})\gamma_{0,j}(\mathbf{x_{j+1}}) + \theta_{1,j}(\mathbf{x_j})\gamma_{1,j}(\mathbf{x_{j+1}}) + \ldots + \theta_{t-1,j}(\mathbf{x_j})\gamma_{t-1,j}(\mathbf{x_{j+1}})$ where $\theta_j = (\theta_{0,j}, \theta_{1,j}, \ldots, \theta_{t-1,j})$, $\gamma_j = (\gamma_{0,j}, \gamma_{1,j}, \ldots, \gamma_{t-1,j})$ and all $\theta_{i,j}, \gamma_{i,j}$ are balanced functions : $Z_2^t \rightarrow Z_2$, chosen so that θ_j and γ_j are permutations.

Corollary 1. *The length $N = 2^n$ sequences, $\mathbf{s}$, of Construction 2, satisfy PAR$(\mathbf{s}) \leq 2^t$ wrt all $N \times N$ LUUTs.*

Proof. Construction 2 is a special case of Construction 1 where all $\mathbf{E_j}$ are $2^t \times 2^t$ WHTs. The Corollary therefore follows from Theorem 1. □

When $L = 2$ and when θ or γ is the identity permutation, then Construction 2 reduces to the Maiorana McFarland construction over $2t$ variables. [1] It is helpful to illustrate Construction 2 graphically, and Fig 2 illustrates the construction for $t = 3$, where we are also free to permute the indices, i, of x_i using π. An example for Fig 2 could be,

$$\begin{aligned} p(\mathbf{x}) = \quad & (x_0)(x_3 + x_5) + (x_1)(x_5) + (x_1 + x_2)(x_4) + (x_3 + x_4)(x_6 + x_7 + x_8) \\ & + (x_3)(x_6) + (x_5)(x_7) + g_0(x_0, x_1, x_2) + g_1(x_3, x_4, x_5) + g_2(x_6, x_7, x_8) \end{aligned}$$

where g_0, g_1, g_2 are any functions: $Z_2^3 \rightarrow Z_2$. This example has guaranteed 8-PAR ≤ 8.0 wrt all 8-LUUTs, which includes all 2-LUUTs, but with index permutation of the x_i, PAR ≤ 8.0 is only guaranteed wrt all 2-LUUTs.

Theorem 2. *For fixed t, let $\mathbf{P}$ be the subset of $p(\mathbf{x})$ of degree μ or less, generated using Construction 2. Then $D \geq 2^{n-\mu}$, where D is the Hamming Distance between members of*

[1] Thanks to V.Rijmen for pointing out the Maiorana-McFarland connection.

$\mathbf{P}$*, and,*

$$\begin{aligned} |\mathbf{P}| &\leq B = \frac{n!}{\Gamma}\left(\frac{2^{t+\binom{t}{2}}\Gamma}{t!}\right)^{\frac{n}{t}} && \mu = 2 \\ &\leq B = \frac{n!}{V}\left(\frac{2^{2^t-1}V}{t!}\right)^{\frac{n}{t}} && \mu = 2t-2, t>1 \end{aligned} \tag{4}$$

where $\Gamma = \prod_{i=0}^{t-1}(2^t - 2^i) = |GL(t,2)|$*, (GL is the General Linear Group), and* $V = ((2^t-1)!)^2 - (\Gamma^2 - \Gamma)$*. (For* $t = 1$ *the bound is exact). (Note that this paper does not give upper bounds on the size of* $\mathbf{P}$ *for the intermediate cases where* $2 < \mu < 2t-2$*.)*

Proof. The result on Hamming Distance, D, is a well-known propery of Reed-Muller codes [13]. Let us now prove (4). When $\mu = 2$ then θ and γ are linear permutations. In this case the two-way permutation, $\mathbf{x_j}\gamma(\mathbf{x_{j+1}})$, covers the same set of permutations as $\theta(\mathbf{x_j})\gamma(\mathbf{x_{j+1}})$. So we can set θ to the identity permutation. Each term, $\mathbf{x_j}\gamma_j(\mathbf{x_{j+1}})$, for γ_j linear, is isomorphic to $\mathrm{GL}(t,2)$, where GL is the General Linear Group. Therefore we can represent the linear permutations at each iteration by the set, $\mathrm{GL}(t,2)$ of binary invertible $t \times t$ matrices, where $\Gamma = |\mathrm{GL}(t,2)| = \prod_{i=0}^{t-1}(2^t - 2^i)$. For $L = \frac{n}{t}$ and $L-1$ iterations we have Γ^{L-1} possible combinations of permutations. There are $\frac{1}{2}\prod_{i=1}^{L}\binom{it}{t}$ ways of ordering a linked line of subsets of t disjoint variables out of n variables. At each iteration we can choose g_j from one of $2^{t+\binom{t}{2}}$ quadratic functions of t variables. Over L iterations we therefore have a choice of $(2^{t+\binom{t}{2}})^L$ combinations of functions, g_j. The first part of (4) follows by noting that $\prod_{i=1}^{L}\binom{it}{t} = \frac{n!}{(t!)^L}$.
The case $\mu = 2t-2$ occurs when θ and γ are permutation polynomials each up to degree $t-1$ ($t-1$ is the maximum possible degree of a permutation polynomial from $Z_2^t \to Z_2^t$). Therefore each of θ and γ can be chosen from $\frac{(2^t)!}{2^t}$ different polynomials to make a total of $\left(\frac{(2^t)!}{2^t}\right)^2$ polynomial configurations for one iteration. [2] However remember that the case of $\theta\gamma$ quadratic corresponds to θ and γ both linear in which case we can, without loss of generality, make θ the identity. Therefore instead of contributing Γ^2 configurations, the case of $\theta\gamma$ quadratic contributes only Γ configurations, so the total number of polynomial configurations after one iteration is $V = \frac{(2^t)!}{2^t} - (\Gamma^2 - \Gamma)$. Therefore, after $L-1$ iterations we have V^{L-1} possible combinations of permutations. We therefore replace Γ in the first line of equation (4) with V. At each iteration we can now choose g from one of 2^{2^t-1} functions of t variables of degree $\leq t$ (ignoring constant offset). The second part of (4) follows. □

Definition 10. *A* $[2^n, k, D, W]$ *nonlinear error-correcting code has length* 2^n*, dimension* k *(*$\log_2$ *of the number of codewords), Hamming Distance* D*, and each codeword has PAR* $\leq W$ *wrt all LUUTs.*

Corollary 2. *Application of Construction 2 and reference to Theorem 2 allows us to construct and parameterise* $[2^n, \log_2(|\mathbf{P}|), 2^{n-\mu}, 2^t]$ *nonlinear error-correcting codes.*

4.3 Examples for Construction 2

The WHT, NHT, and DFT_1^∞ are used as 'spot-checks' in the following examples to validate the PAR upper-bound. Furthermore, the PAR is lower-bounded by the maximum PAR resulting from these three spot-checks.

[2] Note that we divide by 2^t so as not to include all offsets of the permutation θ (or γ) by the constant '1', i.e. we ignore permutations which have one or more constituent elements of the form $\theta_{i,j}(\mathbf{x_j}) + 1$ (or $\gamma_{i,j}(\mathbf{x_j}) + 1$). These constant offsets to the permutations are implicitly included by suitable assignments to the g_j polynomials in (5).

There are, of course, an infinite number of LUUTs, all of which validate the PAR upper-bound for the constructed set.

4.3.1 Example 1, Identity Permutations

Let θ_j and γ_j be identity permutations $\forall j$. Then, $\theta(\mathbf{x_j}) = \gamma(\mathbf{x_j}) = \mathbf{x_j}$ and Construction 2 becomes,

$$p(\mathbf{x}) = \sum_{j=0}^{L-2} \sum_{l=0}^{t-1} x_{\pi(tj+l)} x_{\pi(t(j+1)+l)} + \sum_{j=0}^{L-1} g_j(\mathbf{x_j}) \tag{5}$$

When $\deg(g_j) < 2, \forall j$, it is well-known that $\mathbf{s} = 2^{\frac{-n}{2}}(-1)^{p(\mathbf{x})}$ is Bent (PA = 1 wrt the WHT) for L even [13] and (perhaps not known) that $\mathbf{s}$ has PA $= 2^t$ wrt the WHT for L odd. In general, for any g_j, $\mathbf{s}$ has PAR $\leq 2^t$ wrt all LUUTs. For example, if $L = 4$, $t = 3$, and $p(\mathbf{x}) = x_0x_3 + x_1x_4 + x_2x_5 + x_3x_6 + x_4x_7 + x_5x_8 + x_6x_9 + x_7x_{10} + x_8x_{11}$, then $\mathbf{s}$ has PA $= 1.0$ wrt WHT and NHT, and PA $= 7.09$ wrt DFT_1^∞. Similarly, let $g_0(x_0, x_1, x_2) = x_1x_2$, $g_1(x_3, x_4, x_5) = x_3x_4x_5$, and $g_2(x_6, x_7, x_8) = 0$. Then $\mathbf{s}' = 2^{\frac{-n}{2}}(-1)^{p(\mathbf{x})+g_0+g_1+g_2}$ has PAs 4.0, 2.0, and 7.54 wrt WHT, NHT, and DFT_1^∞, respectively. In all cases, PAR $\leq 2^t = 8.0$.

4.3.2 Example 2, PAR ≤ 2.0, ($t = 1$)

Let $t = 1$. We need only consider the identity permutations, $\theta_j(x_{\pi(j)}) = \gamma_j(x_{\pi(j)}) = x_{\pi(j)}$, as $\theta_j(x_{\pi(j)}) = \gamma_j(x_{\pi(j)}) = x_{\pi(j)} + 1$ is implicitly covered by $g_j(\mathbf{x_j})$. From Construction 2,

$$p(\mathbf{x}) \quad = \textstyle\sum_{j=0}^{L-2} x_{\pi(j)} x_{\pi(j+1)} + c_j x_j + k, \qquad c_j, k \in Z_2 \tag{6}$$

This is exactly the DJ set of binary quadratic cosets of RM$(1, n)$, where $n = L$, as described by Davis and Jedwab [4]. This set has PA ≤ 2.0 wrt DFT_1^∞ [4]. Such sequences are Bent for n even [13, 26] and, in [16, 17] it is shown that such a set has PA $= 2.0$ wrt WHT for n odd, and also, wrt NHT, has PA $= 1.0$ for $n \neq 2 \bmod 3$ (NegaBent), and PA $= 2.0$ for $n = 2 \bmod 3$. More generally the DJ set has PAR ≤ 2.0 wrt any LUUT [17], and this agrees with Theorem 1. For example, let $p(\mathbf{x}) = x_0x_4 + x_4x_1 + x_1x_2 + x_2x_3 + x_1 + 1$. Then $\mathbf{s}$ has PAR $= 2.0$ wrt the WHT, NHT, and DFT_1^∞. The DJ set, being cosets of $R(2, n)$, forms a codeset with Hamming Distance, $D \geq 2^{n-2}$. The rate of the DJ codeset is $\frac{(\frac{n!}{2})2^{n+1}}{2^{2^n}}$. Therefore we can construct a $[2^n, \log_2(n!) + n, 2^{n-2}, 2.0]$ error-correcting code. The primary drawback of this code is that its rate vanishes rapidly as n increases.

4.3.3 Example 3, PAR ≤ 4.0, ($t = 2$)

[4, 24, 16, 17, 26] all propose techniques for the inclusion of further quadratic cosets, so as to improve rate at the price of increased PAR. We here propose an improved rate quadratic code (although still vanishing, asymptotically), where PAR ≤ 4.0. To achieve this we set $t = 2$ in Construction 2. For $t = 2$ then the algebraic degree of all sequences is $\mu = 2$. Therefore, as stated in the proof of Theorem 2, we can set θ to the identity permutation. There are $\Gamma = \frac{(2^t)!}{2^t} = 6$ non-trivial linear permutation polynomials, γ_j, (ignoring constant offset). These polynomials map from $Z_2^2 \to Z_2^2$, and comprise the set, $\gamma(x_r, x_s) \in \{(x_r, x_s), (x_r + x_s, x_s), (x_r, x_r + x_s), (x_s, x_r), (x_r + x_s, x_r), (x_s, x_r + x_s)\}$. Substituting for γ_j and g_j in Construction 2 gives a large set of polynomials with PAR≤ 4.0 wrt all LUUTs. We now list, for this construction, the $p(\mathbf{x})$ arising from the 6 invertible polynomials, γ, for one 'iteration' of Construction 2, i.e. for $L = 2$, where $n = Lt = 4$, and where we fix π to the identity.

$$
\begin{aligned}
p(\mathbf{x}) &= x_0x_2 + x_1x_3 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)\\
p(\mathbf{x}) &= x_0(x_2 + x_3) + x_1x_3 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)\\
p(\mathbf{x}) &= x_0x_2 + x_1(x_2 + x_3) + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)\\
p(\mathbf{x}) &= x_0x_3 + x_1x_2 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)\\
p(\mathbf{x}) &= x_0(x_2 + x_3) + x_1x_2 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)\\
p(\mathbf{x}) &= x_0x_3 + x_1(x_2 + x_3) + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)
\end{aligned}
\tag{7}
$$

where $c_0, c_1 \in Z_2$. The permutations, γ_j, above are isomorphic to a distinct invertible boolean $t \times t$ matrix, where $t = 2$ (Section 4.4), as the permutation polynomials form a group isomorphic to the binary General Linear Group, $\mathrm{GL}(t,2)$, where $|\mathrm{GL}(t,2)| = \prod_{i=0}^{t-1}(2^t - 2^i)$ [11]. Explicitly,

$$
\mathrm{GL}(2,2) = \left\{ \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix} \right\}
$$

Note that, by inspection, any two of the quadratics in (7) are inequivalent under permutation, π, of the indices of the four variables, e.g., $p(\mathbf{x}) = x_0x_2 + x_1x_3 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)$ and $p(\mathbf{x}) = x_0(x_2 + x_3) + x_1x_3 + c_0x_0x_1 + c_1x_2x_3 + \mathrm{RM}(1,4)$. An upper bound, B, on $|\mathbf{P}|$ is given by Theorem 2. Substituting $t = 2$ into (4),

$$
|\mathbf{P}| < B = \frac{n!}{6} 24^{\frac{n}{2}} \tag{8}
$$

Therefore we can construct a $[2^n, \log_2(|\mathbf{P}|), 2^{n-2}, 4.0]$ error-correcting code. Exact enumeration and unique generation for this set remains open, due to extra symmetries, induced by π, which occur for $t > 1$. As an example of this π-induced symmetry, consider the two coset leaders, $x_0x_2 + x_1x_3 + g_0(x_0, x_1) + g_1(x_2, x_3)$ and $x_0x_1 + x_2x_3 + g'_0(x_0, x_2) + g'_1(x_1, x_3)$ which both contribute to the count in the above enumeration, but are equal when $g_0(x_0, x_1) = x_0x_1$, $g_1(x_2, x_3) = x_2x_3$, $g'_0(x_0, x_2) = x_0x_2$, $g'_1(x_1, x_3) = x_1x_3$. This equality leads to an overcount and such symmetries render B a strict upper bound for all cases but $t = 1$. We computed the exact number of quadratic coset leaders for $n = 4, 6, 8, 10$, by simply counting the number of distinct coset leaders, and these are compared to the upper bound, B, of (8) in Table 1. They are also compared to the $\frac{n!}{2}$ quadratic coset leaders in the binary DJ set (Example 2). Thus, for instance, Table 1 shows the existence of a $[64, 20.2, 16, 4.0]$ low PAR error-correcting code, i.e. of length 64, dimension $k = 20.2$, distance $D = 16$, and PAR ≤ 4.0, which can be compared with the fundamental DJ binary codeset for $n = 6$, which is a $[64, 15.5, 16, 2.0]$ low PAR error-correcting code. We see that rate has been improved over the DJ codeset at the price of PAR, which also increases. Thus, by assigning $t = 2$ we have a construction for a much larger codeset than

Table 1: The Number of Quadratic Coset Leaders for Construction 2 when $t = 2$

n	4	6	8	10
Theorem 2, (8),(4), $B/2^{n+1}$	72	12960	4354560	2351462400
Exact Computation(3), $\lvert\mathbf{P}\rvert/2^{n+1}$	36	9240	4086096	2317593600
$\lvert$DJ Code $\rvert/2^{n+1}$	12	360	20160	1814400
$\log_2(B/2^{n+1})$	6.2	13.7	22.1	31.1
$\log_2(\lvert\mathbf{P}\rvert/2^{n+1})$	5.2	13.2	22.0	31.1
$\log_2$(Number of homogeneous quadratics)	6	15	28	45

the DJ codeset and with the same Hamming Distance, $D = 2^{n-2}$, but now PAR is upper-bounded by 4.0 instead of 2.0. Table 1 also shows the $\log_2$ of the size of the complete set of homogeneous quadratic functions, and it is evident from Table 1 that $\mathbf{P}$ contains a

significant proportion of these homogeneous quadratic functions for $n \leq 10$. Note that, as n increases, the discrepancy between the upper bound, B, and $|\mathbf{P}|$ becomes negligible as a fraction of $|\mathbf{P}|$. Therefore, in practice, for $n \geq 10$, it may be acceptable, from the viewpoint of an engineer who wishes to use this codeset in an OFDM system, to incorporate the coding collision errors induced by π into the overall error-rate without significant detriment to performance. In which case we can already claim to have constructed an *implementable* low PAR error-correcting code for OFDM systems using 1024 or more carriers which is significantly larger than any previously proposed that uses construction techniques. However Table 1 also indicates that the rate of this code is still unacceptably small for $n \geq 10$. For instance, from Table 1, when $n = 10$, we see that the code rate of $\mathbf{P}$ is $\frac{42.1}{1024}$, which is very small.

As an example of a codeword from this set, let $p(\mathbf{x}) = x_0x_2 + x_1x_2 + x_1x_6 + x_2x_5 + x_6x_3 + x_6x_5 + x_5x_4 + x_3x_7 + x_0x_1 + x_5x_3 + x_7 + x_1$. Then $\mathbf{s}$ has PAs $= 1.0, 2.0$, and 3.43 wrt WHT, NHT, and DFT_1^∞, respectively.

Table 2: The Number of Quadratic Coset Leaders for Construction 2 when $t = 3$

n	6	9	12	15
$\log_2(B/2^{n+1})$	16.7	33.5	51.7	70.9
$\log_2$(Number of homogeneous quadratics)	15	36	66	105

4.3.4 Example 4, PAR ≤ 8.0, ($t = 3$)

There are now $\frac{(2^t)!}{2^t} = 5040$ non-trivial permutation polynomials from $Z_2^3 \to Z_2^3$, and of linear or quadratic degree for each of θ, and γ (ignoring constant-offset). Thus, $\theta\gamma$ can be quadratic, cubic or quartic according to the subset of permutations used. In this paper we only explicitly enumerate upper bounds for the quadratic and quartic cases, leaving the cubic case to future work.

Quadratic Construction ($\mu = 2$):
When $\mu = 2$ we have a quadratic construction, and θ and γ are linear permutations. For this case, as discussed previously, we can, without loss of generalisation, set θ to the identity permutation. There are $\Gamma = (2^3 - 1)(2^3 - 2)(2^3 - 2^2) = 168$ linear permutation polynomials. By inspection, these 168 polynomials can be represented by the following 7 linear permutations which are inequivalent under input and output variable index permutation.

$$\gamma(x_q, x_r, x_s) \in \quad \{(x_q, x_r, x_s), (x_q + x_s, x_r, x_s), (x_q + x_s, x_r + x_s, x_s), (x_q + x_r + x_s, x_r, x_s), \\ (x_q + x_r, x_r + x_s, x_s), (x_q + x_r + x_s, x_r + x_s, x_s), (x_q + x_s, x_r + x_q, x_s + x_q + x_r)\}$$

Substituting for γ and g in Construction 2, with θ fixed as the identity, gives a large set of polynomials with PAR≤ 8.0 wrt all LUUTs. We now list, for this construction, all quadratic $p(\mathbf{x})$ arising from the 7 inequivalent degree-one permutations, γ, for one 'iteration' of Construction 2, i.e. for $L = 2$, where π is fixed as the identity:

$$
\begin{aligned}
p(\mathbf{x}) &= x_0x_3 + x_1x_4 + x_2x_5 + g(\mathbf{x}) \\
p(\mathbf{x}) &= x_0x_3 + x_0x_5 + x_1x_4 + x_2x_5 + g(\mathbf{x}) \\
p(\mathbf{x}) &= x_0x_3 + x_0x_5 + x_1x_4 + x_1x_5 + x_2x_5 + g(\mathbf{x}) \\
p(\mathbf{x}) &= x_0x_3 + x_0x_4 + x_0x_5 + x_1x_4 + x_2x_5 + g(\mathbf{x}) \\
p(\mathbf{x}) &= x_0x_3 + x_0x_4 + x_1x_4 + x_1x_5 + x_2x_5 + g(\mathbf{x}) \\
p(\mathbf{x}) &= x_0x_3 + x_0x_4 + x_0x_5 + x_1x_4 + x_1x_5 + x_2x_5 + g(\mathbf{x}) \\
p(\mathbf{x}) &= x_0x_3 + x_0x_5 + x_1x_3 + x_1x_4 + x_2x_3 + x_2x_4 + x_2x_5 + g(\mathbf{x})
\end{aligned}
$$

where $g(\mathbf{x}) = c_0x_0x_1 + c_1x_0x_2 + c_2x_1x_2 + c_3x_0x_1x_2 + c_4x_3x_4 + c_5x_3x_5 + c_6x_4x_5 + c_7x_3x_4x_5 + \mathrm{RM}(1,6)$, $c_0, c_1, \ldots, c_7 \in Z_2$, with $c_3 = c_7 = 0$. An upper bound, B, to $|\mathbf{P}|$ can be computed from Theorem 2, (4), with $\mu = 2$, and the upper bound is compared to the total number of homogeneous quadratics in n binary variables in Table 2. Once again, a substantial proportion of the possible homogeneous quadratics appear to be contained in $\mathbf{P}$ for $n \leq 15$. As with $t = 2$, exact enumeration and unique generation for this set remains open, due to extra symmetries induced by π. This codeset has Hamming Distance, $D \geq 2^{n-2}$ and PAR ≤ 8.0 wrt all LUUTs. We can therefore construct a $[2^n, \log_2(|\mathbf{P}|), 2^{n-2}, 8.0]$ error-correcting code. For instance, Table 2 shows the existence of a $[64, \simeq 23.7, 16, 8.0]$ low PAR error-correcting code.

Cubic Construction ($\mu = 3$):
For $t = 3$ we can also include cubic forms in Construction 2, where θ and γ are each quadratic or linear. There are 168 linear and $5040 - 168 = 4872$ quadratic permutations for each of θ and μ and, by inspection, this set can be represented by 7 linear and 147 quadratic permutation polynomials which are inequivalent under input and output variable permutation. This makes a total of 154 inequivalent permutation polynomials for $t = 3$ [8, 31]. Substituting for θ, γ and g in Construction 2 gives a large set of polynomials with PAR≤ 8.0 wrt all LUUTs, and Hamming Distance, $D \geq 2^{n-3}$. However, we leave to further work the challenge of upper bounding, enumerating and uniquely generating this set. Here is an example from this codeset, where ijk, uv is short for $x_ix_jx_k + x_ux_v$, π is the identity, θ_j is linear and γ_j is quadratic $\forall j$. Let,

$$
\begin{aligned}
p(\mathbf{x}) = \quad & 034, 035, 045, 135, 145, 234, 235, 245, 367, 368, 378, 567, 568, 69A, 79A, 7AB, \\
& 89A, 345, 9AB, 03, 05, 14, 24, 25, 36, 38, 47, 58, 69, 6A, 6B, 7A, 7B, 89, 8B, 67, 78, AB
\end{aligned}
$$

Then $\mathbf{s}$ has PAs 4.0, 6.625, and 7.66 wrt the WHT, NHT, and DFT_1^∞, respectively. Moreover, PAR ≤ 8.0. Here is another example from this codeset, where π is the identity, θ_0 is linear, γ_0 is quadratic, θ_1 and γ_1 are both linear, and θ_2 is quadratic, γ_2 is linear. Let,

$$
\begin{aligned}
p(\mathbf{x}) = \quad & 034, 035, 045, 134, 135, 145, 234, 235, 245, 789, 67A, 68A, 67B, 68B, \\
& 03, 05, 14, 15, 36, 38, 46, 47, 56, 57, 58, 69, 79, 89, 8A, 7B
\end{aligned}
$$

Then $\mathbf{s}$ has PAs 1.0, 2.5, and 5.44 wrt the WHT, NHT, and DFT_1^∞, respectively. Moreover, PAR ≤ 8.0. Successful enumeration would allow us to construct a $[2^n, k, 2^{n-3}, 8.0]$ error-correcting code.

Quartic Construction ($\mu = 4$):
Finally, for $t = 3$, we can also include quartic forms, $p(\mathbf{x})$, which occur for the subset of cases where both θ and γ are quadratic permutations. This gives a large set of polynomials of degree ≤ 4 with PAR ≤ 8.0 wrt all LUUTs, and Hamming Distance, $D \geq 2^{n-4}$. Table 3 uses (4) to compute an upper bound on the quartic code size for $t = 3$ as n varies. We can therefore construct a $[2^n, \log_2(|\mathbf{P}|), 2^{n-4}, 8.0]$ error-correcting code. For instance, Table 3 shows the existence of a $[64, \simeq 42.9, 4, 8.0]$ error-correcting code.

Table 3: Upper Bound on Size of the Quartic Codeset Using Construction 2 for $t = 3$

n	6	9	12
$\log_2(B)$	42.92	80.91	120.29

We leave the exact enumeration and unique generation of this set to future work. Here is an example from this codeset. Let,

$$p(\mathbf{x}) = \begin{array}{l} 0235, 0245, 023, 025, 1235, 1245, 0234, 0235, 0245, 1234, 1235, 1245, \\ 123, 125, 035, 045, 134, 145, 134, 135, 145, 234, 235, 245, 03, 05, 14, 15 \end{array}$$

Then $\mathbf{s}$ has PAs 6.25, 3.25, and 3.74 wrt the WHT, NHT, and DFT_1^∞, respectively. In all cases, PAR ≤ 8.0.

4.3.5 Example 5, PAR ≤ 16.0, ($t = 4$)

Table 4 uses (4) to compute an upper bound on the sextic ($\mu = 6$) code size for $t = 4$ as n varies. We can therefore construct a $[2^n, \log_2(|\mathbf{P}|), 2^{n-6}, 16.0]$ error-correcting code. For instance, Table 4 shows the existence of a $[256, \simeq 116.6, 4, 16.0]$ error-correcting code.

Table 4: Upper Bound on Size of the Sextic Codeset Using Construction 2 for $t = 4$

n	8	12	16
$\log_2(B)$	116.63	221.08	312.00

We leave the exact enumeration and unique generation of this set to future work.

4.4 A Matrix Construction for all Quadratic Codes from Construction 2

For the case $\mu = 2$ we can, without loss of generality, fix θ to the identity permutation, and then aim to construct all possible linear permutations for γ. Each degree-one permutation, γ: $Z_2^t \to Z_2^t$ can be viewed as a $t \times t$ binary adjacency matrix under the mapping,

$M = \{m_{i,l}\} \Leftrightarrow \gamma_j(\mathbf{x_j}) = (\gamma_{0,j}(\mathbf{x_j}), \gamma_{1,j}(\mathbf{x_j}), \ldots, \gamma_{t-1,j}(\mathbf{x_j})), \qquad \gamma_{l,j} : Z_2^t \to Z_2, \deg(\gamma_{l,j}) = 1, \quad \forall l$
$m_{i,l} = 1$ if $\gamma_{l,j}(\mathbf{x_j})$ contains the linear term, x_i
$m_{i,l} = 0$ otherwise

The above mapping is an isomorphism from degree-one permutations to the General Linear Group, $\mathbf{G} = \mathrm{GL}(t, 2)$, of all binary $t \times t$ invertible matrices, mod 2 [11]. Therefore, to construct all quadratics, $p(\mathbf{x})$, for a given n and t we need to generate all degree one permutations, γ, which can, in turn, be constructed by generating all of $\mathbf{G} = \mathrm{GL}(t, 2)$, as follows [1, 2]:

Definition 11. *A binary $t \times t$* transvection *matrix, X_{ab}, satisfies,*

$$X_{ab} = \{u_{i,j}\}, \quad \begin{array}{ll} \textit{where } u_{i,j} = 1, & i = j, \textit{ and } i = a, j = b \\ u_{i,j} = 0, & \textit{otherwise} \end{array}$$

Definition 12. *The Borel subgroup of* $\mathbf{G}$ *over* Z_2 *is the set of* $t \times t$ *upper-triangular binary matrices,* $\mathbf{B}$.

Definition 13. *The Weyl subgroup of* $\mathbf{G}$ *is the set of* $t \times t$ *permutation matrices,* $\mathbf{W}$.

Arbitrarily assign a fixed ordering, O, to the $\binom{t}{2}$ matrices, X_{ab}, $a < b$. Let $w \in \mathbf{W}$ be a $t \times t$ permutation matrix where w also represents a permutation of Z_t such that $w \begin{pmatrix} a_0 \\ a_1 \\ \cdots \\ a_{t-1} \end{pmatrix} = \begin{pmatrix} a_{w(0)} \\ a_{w(1)} \\ \cdots \\ a_{w(t-1)} \end{pmatrix}$ For each w, form the matrix product, X_w, comprising all X_{ab} which satisfy $a < b = w(a) > w(b)$, where the X_{ab} in X_w are ordered according to O.

Theorem 3. *[1, 2] ('Bruhat Decomposition')*

$$\mathbf{G} = \mathbf{X'_w W B} \tag{9}$$

where $\mathbf{X'_w}$ *is the set of sub-products of* X_w *that maintain the ordering of the* X_{ab} *matrices in* X_w*, including the identity matrix.*

All linear permutations, γ, can be uniquely constructed using Theorem 3, where $|\mathbf{G}| = \Gamma = \prod_{i=0}^{t-1}(2^t - 2^i)$. This means that we can generate all quadratics, $p(\mathbf{x})$, for Construction 2 for any t and L. However, as indicated previously, the $p(\mathbf{x})$ are not guaranteed to be unique due to the extra symmetries induced by π. We leave to further work the challenge of modifying the Bruhat decomposition to eliminate these residual symmetries.

4.5 Examples of Bruhat Decomposition

$t = 2$**:**
For $t = 2$, $X_{01} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$, $\mathbf{B} = \{\left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right), \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)\}$, $\mathbf{W} = \{\left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right), \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)\}$. Assign the trivial ordering X_{01} to the one matrix, X_{ab}. Now $w = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right)$ defines the identity permutation $(0)(1)$ and makes $X_w = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right)$. Moreover $w = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ defines the permutation $(0, 1)$ and makes $X_w = X_{01}$. Therefore, when w defines $(0)(1)$ we generate 2 matrices of $\mathbf{G}$, and when w defines $(0, 1)$ we generate 4 matrices of $\mathbf{G}$, bringing the total to 6, which is correct.
$t = 3$**:**
For $t = 3$, $X_{01} = \left(\begin{smallmatrix} 1 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{smallmatrix}\right)$, $X_{02} = \left(\begin{smallmatrix} 1 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{smallmatrix}\right)$, $X_{12} = \left(\begin{smallmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{smallmatrix}\right)$, $|\mathbf{B}| = 8$, $|\mathbf{W}| = 6$. We can arbitrarily choose to assign the ordering $X_{01}X_{02}X_{12}$ to the 3 matrices, X_{ab}. The partitioning of matrices in $\mathbf{G}$ is then as follows:

w	X_w	$\lvert$subset of $\mathbf{G}\rvert$
$(0)(1)(2)$	I	8
$(0)(1, 2)$	X_{12}	16
$(0, 1)(2)$	X_{01}	16
$(0, 2)(1)$	$X_{01}X_{02}X_{12}$	64
$(0, 2, 1)$	$X_{01}X_{02}$	32
$(0, 1, 2)$	$X_{02}X_{12}$	32
		Total $= \lvert\mathbf{G}\rvert = 168$

5 A Further Generalisation

Lemma 20 of [25] extends the Maiorana-McFarland construction to a large codeset with near-Bent properties, where a 1-1 map is replaced by a 2^{δ}-1 map. In this section we apply similar ideas to Construction 2 to obtain Construction 3 below, (proofs omitted). Construction 3 is quite complicated and so far we have not found a better way to express the construction. We advise readers to skip this section on first reading. We do, however, provide some examples in the appendix which will help to clarify the construction.

Construction 3 tackles the case when the number of variables in each of the L iterations is allowed to vary. Using the terminology of Construction 1, this implies more than one $\mathbf{E}$ matrix for some iterations, where each $\mathbf{E}$ matrix is unitary and is associated with an independently chosen row/column permutation. Before describing the construction we must first specify some new terminology.

Let permutation $\theta : Z_2^t \rightarrow Z_2^t$ have as domain the t binary variables, $\mathbf{x}$. Let $f : Z_2^u \rightarrow Z_2$ have as domain the set of u binary variables, $\mathbf{z}$. Let us now assume that the form of θ depends on the output of $f(\mathbf{z})$. We write this as $\theta(\mathbf{x})\{f(\mathbf{z})\}$ and this expression can be partly evaluated as,

$$\theta(\mathbf{x})\{f(\mathbf{z})\} = (f(\mathbf{z})+1)\theta^0(\mathbf{x}) + f(\mathbf{z})\theta^1(\mathbf{x})$$

where we must define 2 permutations, θ^0 and θ^1, from $Z_2^t \rightarrow Z_2^t$. For brevity we can write this as $\theta\{f\}$. We can generalise this definition to make θ dependent on v associated functions, f_i, from $Z_2^{u_i} \rightarrow Z_2, 0 \leq i < v$. We write this as $\theta(\mathbf{x})\{f_0(\mathbf{z_0}), f_1(\mathbf{z_1}), \ldots, f_{v-1}(\mathbf{z_{v-1}})\}$, and we must now define 2^v permutations, $\theta^0, \theta^1, \ldots, \theta^{2^v-1}$, from $Z_2^t \rightarrow Z_2^t$, one of which is 'selected' according to the combined outputs of the f_i. For brevity we can write this as $\theta\{f_0, f_1, \ldots, f_{v-1}\}$. We can further abbreviate the notation by labeling $\{F\} = \{f_0, f_1, \ldots, f_{v-1}\}$. We can then *NEST* dependencies $F_0, F_1, F_2, \ldots$. This is written as $\theta = \theta\{F_0\{F_1\{F_2\{\ldots\}\}\}\}$, and means that the form of the functions in F_{i-1} depend on the outputs of the functions F_i. We express the *NEST* operation as,

$$NEST(\theta\{F\}, \{F'\}) \rightarrow \theta\{F\{F'\}\}$$

Let $|F|$ mean the number of functions labeled by F. Let $v = \sum_{i=0}^{Q-1} |F_i|$. Then, if we *NEST* to a depth of Q using the function sets, $F_i, 0 \leq i < Q$, then we must define 2^v permutations, $\theta^0, \theta^1, \ldots, \theta^{2^v-1}$, from $Z_2^t \rightarrow Z_2^t$, one of which is 'selected' according to the combined outputs of the F_i. As an example, let $F_0 = \{f_0(\mathbf{z_0}), f_1(\mathbf{z_1}))\}$, and $F_1 = \{f_2(\mathbf{z_2})\}$. Then, with f_0, f_1, f_2 outputting $\rightarrow Z_2$,

$$\theta(\mathbf{x})\{F_0\{F_1\}\} = \theta(\mathbf{x})\{f_0(\mathbf{z_0}), f_1(\mathbf{z_1})\{f_2(\mathbf{z_2})\}\}$$

which, for brevity, can be written as,

$$\theta\{F_0, F_1\} = \theta\{f_0, f_1\{f_2\}\}$$

and can be partially evaluated as,

$$\begin{aligned}&(f_2(\mathbf{z_2})+1)((f_1(\mathbf{z_1})+1)(f_0(\mathbf{z_0})+1)\theta^0(\mathbf{x}) + (f_1(\mathbf{z_1})+1)f_0(\mathbf{z_0})\theta^1(\mathbf{x}) + f_1(\mathbf{z_1})(f_0(\mathbf{z_0})+1)\theta^2(\mathbf{x})\\ &+f_1(\mathbf{z_1})f_0(\mathbf{z_0})\theta^3(\mathbf{x})) + f_2(\mathbf{z_2})((f_1'(\mathbf{z_1})+1)(f_0'(\mathbf{z_0})+1)\theta^4(\mathbf{x}) + (f_1'(\mathbf{z_1})+1)f_0'(\mathbf{z_0})\theta^5(\mathbf{x})\\ &+f_1'(\mathbf{z_1})(f_0'(\mathbf{z_0})+1)\theta^6(\mathbf{x}) + f_1'(\mathbf{z_1})f_0'(\mathbf{z_0})\theta^7(\mathbf{x}))\end{aligned}$$

where f_i' is not necessarily the same as f_i, and where 8 permutations, $\theta^i : Z_2^t \rightarrow Z_2^t$, $0 \leq i < 8$, must be defined with domain $\mathbf{x}$.

We will also decompose the permutation $\theta_j : Z_2^t \rightarrow Z_2^t$ as $\theta_j = (\theta_{0,j}, \theta_{1,j}, \ldots, \theta_{t-1,j})$, where $\theta_{i,j} : Z_2^t \rightarrow Z_2$. Similarly, $\gamma_j : Z_2^t \rightarrow Z_2^t$ is decomposed as $\gamma_j = (\gamma_{0,j}, \gamma_{1,j}, \ldots, \gamma_{t-1,j})$, where $\gamma_{i,j} : Z_2^t \rightarrow Z_2$.

We now define the *EXTEND* operation. Let F be a length $t' - t$ vector of functions of arbitrary domain each of which outputs $\rightarrow Z_2$ (where it is assumed that $t' \geq t$). Then,

$$EXTEND(\theta_j, F) \rightarrow (\theta_{j,0}, \theta_{j,1}, \ldots, \theta_{j,t-1}, F)$$

is a mapping $\rightarrow Z_2^{t'}$. In other words, θ_j has been extended by means of the vector F from a permutation of Z_2^t to a mapping which outputs to $Z_2^{t'}$. Construction 3 uses combinations of *NEST* and *EXTEND* to construct θ'_j and γ'_j, which output (after *NESTING* and *EXTENSION*) to $Z_2^{t\max}$, where $t_{\max}$ is defined below. θ'_j and γ'_j can then be 'multiplied', in the same way as $\theta_j \gamma_j$ in (3), and the resulting expressions added to form the final polynomial, p.

We are now ready to describe Construction 3.

Construction 3: *To construct a function of n boolean variables with PAR $\leq 2^{tmax}$ wrt all LUUTs, we pursue the following strategy (the y_i are auxilliary boolean variables which can be used at the end to select between different sequences):*

- *Choose t_{max} so that $1 \leq t_{max} \leq n$.*
- *Partition the n binary variable indices, $\{0, 1, \ldots, n-1\}$, into L disjoint variable subsets, $\mathbf{S_j}$, such that $t_j = |\mathbf{S_j}| \leq t_{max}$, $\forall j$, $0 \leq j < L$.*
- *For each j, $0 \leq j < L-1$, define θ_j comprising $2^{t_{max}-t_j}$ permutations, $\theta_j^0, \theta_j^1, \ldots, \theta_j^{2^{t_{max}-t_j}-1}$, from $Z_2^{t_j} \rightarrow Z_2^{t_j}$ with domain the set of t_j binary variables $\mathbf{x_j} = \{x_i\}$, $i \in \mathbf{S_j}$. Similarly, for each j, $0 \leq j < L-1$, define γ_j comprising $2^{t_{max}-t_{j+1}}$ permutations, $\gamma_j^0, \gamma_j^1, \ldots, \gamma_j^{2^{t_{max}-t_{j+1}}-1}$, from $Z_2^{t_{j+1}} \rightarrow Z_2^{t_{j+1}}$ with domain the set of t_{j+1} binary variables $\mathbf{x_{j+1}} = \{x_i\}$, $i \in \mathbf{S_{j+1}}$.*
- *For $j = 0$, $j < L-1$, j++ do:*

  {
  . $t = t_j$.
  . *Assign F as the zero vector of length $t_{max} - t_j$.*
  . *For $i = j+1$, $i \leq L-1$, i++ do:*
  . {
  . *if* $t < t_i$
  . {
  . *assign* $\theta_j = NEST(\theta_j, \{\gamma_{i-1,t}, \gamma_{i-1,t+1}, \ldots, \gamma_{i-1,t_i-1}\})$.
  . *set* $t = t_i$.
  . }
  . }
  . *if* $t < t_{max}$
  . *assign* $\theta_j = NEST(\theta_j, \{y_t, y_{t+1}, \ldots, y_{t_{max}-1}\})$.
  . $\theta'_j = EXTEND(\theta_j, F)$.
  . $t = t_{j+1}$.
  . $F = ()$.
  . *For $i = j+1$, $i < L-1$, i++ do:*
  . {
  . *if* $t < t_{i+1}$
  . {
  . *assign* $F = \{\gamma_{i,t}, \gamma_{i,t+1}, \ldots, \gamma_{i,t_{i+1}-1}\}$.
  . *assign* $\gamma_j = NEST(\gamma_j, F)$.
  . *assign* $\gamma_j = EXTEND(\gamma_j, F)$.
  . *set* $t = t_{i+1}$.

PAR ≤ 8.0

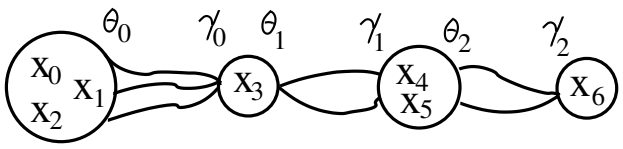

Figure 3: Example of Construction 3 where $t_{\max} = 4$

```
.           }
.      }
.      if t < t_max
.      {
.           assign F = {y_t, y_{t+1}, ..., y_{t_max - 1}}.
.           assign γ_j = NEST(γ_j, F).
.           assign γ_j = EXTEND(γ_j, F).
.      }
.      γ'_j = γ_j.
}
```

- *Then* $\mathbf{s} = 2^{\frac{-n}{2}}(-1)^{p(\mathbf{x})}$*, where p is given by,*

$$p(\mathbf{x}) = \sum_{j=0}^{L-2} \theta'_j \gamma'_j + \sum_{j=0}^{L-1} g_j(\mathbf{x_j}) \tag{10}$$

where $2^{t_{max} - t_{L-1}}$ *different sequences are generated according to the assignments given to the* $t_{max} - t_{L-1}$ *auxilliary variables,* y_i*, which are present in the* θ'_j *or* γ'_j*, and where the* g_j *are arbitrary functions of* $\mathbf{x_j}$*, outputting* $\rightarrow Z_2$*. (Note that, for this generalisation, the permutation,* π*, of the indices* $\{0, 1, \ldots, n-1\}$ *is implicitly included in the initial index partition operation).*

Corollary 3. *The length* $N = 2^n$ *sequences,* $\mathbf{s}$*, of Construction 3, satisfy PAR*$(\mathbf{s}) \leq 2^{t_{\max}}$ *wrt all* $N \times N$ *LUUTs.*

Fig 3 illustrates Construction 3 for the case of Example 1 in the Appendix, where we are also free to permute indices, i, of x_i.

Corollary 4. *Each of the* $2^{t_{max} - t_{L-1}}$ *sequences,* $\mathbf{s}$*, of Construction 3 is a coset leader for a coset of* $2^{t_{L-1}}$ *sequences formed from any linear offset of* $\mathbf{s}$ *by linear combinations of members of* $\mathbf{x_{L-1}}$*. The union of these* $2^{t_{max} - t_{L-1}}$ *cosets forms a CS set of* $2^{t_{max}}$ *sequences of length* 2^n*.*

The Appendix provides examples for Construction 3.

In Construction 3, if $t_j = t_{\max}, \forall j$, then there is no *NESTING* or *EXTENSION* and the construction simplifies to Construction 2. It remains open to exactly enumerate and uniquely generate the sequences in Construction 3. Note that, just as Construction 2 is a special case of Construction 1, so Construction 3 is a special case of a more general construction where the $\mathbf{E}$ matrices are not necessarily WHT matrices. This further generalisation is conceptually straightforward once Construction 3 is understood. Note also that Construction 3 allows us to add yet more sequences to our low PAR codesets without degrading distance, and these improvements in code rate will be discussed in future papers.

6 Discussion and Open Problems

This paper presented a construction for low PAR error-correcting codes which significantly generalises the fundamental codeset of Davis and Jedwab, and concisely summarises the complementary set constructions of Golay, Turyn, and Tseng and Liu. An important subcase, Construction 2, can be viewed either as recursion or specialisation of a two-sided Maiorana-McFarland construction. The paper highlights the central importance for PAR constructions of generating permutation polynomials of prescribed maximum degree, and provides motivation for further research work in this area, and also motivates the search for solutions to a number of open problems which we will now discuss.

Open Problems:

- The constructions of this paper only provide a unique, implementable encoder if we can provide algorithms to generate all permutations and/or many-to-one/one-to-many mappings of specified maximum algebraic degree. Symmetric permutations are straightforward. Section 4.4 provides a (previously-known) generation scheme for linear permutations (producing 'quadratic' sequences). But the problem of unique generation of permutations of degree greater than one is, as far as the authors know, unsolved. Solutions to this problem would have far-reaching application in cryptography, and this paper shows that such algorithms are central to the development of constructions for low PAR error-correcting codes.

- Given an algorithm to generate all permutation polynomials, then Construction 2 only generates distinct $p(\mathbf{x})$ for $t = 1$. For $t > 1$, π, the permutation of variable indices induces extra symmetries causing a few $p(\mathbf{x})$ to be generated more than once. In other words, for $t > 1$ it is possible that the action of two (or more) distinct permutations, π and π', may result in the same polynomial, $p(\mathbf{x})$. This situation is reflected in (4), which is a strict upper bound for $t > 1$. It remains open to provide an algorithm to generate all distinct $p(\mathbf{x})$. Such an algorithm would replace (4) with an exact expression and provide a 'black-box' encoding solution for OFDM systems. The problem is closest to solution for the case of linear permutations, where Section 4.4 solves the permutation generation part, and it remains to eliminate the coding collisions caused by distinct permutations π. We have not yet tackled the problem of unique generation of codewords for Construction 3, but this is clearly an even harder task.

- It would also be interesting to choose the $\mathbf{E_j}$ other than WHTs for Constructions 1 and 3. In particular, note that the case of $t = 1, 2, 3$ refers to Hadamard matrices of size $2, 4, 8$, respectively (PAR $\leq 2, 4, 8$, respectively). It is known that, for $t \leq 3$, all Hadamard matrices are row/column permutation equivalent to WHT matrices, so Construction 2 covers all cases. However, for $t = 4$, (PAR ≤ 16) we know that there are 5 row/column permutation inequivalent 16×16 Hadamard matrices, one of which is the WHT [32]. Therefore, for $t = 4$, there are essentially 5 different versions of Construction 1, one of which is Construction 2. As t increases we have yet more inequivalent classes of Hadamard matrices. This paper therefore establishes a direct link between the classification of Hadamard matrices, and the classification of PAR classes, and provides a strong motivation to discover manageable ANF descriptions for each of these classes.

- One important way to improve code rate whilst keeping PAR low is to choose rectangular $\mathbf{E_j}$, with more rows than columns, where the rows form a set of near-orthogonal sequences. Application of Construction 1 would then result in a slowly rising PAR bound as L increases, but the rate of the code would also improve compared to the

cases where $\mathbf{E_j}$ is a square matrix. This raises the possibility of even higher rate low PAR error-correcting codes. For instance, in CDMA, the WHT rows can be used as a sequence set, due to their orthogonality. But larger near-orthogonal sequence sets are highly desirable, and the set of Gold sequences is such a set. The set of Kerdock sequences is an even larger set [9]. One could therefore use one of these larger sequence sets to form our $\mathbf{E}$ matrices, one sequence per row. Our row permutation, γ, would then operate over a larger space, resulting in an improved code rate. And the near-orthogonality of the sequence set would ensure the upper-bound on PAR only rose slowly after each iteration of the construction, although computing the precise upper-bound in such cases remains an open challenge.

- In this paper we have proposed the study of PAR wrt all LUUTs. One can completely generalise the set of LUUTs to the set of *Linear Unitary Transforms* (LUTs) by including unitary matrices which are the tensor product of $r \times r$ unitary matrices such that each matrix entry is no longer constrained to have a magnitude of $\frac{1}{\sqrt{r}}$. For instance, linear unitary matrices which have $\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ and $\frac{1}{2}\begin{pmatrix} \sqrt{3} & 1 \\ 1 & -\sqrt{3} \end{pmatrix}$ as tensor factors are in the set of LUTs but not the smaller subset represented by LUUTs. It is of interest to study the PAR of sequences wrt all LUTs. This study has been initiated in [18, 19] where it was shown that the length 2^n sequences which represent indicator functions for linear error-correcting codes of blocklength n have PAR wrt all LUTs lower bounded by $2^{\frac{n}{2}}$. Moreover, it is proved in [18] that, for indicator functions which represent linear error-correcting codes (functions outputting to 0 or 1), the worst-case spectral peak wrt all LUTs, (and hence the peak which defines the PAR wrt all LUTs), occurs in one or more of the spectra generated by action of the set of transforms formed from all possible tensor products of the matrices $\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ and $\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$. The nice thing about this result is that we don't have to search the complete infinite space of LUTs to find the worst-case spectral peak. However, little more is known about the PAR wrt all LUTs for more general functions. The study has direct relevance to Quantum Entanglement and it has recently been shown that the spectral index of the worst-case spectral peak wrt all LUTs identifies a generalised linear weakness for classical cryptosystems [27], where a large PAR means a large linear bias.

- One celebrated area of study is the unresolved quest to find flat polynomials on the unit circle [12]. This translates, in the terminology of this paper, into the search for a sequence construction of length 2^n (restricted, say, to the alphabet $\{1, -1\}$), such that the sequence has PAR wrt DFT_1^∞ of $1.0 + \epsilon_0$ and a lowest spectral power trough of $1.0 - \epsilon_1$ such that the ϵ terms vanish as length, 2^n, increases. No construction with these properties is known for the bipolar case. We can pose a more general problem. Do flat polynomials exist wrt all LUUTs (not just DFT_1^∞)? And an even more general problem would be: Do flat polynomials exist wrt all LUTs? More realistically, how well can we do for these transform sets?

7 Acknowledgements

We would like to thank Kenneth G. Paterson for giving helpful and encouraging advice regarding this paper.

8 Appendix

We provide some examples for Construction 3.

8.1 Example 1

Let $n = 7$. Consider the partition, $\mathbf{S_0} = \{0, 1, 2\}$, $\mathbf{S_1} = \{3\}$, $\mathbf{S_2} = \{4, 5\}$, $\mathbf{S_3} = \{6\}$, as shown in Fig 3. Then $t_0 = 3$, $t_1 = 1$, $t_2 = 2$, $t_3 = 1$, $t_{\max} = t_0 = 3$, and $L = 4$.

Applying Construction 3, we must initially define the following permutations:

θ_0^0	with domain (x_0, x_1, x_2)
$\gamma_0^0, \gamma_0^1, \gamma_0^2, \gamma_0^3,$ and $\theta_1^0, \theta_1^1, \theta_1^2, \theta_1^3$	with domain (x_3)
$\gamma_1^0, \gamma_1^1,$ and θ_2^0, θ_2^1	with domain (x_4, x_5)
$\gamma_2^0, \gamma_2^1, \gamma_2^2, \gamma_2^3$	with domain (x_6)

It then follows, from Construction 3, that,

$$\begin{array}{ll} \theta_0' \leftarrow \theta_0(x_0, x_1, x_2) & \gamma_0' \leftarrow (\gamma_0(x_3)\{\gamma_{1,1}\{y_2\}\}, \gamma_{1,1}\{y_2\}, y_2) \\ \theta_1' \leftarrow (\theta_1(x_3)\{\gamma_{1,1}\{y_2\}\}, 0, 0) & \gamma_1' \leftarrow (\gamma_1(x_4, x_5)\{y_2\}, y_2) \\ \theta_2' \leftarrow (\theta_2(x_4, x_5)\{y_2\}, 0) & \gamma_2' \leftarrow (\gamma_2(x_6)\{y_1, y_2\}, y_1, y_2) \end{array}$$

Let us now assign, as examples, specific (arbitrary) permutation polynomials to each of the θ_j and γ_j. Let,

$$\begin{array}{ll} \theta_0 = (x_0, x_1, x_2) & \gamma_0^0 = (x_3), \gamma_0^1 = (x_3), \gamma_0^2 = (x_3), \gamma_0^3 = (x_3 + 1) \\ \theta_1^0 = (x_3 + 1), \theta_1^1 = (x_3), \theta_1^2 = (x_3), \theta_1^3 = (x_3) & \gamma_1^0 = (x_4, x_5), \gamma_1^1 = (x_4 + x_5, x_5) \\ \theta_2^0 = (x_4 + x_5, x_5), \theta_2^1 = (x_4, x_5) & \gamma_2^0 = (x_6), \gamma_2^1 = (x_6), \gamma_2^2 = (x_6), \gamma_2^3 = (x_6 + 1) \end{array} \tag{11}$$

Given these permutation assignments we can evaluate:

$$\begin{array}{l} \gamma_0(x_3)\{\gamma_{1,1}\{y_2\}\} = (y_2 + 1)((x_5 + 1)x_3 + x_5x_3) + y_2((x_5 + 1)x_3 + x_5(x_3 + 1)) = x_3 + x_5y_2 \\ \theta_1(x_3)\{\gamma_{1,1}\{y_2\}\} = (y_2 + 1)((x_5 + 1)(x_3 + 1) + x_5x_3) + y_2((x_5 + 1)x_3 + x_5x_3) = x_3 + x_5 + 1 + (x_5 + 1)y_2 \\ \gamma_1(x_4, x_5)\{y_2\} = (y_2 + 1)(x_4, x_5) + y_2(x_4 + x_5, x_5) = (x_4 + x_5y_2, x_5) \\ \theta_2(x_4, x_5)\{y_2\} = (y_2 + 1)(x_4 + x_5, x_5) + y_2(x_4, x_5) = (x_4 + x_5 + x_5y_2, x_5) \\ \gamma_2(x_6)\{y_1, y_2\} = (y_1 + 1)(y_2 + 1)x_6 + y_1(y_2 + 1)x_6 + (y_1 + 1)y_2x_6 + y_1y_2(x_6 + 1) = x_6 + y_1y_2 \end{array}$$

Therefore,

$$\begin{aligned} \theta_0'\gamma_0' &= x_0x_3 + x_1x_5 + y_2(x_0x_5 + x_2) \\ \theta_1'\gamma_1' &= x_3x_4 + x_4x_5 + x_4 + y_2(x_0x_5 + x_2) \\ \theta_2'\gamma_2' &= x_4x_6 + x_5x_6 + y_1x_5 + y_2x_5x_6 + y_1y_2x_4 \end{aligned}$$

Therefore,

$$\sum_{j=0}^{2} \theta_j'\gamma_j' = x_0x_3 + x_1x_5 + x_3x_4 + x_4x_5 + x_4x_6 + x_5x_6 + x_4 + y_1x_5 + y_2(x_0x_5 + x_3x_5 + x_4x_5 + x_5x_6 + x_2 + x_4) + y_1y_2x_4$$

Let us arbitrarily first consider that all g functions in (10) are zero (for ease of exposition). Then, $p = \sum_{j=0}^{2} \theta_j'\gamma_j'$. Moreover we have 4 different choices of sequence, $\mathbf{s}$, depending on the values of y_1 and y_2. Table 5 shows the PARs wrt WHT, NHT, and DFT_1^∞, for each of these 4 sequences.

In all cases the PAR is upper-bounded by $2^{t\max} = 8.0$, as predicted by Corollary 3. Note that, as stated by Corollary 4, the final optional addition of '$+x_6$' onto each of the 4 sequences in Table 5 produces a CS set of 8 sequences (of length 128) wrt all LUUTs.

Table 5: PAs of Example 1 wrt WHT, NHT, and DFT_1^∞

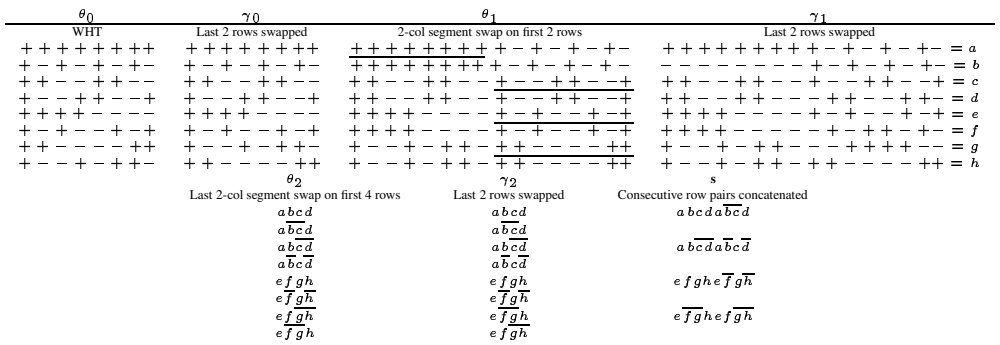
y_1y_2	p	PA: WHT	NHT	DFT_1^∞
00	$x_0x_3 + x_1x_5 + x_3x_4 + x_4x_5 + x_4x_6 + x_5x_6 + x_4$	2.0	1.0	4.18
10	$x_0x_3 + x_1x_5 + x_3x_4 + x_4x_5 + x_4x_6 + x_5x_6 + x_4 + x_5$	2.0	1.0	4.25
01	$x_0x_3 + x_0x_5 + x_1x_5 + x_3x_4 + x_3x_5 + x_4x_6 + x_2$	2.0	1.0	5.79
11	$x_0x_3 + x_0x_5 + x_1x_5 + x_3x_4 + x_3x_5 + x_4x_6 + x_2 + x_4 + x_5$	2.0	1.0	6.02

It is helpful to alternatively construct these sequences visually, by using a generalised version of the strategy outlined in Section 3, which is also the foundation for Construction 1. Although we have not formally proved Construction 3 in this paper, the following construction technique essentially provides the proof for Construction 3. We use unitary WHT matrices, $\mathbf{E_j^k}$, $0 \leq k < 2^{t\text{max}-t_j}$. Specifically, for Example 1, we have one 8×8 matrix, $\mathbf{E_0}$, four 2×2 matrices, $\mathbf{E_1^0}, \mathbf{E_1^1}, \mathbf{E_1^2}, \mathbf{E_1^3}$, and two 4×4 matrices, $\mathbf{E_2^0}, \mathbf{E_2^1}$. The rows and columns of $\mathbf{E_j^k}$ are permuted by γ_{j-1}^k and θ_j^k, respectively. Specifically,

θ_0 permutes columns of $\mathbf{E_0}$,
θ_1^k permutes columns of $\mathbf{E_1^k}$, $0 \leq k < 4$,
θ_2^k permutes columns of $\mathbf{E_2^k}$, $0 \leq k < 2$,

γ_0^r permutes consecutive row pairs of $\mathbf{E_0}$, $0 \leq r < 4$
γ_1^r permutes consecutive sets of four rows of column-concatenated $\mathbf{E_1^k}$, $0 \leq r < 2$
γ_2^r permutes consecutive row pairs of column-concatenated $\mathbf{E_2^k}$, $0 \leq r < 4$

Let us choose the permutations for $\theta$and γ as shown in (11) of Example 1. Then these permutations act in conjunction with the $\mathbf{E}$ matrices as follows (where '$\overline{a}$' means multiply a by -1). Note that, after each γ permutation, the appropriate rows are concatenated before point-multiplying by elements of the appropriate E matrix:



It is straightforward to check that the above 4 sequences, $\mathbf{s}$, correspond exactly to the 4 sequences, $\mathbf{s}$, in Table 5, as represented by p. This example also illustrates that if the $\mathbf{E_j^k}$ are chosen to be row/column inequivalent to WHT matrices, then we can further generalise Construction 3.

Finally, for Example 1, let us now make the g functions non-zero. Arbitrarily, let $g_0(x_0, x_1, x_2) = x_0x_1x_2 + x_2$, $g_1(x_3) = x_3$, $g_2(x_4, x_5) = x_4x_5 + x_5$, and $g_3(x_6) = 0$. Table 6 shows the PAs after addition of $g_0 + g_1 + g_2 + g_3$ onto each of the four sequences of Table 5.

Once again, in all cases the PAR is upper-bounded by $2^{t\text{max}} = 8.0$, as predictedby Corollary 3. Note that, as stated by Corollary 4, the final optional addition of '$+x_6$' onto each of the 4 sequences in Table 6 forms a CS set of 8 sequences wrt all LUUTs.

Table 6: PAs of Example 1 wrt WHT, NHT, and DFT_1^∞ after Addition of $g_0 + g_1 + g_2 + g_3$

$y_1 y_2$	p	PA: WHT	NHT	DFT_1^∞
00	$x_0x_1x_2 + x_0x_3 + x_1x_5 + x_3x_4 + x_4x_6 + x_5x_6 + x_4 + x_2 + x_3 + x_5$	4.5	2.5	4.04
10	$x_0x_1x_2 + x_0x_3 + x_1x_5 + x_3x_4 + x_4x_6 + x_5x_6 + x_4 + x_2 + x_3$	4.5	2.5	4.83
01	$x_0x_1x_2 + x_0x_3 + x_0x_5 + x_1x_5 + x_3x_4 + x_3x_5 + x_4x_5 + x_4x_6 + x_3 + x_5$	4.5	2.0	3.59
11	$x_0x_1x_2 + x_0x_3 + x_0x_5 + x_1x_5 + x_3x_4 + x_3x_5 + x_4x_5 + x_4x_6 + x_4 + x_3$	4.5	2.0	3.51

PAR ≤ 8.0

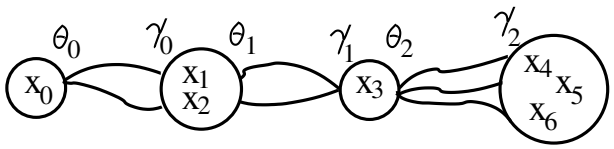


Figure 4: Example of Construction 3 where $t_{\max} = 4$ (Reverse of Figure 3)

8.2 Example 2

Except for the special case of Construction 2, Construction 3 does not give the same set of sequences when starting from the rightmost variable set (as shown), instead of the left-most variable set. Example 2 emphasises this point by describing the construction for the partition of Figure 4, which is clearly the reverse of Figure 3.

The partition is, $\mathbf{S_0} = \{0\}$, $\mathbf{S_1} = \{1, 2\}$, $\mathbf{S_2} = \{3\}$, $\mathbf{S_3} = \{4, 5, 6\}$, as shown in Fig 4. Then $t_0 = 1$, $t_1 = 2$, $t_2 = 1$, $t_3 = 3$, $t_{\max} = t_3 = 3$, and $L = 4$.

Applying Construction 3, we must initially define the following permutations:

$\theta_0^0, \theta_0^1, \theta_0^2, \theta_0^3$	with domain (x_0)
γ_0^0, γ_0^1 and θ_1^0, θ_1^1	with domain (x_1, x_2)
$\gamma_1^0, \gamma_1^1, \gamma_1^2, \gamma_1^3,$ and $\theta_2^0, \theta_2^1, \theta_2^2, \theta_2^3$	with domain (x_3)
γ_2^0	with domain (x_4, x_5, x_6)

It then follows, from Construction 3, that,

$$\begin{array}{ll} \theta_0' \leftarrow (\theta_0(x_0)\{\gamma_{0,1}\{\gamma_{2,2}\}\}, 0, 0) & \gamma_0' \leftarrow (\gamma_0(x_1, x_2)\{\gamma_{2,2}\}, \gamma_{2,2}) \\ \theta_1' \leftarrow (\theta_1(x_1, x_2)\{\gamma_{2,2}\}, 0) & \gamma_1' \leftarrow (\gamma_1(x_3)\{\gamma_{2,1}, \gamma_{2,2}\}, \gamma_{2,1}, \gamma_{2,2}) \\ \theta_2' \leftarrow (\theta_2(x_3)\{\gamma_{2,1}, \gamma_{2,2}\}, 0, 0) & \gamma_2' \leftarrow \gamma_2(x_4, x_5, x_6) \end{array}$$

Let us now assign the same permutations as Example 1, but in reverse, to each of the θ_j and γ_j. Let,

$$\begin{array}{ll} \theta_0^0 = (x_0), \theta_0^1 = (x_0), \theta_0^2 = (x_0), \theta_0^3 = (x_0 + 1) & \gamma_0^0 = (x_1 + x_2, x_2), \gamma_0^1 = (x_1, x_2) \\ \theta_1^0 = (x_1, x_2), \theta_1^1 = (x_1 + x_2, x_2) & \gamma_1^0 = (x_3 + 1), \gamma_1^1 = (x_3), \gamma_1^2 = (x_3), \gamma_1^3 = (x_3) \\ \theta_2^0 = (x_3), \theta_2^1 = (x_3), \theta_2^2 = (x_3), \theta_2^3 = (x_3 + 1) & \gamma_2 = (x_4, x_5, x_6) \end{array}$$

Given these permutation assignments we can evaluate:

$$\begin{array}{l} \theta_0(x_0)\{\gamma_{0,1}\{\gamma_{2,2}\}\} = x_2x_6 + x_0 \\ \gamma_0(x_1, x_2)\{\gamma_{2,2}\} = (x_2x_6 + x_1 + x_2, x_2) \\ \theta_1(x_1, x_2)\{\gamma_{2,2}\}, 0) = (x_2x_6 + x_1, x_2) \\ \gamma_1(x_3)\{\gamma_{2,1}, \gamma_{2,2}\} = x_5x_6 + x_3 + x_5 + x_6 + 1 \\ \theta_2(x_3)\{\gamma_{2,1}, \gamma_{2,2}\} = x_5x_6 + x_3 \end{array}$$

Therefore,

$$\begin{aligned}\theta'_0\gamma'_0 &= x_0x_2x_6 + x_1x_2x_6 + x_0x_1 + x_0x_2\\ \theta'_1\gamma'_1 &= x_1x_5x_6 + x_2x_3x_6 + x_1x_3 + x_1x_5 + x_1x_6 + x_2x_5 + x_1\\ \theta'_2\gamma'_2 &= x_4x_5x_6 + x_3x_4\end{aligned}$$

Therefore,

$$\sum_{j=0}^{2}\theta'_j\gamma'_j = x_0x_2x_6+x_1x_2x_6+x_1x_5x_6+x_2x_3x_6+x_4x_5x_6+x_0x_1+x_0x_2+x_1x_3+x_1x_5+x_1x_6+x_2x_5+x_3x_4+x_1 \quad (12)$$

Let us, arbitrarily, consider that all g functions in (10) are zero (for ease of exposition). Then, $p = \sum_{j=0}^{2}\theta'_j\gamma'_j$. Unlike Example 3, we now only have 1 choice of sequence, $\mathbf{s}$. This sequence has a PA of 8.0, 2.5, and 4.93 wrt the WHT, NHT, and DFT_1^∞, respectively. In all cases the PAR is upper-bounded by $2^{t\max} = 8.0$, as predicted by Corollary 3. Note that, as stated by Corollary 4, a CS set of 8 sequences (of length 128) wrt all LUUTs is formed by $\mathbf{s}$ and all linear offsets of $\mathbf{s}$ over the variables $\{x_4, x_5, x_6\}$.

We can, alternatively, construct this sequence using a generalised version of the strategy outlined in Section 3. We obtain the following construction steps:

θ_0	γ_0	θ_1	γ_1	θ_2	
Cols swapped on last 2 rows	Second pair of rows swapped	Last 2 col segments swapped on last 4 rows	First 2 rows swapped	Col segments swapped on last 2 rows	
++	++	++++−+−++	++−++−−−	++−++−−−++++−+−++	= a
+−	+−	++++−+−++	+++−+−++	++−++−−−++++−+−++	= b
++	+−	+++−++−−+	+++−−+−−	+++−−+−−++−+−+++	= c
+−	++	+++−++−++	+++−+−+++	+++−−+−−++−+−+++	= d
++	++	+++−+−+−+	+++−+++−+	+++−+−+−+++−−−+	= e
+−	+−	++++−++−+	+++−+−−−+	+++−+−+−+++−+−−+	= f
++	++	++++−+−−+	+++−−−+−	+++−−−+−++−+++−+	= g
−+	−+	++++−+−+−	+++−+++−	+++−−−+−++−+++−+	= h

Finally, γ_2 generates $\mathbf{s} = abcdefg$

It is straightforward to check that the above sequence, $\mathbf{s}$, corresponds exactly to the $\mathbf{s}$, as represented by p in (12).

Ana's Golden Fractal

ABSTRACT. . *In his fascinating book "Wonders of Numbers", Clifford Pickover introduces the Ana sequence and fractal, two self-referential constructions arising from the use of language. This paper answers Pickover's questions on the relative composition of sequence terms and the dimension of the fractal. In the process, it introduces a novel way of obtaining fractals from iterative set operations. Also, it presents a beautiful variant of the Ana constructions involving the golden ratio. In conclusion, it suggests ways of constructing similar fractals for the Morse-Thue and "Look and Say" sequences.*

On a Generalization of Perfect Numbers

A Problem Proposal

ABSTRACT. *This paper presents a notion of perfect numbers relative to arithmetical functions: an arithmetical function f produces a set of f-perfect numbers. Two among the many examples considered are small "perturbations" of the normal definition; late in these two sequences, odd perfect numbers appear! (Could the situation be similar for the usual perfect numbers?) Also, this paper generalizes amicable pairs and sociable chains. Mysteries and open problems abound for those who like a challenge. There is also Mathematica code to start the reader on his own explorations.*

Download the paper (File: fperfect.pdf, about 178 Kb). To appear in *The Journal of Recreational Mathematics* 31(3).

A web page version is also available, but is not very well formatted (since it was automatically generated by MS Word).

Here is a paper on an especially intriguing sequence of generalized perfect numbers: Picture-Perfect Numbers and Other Digit-Reversal Diversions.

Meaningful and Meaningless Solutions for Cooperative *N*-person Games

Aleksandar Pekec

December 1996

Abstract:

Game values often represent data that can be measured in more than one acceptable way (e. g., monetary amounts). We point out that in such cases a statement about cooperative *n*-person game model might be ``meaningless'' in the sense that its truth or falsity depends on the choice of an acceptable way to measure game values. In particular we analyze statements about solution concepts such as the core, stable sets, the nucleolus, the Shapley value (and its generalizations)

A Combinatorial Interpretation of the Area of Schröder Paths

An elevated Schröder path is a lattice path that uses the steps $(1,1)$, $(1,-1)$, and $(2,0)$, that begins and ends on the x-axis, and that remains strictly above the x-axis otherwise. The total area of elevated Schröder paths of length $2n+2$ satisfies the recurrence $f_{n+1} = 6f_n - f_{n-1}$, $n \geq 2$, with the initial conditions $f_0 = 1$, $f_1 = 7$. A combinatorial interpretation of this recurrence is given, by first introducing sets of unrestricted paths whose cardinality also satisfies the recurrence relation and then establishing a bijection between the set of these paths and the set of triangles constituting the total area of elevated Schröder paths.

APPROXIMATIONS DE SÉRIES GÉNÉRATRICES ET QUELQUES CONJECTURES

AOÛT 1992

AVANT-PROPOS

Un livre très intéressant a été publié en 1973 par N.J.A. Sloane. Il portait le titre "*A Handbook of Integer Sequences* " et comporte plus de 2372 suites d'entiers prises dans tous les domaines des mathématiques et des sciences en général. Depuis sa publication, des milliers de suites nouvelles ont été trouvées, spécialement en combinatoire. L'auteur invitait ses lecteurs à lui communiquer toute correction ou information nouvelle concernant une suite. Il a reçu environ un mètre cube de lettres depuis.

J'entrepris de taper le livre au complet à la main dans un ordinateur au début de 1990; cela m'a demandé 6 mois de travail. Je n'étais pas au bout de mes peines, car une fois cette tâche terminée, j'envoyai une lettre à l'auteur lui indiquant les erreurs dans certaines d'entre elles et que j'avais commencé à constituer une banque de données avec ses suites, etc. Je reçus un coup de téléphone environ deux semaines plus tard. L'auteur était un peu surpris (et moi donc) que quelqu'un se soit donné la peine de taper tout le livre alors que lui avait un fichier sur ordinateur qui contenait toutes les suites. Après une heure de discussion, l'auteur disait qu'il était temps qu'il fasse la 2ème édition de ce livre. Moi je lui disais qu'il était temps que je complète mes études, etc. C'est là que tout a commencé. C'est en essayant de vérifier les suites d'entiers avec un programme que ce projet est né. Je voulais pouvoir vérifier les chiffres des suites pour qu'il n'y ait pas d'erreurs.

C'est également avec l'encouragement et la vision de mon directeur, Gilbert Labelle, que ce mémoire a vu le jour, à la confiance de Pierre Leroux, aux idées génératrices de mon co-directeur, François Bergeron. Tous les autres aussi, qui sont en France, à Bordeaux au LaBRI avec leurs chauds encouragements. Je pense à Xavier Viennot qui m'impressionnait tellement avec ses conférences en 1985, à Maylis Delest, Serge Dulucq, Jean-Guy Penaud, Jean-Marc Fedou, Mireille Bousquet-Mélou, etc. Ceux de Paris à l'INRIA qui m'ont invité à leur en parler et qui ont contribué grandement à faire que le

programme *gfun* soit une réalité. Je pense à Paul Zimmermann , “en possession tranquille de la vérité”, Bruno Salvy “le fou de Maple” à qui je dois de vraies belles formules trouvées grâce à ses méthodes (elles sont dans la table en appendice), Philippe Flajolet, “le bon maître”. Je leur dois des discussions fort enrichissantes.

A Neil Sloane évidemment, mon guide et mon maître à penser, qui m’a fait l’honneur de bien vouloir être mon “advisor” comme il se plait lui-même à le dire. Je lui dois de précieux conseils.

A ma mère, qui sera pas mal fière et contente que son garçon fasse une maîtrise en mathématiques.

A ma compagne Danièle, qui m’a beaucoup aidé au tout début pour la vérification des suites et qui m’a soutenu jusqu’à la fin. Je lui dois et lui dédie ce mémoire.

RÉSUMÉ

Le présent mémoire tente de répondre à une question simple : Étant donné une suite numérique, comment trouve t-on la fonction génératrice de cette suite? Il s'agit donc de prendre les termes d'une suite et de proposer une façon de les générer à l'aide d'une formule quelconque (simple si possible). Pour ce faire nous avons utilisé des programmes de calcul symbolique couramment disponibles, soit MapleV de l'Université de Waterloo et Pari-GP, un programme développé à l'Université Bordeaux I. Le jeu d'essai des suites est le livre bien connu de Neil J.A. Sloane, *A Handbook of Integer Sequences*[1] . L'exposé se compose de deux parties principales. La première explique les quatre méthodes qui ont permis de répondre à notre question initiale. La deuxième contient une table des formules trouvées à l'aide de ces méthodes. En tout, 1031 fonctions génératrices forment la table sur un total de 4568 suites que composait le jeu d'essai, soit à peu près 23% des suites.

Ces 1031 formules ont toutes été obtenues expérimentalement. C'est donc dire qu'en fait ce sont autant de conjectures. Mais nous verrons que dans presque tous les cas les méthodes sont suffisamment sophistiquées pour pouvoir affirmer que les formules sont les bonnes.

[1] Le jeu d'essai est en fait la 2e édition de ce livre qui est en préparation.

TABLE DES MATIÈRES

INTRODUCTION

Dans toute cette étude nous procéderons selon une seule ligne directrice: il s'agira de prendre une suite numérique finie et à l'aide d'un programme informatique spécialisé, d'identifier un bon candidat pour la fonction génératrice. Une telle approche pourrait se limiter simplement à consulter un livre de table de suites. Dans [GKP] p.42 on note: "the best source for questions about sequences is an amazing little book called the Handbook of Integer Sequences, by Sloane, which lists thousands of sequences by their numerical values."; et aussi: "the look-up method is limited to problems that other people have decided". De plus, après avoir donné un exemple de suite numérique, les auteurs [GKP] p.327, ajoutent: "no closed form is evident, and this sequence isn't even listed in Sloane's Handbook".

Nous présentons ici une solution à ce problème: c'est-à-dire une méthode alternative aux méthodes standard connues dans ce domaine. Ces dernières partent des propriétés mathématiques d'une suite et de là en font l'analyse, le tout étant basé sur la connaisssance a priori des ces propriétés. Dans la présente étude nous proposons de procéder en sens inverse: c'est uniquement à partir de la suite numérique que les propriétés sont établies. A cette fin, nous décrirons quatre méthodes d'analyse d'une suite numérique.

Ces quatre méthodes s'appuient sur quatre modèles de fonctions génératrices. Le premier modèle suppose que les termes de la suite peuvent être générés avec le développement en série de Taylor d'un quotient de polynômes. Le deuxième modèle suppose que la suite satisfait à une récurrence linéaire à coefficients polynomiaux, appelée aussi une P-récurrence. Le troisième modèle suppose que la suite est donnée par le développement en série d'un produit infini, comme la suite des partages d'entiers ordinaires. Le quatrième modèle enfin suppose qu'une transformation simple de la suite permet de retrouver une fonction génératrice connue. Cette dernière est en fait une version améliorée de la "look-up method" de [GKP].

NOTES

Pour éviter les répétitions inutiles tout au long de cette étude, nous emploierons la notation Nxxxx pour désigner la suite numéro xxxx du livre de Sloane [Sl] cité en bibliographie. Par exemple, la suite des nombres de Catalan porte le numéro 577, on y fera référence en écrivant N0577. Les autres suites, celles apparues après 1973 dans la littérature, ont été recataloguées dans une deuxième édition que nous préparons avec Neil J.A. Sloane [PlSl]. Elles portent un numéro séquentiel "absolu" noté Axxxx. Donc quand nous parlerons du numéro de suite A3890, nous entendrons le numéro séquentiel de cette table. C'est cette même numérotation qui apparaît dans la table des résultats en appendice. Pour des raisons évidentes de consistence, il était nécessaire de conserver un numéro qui fasse référence toujours à la même suite sans ambiguité. En résumé :

• Nxxxx :Numéro séquentiel de la suite du livre de Sloane [Sl].

• Axxxx :Numéro séquentiel de la suite du livre [PlSl].

La plupart des algorithmes et méthodes décrites dans cette étude ont été regroupés dans un programme appelé "gfun" qui fait partie de la librairie publique de Maple de l'université de Waterloo. On peut avoir une copie de ce programme par transfert électronique via "ftp/anonymous". Le programme a été écrit en collaboration avec François Bergeron, professeur au département de Mathématiques/Informatique à l'Université du Québec à Montréal et également avec Paul Zimmermann et Bruno Salvy tous deux chercheurs à L'INRIA/Rocquencourt.

CHAPITRE 1

LA MÉTHODE DES APPROXIMANTS DE PADÉ

1.1 Les fractions rationnelles.

Une façon de donner les termes d'une suite est de les engendrer à l'aide d'une fraction rationnelle. Par exemple la suite de Fibonacci peut être générée à l'aide du développement en série de Taylor à l'origine de

(1.1) $1/(1- z - z^2) = 1 + z + 2\,z^2 + 3\,z^3 + 5\,z^4 + 8\,z^5 + 13\,z^6 + ... + a_n z^n + O(z^{n+1})$.

De la même façon ces termes peuvent être calculés avec la récurrence $a_n = a_{n-1} + a_{n-2}$. Les deux représentations sont équivalentes. Il y a une correspondance assez simple entre la fraction rationnelle et la récurrence. Le dénominateur de la fraction rationnelle "est" la relation de récurrence. Le numérateur tient lieu de conditions initiales de cette même récurrence. Le lien se trouve en fait dans la réécriture de la récurrence en termes de z^n plutôt que n. Une procédure simple en quatre étapes, permettant de passer d'une récurrence linéaire à coefficients constants à la fraction rationnelle correspondante, est décrite dans [GKP]. On peut montrer que la réécriture se fait dans l'autre sens également. Cette mécanique est très connue mais suppose toujours que l'on connaisse au moins l'une des deux représentations.

Notre seul point de départ est la série S(z) tronquée à l'ordre k. Ce qu'on désire faire est de la représenter par une fraction rationnelle. Alors si on pose k=L+M et

(1.2) $$S(z) = \frac{u_0 + u_1 z^1 + ... + u_L z^L}{v_0 + v_1 z^1 + ... + v_m z^m} + O(z^{L+M+1})$$

il est toujours possible de trouver une solution à cette équation. La façon de faire est de fixer L et M

d'abord. Puis en multipliant le membre de gauche avec le dénominateur on obtient un système de M équations à M inconnues qui déterminent les constantes en v. Pour poser ces équations, on "identifie" les coefficients de z^i avec $L+1 \leq i \leq L+M$. Une fois trouvés les v_i, on peut faire de même avec le numérateur pour déterminer les constantes en u_j, en identifiant cette fois les coefficients de z^j, $0 \leq j \leq L$. Il est toutefois plus aisé de poser en partant que $v_0 = 1$. On donne le nom d'approximant de Padé [L/M] à l'expression trouvée pour un L et M donnés. Le calcul d'un approximant de Padé se fait en principe de façon mécanique. La plupart des programmes de calcul symbolique sur le marché aujourd'hui effectuent ce calcul automatiquement. On parle ici de la résolution du système d'équations linéaires pour un L et un M donnés. En théorie le problème est clos, mais dans la pratique il en est autrement.

Nous illustrerons les difficultés rencontrées en donnant deux exemples extrêmes d'approximants de Padé.

Exemple 1.1 La suite des parts de gâteaux en 3 dimensions.

Le premier est la suite N0419 qui porte le nom de: "Slicing a cake with n slices"; elle est plutôt simple et connue. C'est le nombre de parts de gâteaux différents avec n coupes en 3 dimensions. Nous nous en tiendrons uniquement aux termes numériques sans tenir compte du contexte. Considérant une quinzaine de termes, on pose les équations et les degrés des deux polynômes, en supposant que les degrés sont de taille égale, i.e. que L=M. La difficulté réside dans le fait que si le système *peut* se réduire, il faut prévoir un algorithme pour le simplifier d'une façon ou d'une autre. Justement, cette suite N0419 est une fraction rationnelle de degré [2/4]. Elle est complètement décrite par cette fraction rationnelle. C'est donc que, ayant pris notre quinzaine de termes et ayant supposé que L=M=7, on aurait été conduit à réduire le système à un nombre d'inconnues et d'équations plus petit. Donc à moins d'être chanceux, i.e. de prévoir exactement à l'avance le degré de la fraction rationnelle, on n'est pas assuré de trouver la *juste* fraction rationnelle.

La deuxième difficulté vient de la taille des calculs. Si la suite considérée EST une fraction rationnelle, comme la suite de Fibonacci (1.1), cela n'a rien de dramatique si on a fait un choix de L et M heureux. Si la suite N'EST PAS une fraction rationnelle, c'est là que les calculs deviennent énormes. Selon l'équation (1.2), il est quand même possible de trouver une fraction rationnelle qui se juxtaposera aux k premiers termes de toute suite, mais elle ne se simplifiera pas.

Exemple 1.2 La suite des nombres premiers : 2,3,5,7,11,13,....

Nous prendrons ici la suite des nombres premiers N0241. On le sait, il n'existe pas de fonction rationnelle qui permette de les obtenir successivement. Si on prend les 20 premiers termes , de 2 à 71 et que l'on cherche une expression rationnelle qui se juxtapose à cette suite, l'expression que l'on trouvera sera une fraction rationnelle d'une taille appréciable. La taille, disons en nombre de caractères, dépassera largement celle de la suite. Il ne faut pas oublier que l'on cherche une solution rationnelle, donc exacte à l'ordre d'approximation de la série de départ; ce ne sont pas des calculs en "virgule flottante". Ainsi, avec les 48 premiers termes de la suite des nombres premiers on obtient une fraction rationnelle d'une taille de l'ordre de 10,000 caractères, chaque coefficient étant de l'ordre de 120 chiffres. La taille de la suite de départ avec ses 48 termes, pour sa part, ne dépasse pas 200 caractères.

Il existe une procédure en Maple qui permet de convertir une série (tronquée) en une fraction rationnelle. Elle porte le nom de "ratpoly" pour "rational polynomial". Cette procédure est une véritable perle de programmation (elle a plus de 500 lignes). Non seulement elle fait le calcul exactement à l'ordre d'approximation de la série, mais en plus elle le fait bien. On le sait, Maple est en mesure d'effectuer des calculs symboliquement et en principe avec une précision infinie. Le résultat en est que les deux difficultés rencontrées plus tôt sont complètement tranparentes à l'utilisateur.

Donc avec cet outil presque "magique" qu'est "ratpoly", il est possible assez facilement d'effectuer le calcul fastidieux de représentation d'une suite sous forme de série avec une fraction rationnelle. En fait, deux critères simples nous permettrons de détecter une *bonne* fraction rationnelle. Le premier est le degré de l'expression trouvée: si le degré total (L + M) retourné par le programme est plus petit que le nombre de termes, on est alors potentiellement en présence d'une bonne représentation. Le deuxième critère est la taille (en nombre de caractères) de l'expression: si la taille de l'expression est plus grande que la taille de la suite testée, on rejette alors l'expression rationnelle candidate. En combinant ces deux critères, il est possible de détecter avec une assez grande certitude une suite qui EST une fraction rationnelle simple.

En soumettant toute notre table de 4568 suites à cette simple procédure qu'est "ratpoly" , nous avons détecté 614 fractions rationnelles. De ce nombre, 580 nous semblent bonnes: elles sont

répertoriées dans la table en appendice. On peut consulter [BP] à ce sujet également.

1.2 La dérivée logarithmique et l'inverse fonctionnel.

Malgré le succès remporté (en nombre de fonctions génératrices trouvées) avec notre méthode des approximants de Padé, une partie du problème demeure. Si 580 suites sur 4568 sont des fractions rationnelles, quelle est alors la nature des quelque 4000 qui restent ? La réponse à cette question est inconnue. Ce que l'on sait, c' est que notre méthode permet de détecter la fraction rationnelle d'une suite comme celle de Fibonacci. Elle permet également de détecter des variantes de celle-ci. Il se trouve que la plupart des opérations simples et connues que l'on peut effectuer sur une suite sont en fait des *transformations rationnelles* . Une TR en plus court. Si S(z) est notre suite sous forme de série tronquée, une TR conservera le caractère rationnel de la fonction génératrice. Par exemple, la différence terme à terme de la suite est une TR puisqu'il suffit d'effectuer S(z)(1-z). La somme de deux termes successifs est également une TR : il suffit de faire S(z)(1+z). La suite des sommes partielles s'obtient en prenant S(z)/(1-z), etc. Il en est de même de l'inverse de ces transformations. Ce point est essentiel.

Donc les suites qui ont une fonction génératrice qui est une fraction rationnelle et toutes les variations usuelles de celles-ci sont détectées avec notre méthode.

L'idée fort simple est alors d'utiliser notre méthode et une transformation qui ne soit pas rationnelle dans les deux sens, dans le but de détecter d'autres types de fonctions génératrices. Par exemple, bien que la dérivée soit une transformation qui conserve le caractère rationnel d'une expression, il suffit de prendre une fraction rationnelle quelconque pour se rendre compte que l'intégrale n'est pas une fraction rationnelle en général. En effectuant une dérivation et en appliquant ensuite notre méthode de détection, on pourra obtenir des fonctions génératrices qui sont en fait des intégrales de fractions rationnelles. En poussant le même raisonnement plus loin, on pourrait effectuer d'autres transformations de ce type comme la dérivée du logarithme ou l'inverse fonctionnel. Si nous pouvons toujours retourner sur nos pas à chaque fois, cela nous donne une façon de détecter des expressions qui font partie d'une classe plus vaste que les fractions rationnelles. Avec la dérivée, il est facile de revenir en arrière: une fois le test effectué, si c'est rationnel, il suffit de faire l'intégrale de l'expression. La dérivée du logarithme est aussi "réversible": il suffit de faire l'exponentielle de l'intégrale de l'expression trouvée. L'inverse fonctionnel d'une série est également "réversible" à condition que la suite débute par 0,1,…:

en effet, l'inverse d'une série à coefficients entiers est aussi à coefficients entiers, si la série s'annule en zéro et son premier terme non nul est 1.

C'est l'expérience qui a orienté le choix des transformations judicieuses à effectuer. Le succès d'une transformation plutôt que d'une autre étant guidé simplement par le nombre de fonctions génératrices trouvées une fois la table complète traitée par le programme. Le rejet ou l'acceptation d'une expression est donné par les deux critères énoncés plus haut. Il y a aussi le fait que plus on tranforme une suite avec de telles opérations, plus précises et strictes sont les conditions imposées à la suite de départ. Par exemple, l'inverse fonctionnel de la dérivée du logarithme d'une suite sous forme de série tronquée doit se faire seulement si les coefficients sont restés entiers et débutent par 0,1, ... , une fois que la première transformation a été effectuée.

Notre choix s'est arrêté sur la dérivée, la dérivée logarithmique et l'inverse fonctionnel. Ce sont ces opérations qui ont remporté le plus de succès. Exactement 120 fonctions génératrices qui ne sont pas des fractions rationnelles ont été isolées de cette façon. En tout 700 fonctions génératrices (incluant les fractions rationnelles) ont été trouvées grâce à la procédure "ratpoly". Les résultats sont présentés en appendice.

CHAPITRE 2

LA MÉTHODE DES P-RÉCURRENCES

2.1 Les suites P-récurrentes.

L'hypothèse de travail que nous posons ici sur la suite a_n consiste à dire que chaque terme de celle-ci peut être calculé à partir des termes précédents. Dans [Sta80] on introduit ce genre de dépendance sur les autres termes en disant que la suite a_n est une suite P-récurrente, si elle satisfait l'équation suivante

(2.1) $$a_n P_0(n) = a_{n-1} P_1(n) + a_{n-2} P_2(n) + \ldots, + a_{n-k} P_k(n)$$

où les $P_i(n)$, $0 \leq i \leq k$, sont des polynômes à coefficients rationnels. Ce type de relation est une classe plus vaste que les relations de récurrences linéaires ordinaires à coefficients constants rencontrées au chapitre précédent. En effet, il y a équivalence entre les fonctions génératrices rationnelles et les relations de récurrence à coefficients constants. Il n'y a cependant pas d'équivalent en termes de fonctions génératrices pour les P-récurrences en général. A l'heure actuelle, il n'existe pas de méthode pour trouver la fonction génératrice correspondant à une P-récurrence quelconque; seuls certains types de P-récurrences peuvent être résolus. Ce qui peut être fait, par contre, est de vérifier si la suite satisfait *numériquement* une P-récurrence. On ne peut donner qu'une P-récurrence *vraisemblable*.

Il faut donc procéder pas-à-pas en augmentant le degré et le nombre de termes. Nous posons d'abord les équations et, en supposant que la suite satisfasse l'équation (2.1) où les $P_i(n)$ sont des polynômes de degré d, il y aura (d+1)(k+1) équations (il faut tenir compte du terme de rang 0). On dira alors qu'elle satisfait une P-récurrence de type (d,k). On remarque que le système admet toujours une solution nulle. S'il y a solution, il y en aura une infinité, ce qui découle du fait que le système d'équations est non-homogène. Ceci est évident, puisque l'on peut multiplier par une constante C arbitraire de chaque côté sans changer l'équation. On prendra donc soin de garder la solution la plus simple. La

résolution d'un système d'équations linéaires est une chose que les programmes de calcul symbolique comme Maple font couramment. Un programme a donc été écrit pour permettre de résoudre le système à (d+1)(k+1) inconnues. Le voici, en entrée il accepte une suite et en sortie il donne soit 0 soit une ou plusieurs constantes, quand le nombre de constantes est 1 on pose la solution comme étant la plus simple en substituant la constante à 1.

```
1) read suite : listesuite:=":
2) nbrdetermes:=nops(listesuite):
3)    rec:=proc(w,n,t) local ff,c,d,i,j,k,ii;
4)    option remember;
5)    termes:=(n+1)*(t+1);
6)    if termes>=nbrdetermes then RETURN ( `impossible de resoudre` ) fi;
7)    for ii from 1 to nbrdetermes do a(ii):=op(ii,w) od:
8)          ens:={seq(c[jj],jj=1..termes)}:
9)    s:={seq(sum(sum(k**d*c[j*n+jn+d],d=0..n)*a(kj+1),j=1..t+1),
          k=t+1..termes+t)}:
10)   solution:=[solve(s,ens)];
11)         if sol=[] then RETURN (0) else
            RETURN(assign(solution),[seq(c[kk],kk=1..termes)])
            fi;
      end:
```

Donnons une courte description du programme.

1) On lit la suite provenant d'un fichier.

2) On pose que la variable nbrdetermes est égal au nombre d'éléments de la liste qui contient la suite.

3) Appel de la procédure et on pose les variables locales.

4) On prend l'option "remember" , très importante.

5) On prend un nombre de termes suffisant pour résoudre le système d'équations linéaires.

6) Si le nombre de termes nécessaires est trop grand, un message d'erreur est imprimé.

7) On pose les constantes dans notre système d'équations. Ici ce sont les termes de la suite.

8) On pose les inconnues de notre système sous forme d'ensemble.

9) On pose les équations linéaires.

10) On tente de résoudre.

11) Si le système admet une solution nulle (liste vide ici) on retourne 0. Sinon on assigne les solutions trouvées.

Donc en entrée le programme accepte une suite numérique et teste si celle-ci satisfait une équation P-récurrente de degré d à k termes.

Le programme qui détermine si une suite satisfait une P-récurrence est une des méthodes les plus rapides et de plus, une fois la P-récurrence candidate trouvée, il est très facile d'obtenir des centaines de termes de la suite. En principe si on veut calculer les termes d'une suite une fois obtenue une P-récurrence, il suffit de la mettre telle quelle dans un programme. Il n'est cependant pas approprié d'utiliser une procédure qui soit purement récursive même si c'est d'abord ce qui vient à l'esprit. Il faut linéariser le temps de calcul d'une procédure qui s'appelle elle-même, sinon celui-ci devient vite exponentiel. L'exemple souvent donné dans les cours de programmation de base est la suite des nombres factoriels, 1,1,2,6,24,120,720,..., définie par $a_0 = 1$ et $a_n = n\, a_{n-1}$. Ce problème est facilement résoluble en Maple, puisque les procédures récursives peuvent être *linéarisées* simplement en écrivant "option remember" dans l'appel de la procédure. Maple se charge alors de ré-écrire la procédure en créant une table d'adressage (interne) automatiquement.

Comme avec les autres méthodes, nous avons utilisé la table de [PlSl] au complet. A chaque suite, le test a été effectué sur les degrés 1 à 4 et sur un nombre de termes variant de 1 à 5, compte tenu que l'expérience indique que la plupart des suites P-récurrentes ont un degré assez bas. Stanley [Sta80] donne un exemple de suite P-récurrente de degré 3 à 2 termes qui donne les nombres d'une suite de Apéry utilisée dans la preuve de l'irrationalité de $\zeta(3)$.

Exemple 2.1 : $n^3\, a_{(n)} + (n-1)^3\, a_{(n-2)} = (34\, n^3 - 51\, n^2 + 27\, n - 5)\, a_{(n-1)}$,

En tout, 250 des 1031 suites que contient la table en appendice, seraient P-récurrentes. De ces 250, 220 ont une fonction génératrice associée trouvée par d'autre méthodes. Il en reste donc 30 dont on ne connait que la P-récurrence. Sont comptées ici les suites P-récurrentes de degré 1 ou plus; les fractions rationnelles, au nombre de 580, sont aussi P-récurrentes mais de degré 0. C'est de loin la méthode la plus puissante, puisque au total, près de 81 % des suites qui ont une fonction génératrice connue sont P-récurrentes à des degrés divers, ce qui représente 18 % de tout le catalogue des suites de [PlSl].

2.2 Les suites hypergéométriques.

Dans [GKP] on fait une remarque très simple au sujet des P-récurrences d'un certain type. Si une suite t_k satisfait une P-récurrence de type (d,1), c'est donc que le quotient des termes successifs t_{k+1}/t_k = P(k)/Q(k), où P(k) et Q(k) sont deux polynômes. La fonction hypergéométrique est à peu de chose près la même chose. En effet, la définition de celle-ci étant

$$F\left(\begin{matrix}a_1, a_2, \ldots a_m \\ b_1, b_2, \ldots, b_n\end{matrix}\middle| z\right) = \sum_{k=0}^{\infty} \frac{a_1^{\overline{k}} \ldots a_m^{\overline{k}}}{b_1^{\overline{k}} \ldots b_n^{\overline{k}}} \frac{z^k}{k!} \qquad (2.2)$$

où le membre de gauche en est l'écriture avec les paramètres en a et en b et où le membre de droite en est le développement en série sous forme de somme de quotients de produits de polynômes factoriels ascendants. En spécifiant que les termes en b ne s'annulent nulle part, on évite la division par zéro; il suffit simplement pour cela qu'ils soient toujours positifs. Considérons le rapport de deux termes successifs et en posant que le premier terme t_0=1,

$$\frac{t_{k+1}}{t_k} = \frac{a_1^{\overline{k+1}} \ldots a_m^{\overline{k+1}}}{a_1^{\overline{k}} \ldots a_m^{\overline{k}}} \frac{b_1^{\overline{k}} \ldots b_n^{\overline{k}}}{b_1^{\overline{k+1}} \ldots b_n^{\overline{k+1}}} \frac{k!}{(k+1)!} \frac{z^{k+1}}{z^k}$$

il est alors facile de simplifier cette expression en revenant à la définition d'un polynôme factoriel ascendant de degré k+1 et de degré k. D'où l'expression:

$$\frac{t_{k+1}}{t_k} = \frac{(k+a_1)\ldots(k+a_m)z}{(k+b_1)\ldots(k+b_m)(k+1)} \quad .$$

On obtient alors une fraction rationnelle en k seulement. Donc si on a une suite qui débute avec 1 et dont le rapport des termes successifs est une fraction rationnelle (une P-récurrence de type (d,1)), elle pourra être "lue" directement comme étant une série hypergéométrique. L'avantage énorme de la représentation d'une suite comme "hypergéométrique" est que le programme de calcul symbolique Maple est en mesure de manipuler et de simplifier de telles séries. Dans sa version 5, Maple utilise les tables d'identités hypergéométriques qui se trouvent dans [AS1]. Ce livre étant une véritable bible de formules mathématiques, nous avons à notre disposition un outil excessivement puissant. En fait, dès que l'on sait qu'une suite satisfait une P-récurrence de type (d,1) nous disposons déjà d'une information très précieuse.

Cette représentation en série hypergéométrique ouvre la porte à d'autres formes de fonctions génératrices. Le programme Maple est en effet capable, dans certains cas, de donner directement la

fonction génératrice explicite sous forme simplifiée. Il suffit de faire appel à la procédure “simplify” qui réussit à reconnaître les expressions contenant des termes hypergéométriques. C’est alors que les tables d’identités de [AS1] sont appelées et, si la forme le permet, Maple retourne directement une expression algébrique explicite.

Conformément aux autres méthodes nous avons donc, encore une fois, testé toute la table de [PlSl] en recherchant des P-récurrences de type (d,1). Plus de 94 suites satisfont à ce type de récurrence. Dans certains cas, la forme hypergéométrique a été directement simplifiée automatiquement par le programme Maple. Les résultats sont présentés dans la table de fonctions génératrices en appendice.

2.3 L’algorithme LLL[2] .

Nous décrirons ici la méthode qui est la plus complexe et puissante de toute cette étude. On s’intéresse aux suites qui sont P-récurrentes de type (d,k) en général. Cette méthode ne s’applique que si on peut avoir autant de termes de la suite que l’on veut. Comme nous l’avons vu à la section précédente, Maple est en mesure, dans les cas où la P-récurrence est de type (d,1), de donner une forme hypergéométrique et une fois obtenu cette forme, de produire directement la fonction génératrice algébrique lorsqu’elle s’y prête. C’est donc que : les P-récurrences de type (d,1) sont quelquefois algébriques. Il en est de même pour les P-récurrences de d’ordre plus élevé. Ce qui nous manque est la façon d’obtenir la forme close. On ne dispose malheureusement pas de moyen de savoir quel type de P-récurrence représente une suite qui a une fonction génératrice algébrique. D’après Stanley [Sta80], une fonction génératrice algébrique est toujours P-récurrente. Ici c’est l’inverse qu’on cherche, malheureusement ce n’est pas toujours vrai : la fonction exp(x) est P-récurrente mais certainement pas algébrique.

Une suite a une fonction génératrice algébrique si elle satisfait à

$$\sum_{0 \le j,\, k \le m} c_{j,k} S(z)^j z^k = 0 \tag{2.3}$$

[2] **Nommé ainsi à cause des travaux de Lenstra, Lenstra et Lovasz.**

où S(z) est la série qui représente la suite a_n et les $c_{j,k}$ sont constantes. On pourra alors obtenir la fonction génératrice close si on peut isoler S(z). Le problème est double ici: il faut d'abord obtenir l'équation (2.3) et de plus on n'est pas assuré de pouvoir isoler S(z). Ce qui vient à l'esprit est d'essayer de trouver "à tâtons" une équation en S(z) et z qui s'annulera. Il est possible effectivement de faire un programme qui fonctionnerait sur le même principe que les P-récurrences. Mais malheureusement la forme qu'on obtiendra ne sera pas, en général, la plus simple. Par exemple, la suite N0577, les nombres de Catalan, satisfait à une telle équation. Elle est de degré 2 : $S(z)^2z - S(z) + 1 = 0$. Si on résout cette équation par rapport à S(z), on obtient une fonction génératrice close des nombres de Catalan. On s'aperçoit alors qu'il il y a une infinité de telles équations que l'on peut poser. On pourrait peut-être en obtenir une plus simple.

Il existe un algorithme implanté en Maple qui porte le nom de "minpoly". Il fait appel à l'algorithme LLL. Disons simplement qu'il permet de résoudre numériquement le problème exactement inverse de trouver une racine d'un polynôme. La recherche numérique des racines d'un polynôme est un problème résolu. Mais nous posons la question suivante: étant donné un nombre réel, de quel polynôme minimal est-il racine ? Mentionnons dès maintenant qu'on parle ici d'un nombre réel donné avec une certaine précision numérique. On ne pourra (une fois l'opération réussie) qu'isoler un polynôme qui *semble* avoir ce nombre réel comme racine. Il serait un peu long de donner tous les détails qui font qu'aujourd'hui ce problème est pour ainsi dire *numériquement résolu.* Mentionnons cependant qu'au moins trois programmes de calcul symbolique ont implanté cet algorithme: soit Maple, Mathematica et Pari-GP. Pour la description de cet algorithme, on pourra consulter [BaKa] ou l'article original de [LLL]. La meilleure version de cet algorithme et de loin la plus rapide est celle qui existe sur Pari-GP [Pari]; elle est au moins 800 fois plus rapide que la version équivalente sur Maple. Quant à Mathematica, disons qu'il est, de façon générale, 4 fois plus lent que Maple dans tous les calculs. Nous ne l'avons pas considéré ici.

Cette procédure accepte donc en entrée un nombre décimal et donne (selon la précision numérique en vigueur) le polynôme minimal dont il serait racine. La précision numérique en vigueur est celle que l'utilisateur demande. Elle devrait idéalement être infinie. Plus raisonnablement, la limite est d'environ 100 chiffres décimaux sur les machines à notre disposition avec Maple et d'environ 500 chiffres décimaux avec Pari-GP. Le degré maximal du polynôme que l'on puisse demander dépend largement de

la précision. Dans la pratique, la limite est un polynôme de degré 20. Ceci est quand même suffisant pour obtenir des résultats intéressants.

Evidemment, si la fonction génératrice close qui représente S(z) est algébrique et si z=1/m est un nombre rationnel, le résultat, S(1/m) sera alors un nombre algébrique. C'est précisément ici que l'on utilise l'algorithme LLL. Les centaines de termes que nous donnent la P-récurrence serviront pour évaluer S(z) en un point 1/m "très petit", de telle sorte que le résultat soit un nombre algébrique approché à une grande précision numérique. On ira ensuite chercher avec celui-ci le polynôme dont S(1/m) est racine. Une fois le polynôme candidat trouvé, on réévalue la série S(z) en un autre point rationnel ,1/(m+1), et on répète l'appel à l'algorithme. Il se trouve que la version de LLL sur le programme Pari-GP est extrêmement efficace. Non seulement la procédure (qui s'appelle "algdep") retourne en général le bon polynôme, mais de surcroît il est simplifié au maximum. De plus, les solutions trouvées sont *stables*; elles sont stables au point qu'elles permettent de reconstruire la fonction génératrice algébrique. Une fois ces solutions trouvées en fait, la reconstruction de la fonction génératrice se résume à un calcul d'interpolation assez simple. Comme on l'a mentionné plus tôt, l'appel de la procédure demande un nombre décimal et un degré. Pour arrêter notre choix sur le bon polynôme, il nous suffit de rejeter ceux dont la taille est trop grande (en nombre de caractères). Nous utilisons le même critère que notre méthode des approximants de Padé.

La procédure est la suivante, avec en entrée une suite de la table:

1) On teste si la suite est P-récurrente. Si oui on passe à l'étape 2), sinon on arrête.
2) On calcule plusieurs centaines de termes de la récurrence (dans la pratique 200 termes suffisent).
3) On construit une série S(z) avec ces 200 termes.
4) On évalue la série S(z) en des points rationnels 1/m, 1/(m+1),1/(m+2),... . En pratique m=100 et le nombre de termes = 12.
5) On appelle la procédure "algdep" de Pari-GP avec les 12 valeurs trouvées.
6) On teste avec des polynômes de degré 2,3,4,..., (dans la pratique les degrés 2 à 8 sont suffisants).
7) On récupère les bons polynômes, on pose la variable comme étant x.
8) On identifie les coefficients de même degré et on calcule le polynôme d'interpolation en t avec la méthode de Newton.
9) On substitue t=1/z dans l'expression trouvée.
10) On résout (si le degré de l'expression le permet).

Cet algorithme, quoique très technique, fonctionne très rapidement. Il nous a permis de trouver 32 fonctions génératrices algébriques de degré et de complexité assez élevés.

Illustrons cet algorithme en donnant un exemple.

Exemple 2.3 La suite N0768 des cartes planaires.

Cette suite porte le nom de “Rooted Maps” dans [Sl] mais le titre a été modifié dans [PlSl]. Avec l’étape 1) de notre algorithme, on trouve que la suite satisfait la P-récurrence :

$$(n + 1)\, a_n = (12\, n - 18)\, a_{n-1}.$$

C’est une P-récurrence candidate pour notre méthode hypergéométrique plutôt que pour l’algorithme LLL. On procède donc avec celle-ci et il s’avère que c’est une hypergéométrique:

$$ {}_2F_1([1, 1/2], [3], 12\, z).$$

En demandant à Maple de la simplifier avec “simplify”, celui-ci retourne effectivement une expression algébrique.

Mais cette expression n’est pas très élégante:

```
                                    1/2                1/2
        (1 - 12 z + 24 z I (12 z - 1)    - I (12 z - 1)   ) I
   - 1/9 ------------------------------------------------------
                                  1/2             1/2
                 z (1 + I (12 z - 1)   ) (12 z - 1)
```

On voudrait avoir une expression sans valeurs complexes et simplifiée que l’on obtiendrait de façon automatique. On peut toujours la manipuler à la main, mais notre but est d’obtenir une forme close *automatiquement.* On essaye donc avec une autre méthode: la dérivée et les approximants de Padé.
En dérivant S(z) on obtient une expression qui, mise sous forme d’approximant de Padé, nous donne : (une fois factorisée).

```
                  4        3        2                 2
          (81 z  - 648 z  + 234 z  - 27 z + 1) (9 z  - 9 z + 1)
   - 2 ------------------------------------------------------------
                     3       2                  3       2
      (9 z - 1) (27 z  - 81 z  + 18 z - 1) (81 z  - 81 z  + 18 z - 1)
```

Si on intègre par rapport à z, on devrait retrouver l’expression, mais il y a des polynômes qui sont du 4è degré et la solution n’est pas élégante non plus.

On s'en remet donc à notre méthode LLL.

(étape 1) On reprend la P-récurrence et on recalcule la suite mais avec 200 termes.

(étape 2 et 3). On réévalue la série avec ces mêmes 200 termes et nos points d'interpolation 1/(m+i) avec i=0..4 (5 points d'interpolation devraient suffire)

(étape 4). La première valeur, en m=100, nous donne le premier nombre réel à tester, soit :

1.020958097948815111768685182190012108060775963049210932333987559073395437883368700157841649413257744890532928226947206 8...

(étape 5 et 6) En appelant la procédure "algdep" avec ce nombre réel bon à 118 décimales et un polynôme de degré 2, on obtient, pour les valeurs 1/m, 1/(m+1),1/(m+2),1/(m+3),1/(m+4)

(étape 7) On récupère les bons polynômes:

$$27x^2 + 8200x - 8400$$

$$27x^2 + 8383x - 8585$$

$$27x^2 + 8568x - 8772$$

$$27x^2 + 8755x - 8961$$

$$27x^2 + 8944x - 9152$$

(étape 8) Il nous reste à identifier les coefficients de même degré et à calculer les polynômes d'interpolation correspondants. On aura: pour le coefficient de x^2, les valeurs 27,27,27, ... ,. pour le coefficient de x, les valeurs 8200, 8383, 8568, 8755 et 8944, aux points d'interpolation 100,101,102,103 et 104. Enfin, pour le coefficient constant, on aura les valeurs -8400, -8585, -8772, -8961 et -9152 aux mêmes points d'interpolation. On applique alors simplement la formule d'interpolation de Newton pour trouver une expression polynômiale pour chaque degré. On peut faire appel à la procédure de la librairie Maple appelée "interp" qui effectue ce calcul automatiquement. Ce qui nous donnera deux variables, x et t.

(étape 9) Il restera à substituer t=1/z. On obtient finalement:

$$\frac{-1 + 16z + x^2 - 18xz + 27x^2z^2}{z^2}$$

(étape 10) Il ne reste qu'à résoudre cette équation par rapport à x: on prendra alors la solution positive. Finalement l'expression algébrique de notre suite de départ serait :

$$\frac{1}{54}\,\frac{-1+18z+\left(-(12z-1)^2\right)^{3/2}}{z^2}$$

C'est l'expression la plus simple qu'on ait obtenu pour cette suite. La magie de cet algorithme LLL est qu'il trouve une expression polynômiale pour un nombre réel qui est en général minimale. Des expressions de plus haut degré encore ont été obtenues de cette façon, la plus grosse étant de degré 8 et elles sont répertoriées dans notre table en appendice.

CHAPITRE 3

LA MÉTHODE D'EULER

Ainsi nommée parce qu'elle semble avoir été développée à l'époque d'Euler. Nous n'avons pas trouvé de références historiques sur cette méthode, bien que Andrews [And] la mentionne.

L'idée en est simple: étant donné une suite a_n dont on suppose la série génératrice de la forme,

$$S(z) = 1 + \sum_{n=1}^{\infty} a_n z^n = \prod_{n=1}^{\infty} (1 - z^n)^{-c_n}, \tag{3.1}$$

la question est : comment trouver les c_n en fonction des a_n. Comme l'explique Andrews à la page 104, il suffit d'utiliser la formule d'inversion de Möbius. En effet, puisque le membre de droite de (3.1) est un produit infini, c'est en prenant le logarithme ou la dérivée logarithmique que nous retrouvons alors une somme ordinaire. En identifiant le coefficient de degré n (pour exprimer chaque coefficient de a_n) et en inversant (par Möbius) par rapport à la somme, nous obtenons les coefficients c_n en fonction des a_n. La somme s'exprimera en termes des diviseurs de n. Inversement, si nous connaissons les c_n et que l'on cherche les a_n , l'opération est directe; il suffit de développer le produit en série. En prenant soin de garder le même ordre de grandeur des séries correspondantes, nous obtenons le même nombre de termes pour les c_n que pour les a_n. Autrement dit, si les k premiers coefficients de a_n sont connus, il y aura alors k coefficients de bons pour les c_n.

On peut donc programmer la transformation dans les deux sens en une vingtaine de lignes. La procédure accepte en entrée une suite et donne du même coup une représentation en "partages", c'est-à-dire qu'elle propose un produit infini. Par exemple, la suite N0244 énumère les partages

ordinaires de l'entier n. En effectuant le calcul on trouve la suite 1,1,1,1,1,.... C'est la forme de produit infini de ce type la plus simple. Mais pour détecter un bon candidat de produit infini avec ce type de fonction génératrice, dans un cadre plus général, nous avons utilisé la méthode des approximants de Padé qui permet de détecter les "motifs" dans les exposants. En tout, 94 produits infinis ont ainsi été isolés grâce à cette méthode. Les résultats sont présentés dans la table en appendice.

CHAPITRE 4

LA MÉTHODE DES RECOUPEMENTS

4.1 Les recoupements indirects.

L'hypothèse que l'on pose ici est que la suite dont on cherche la fonction génératrice est en fait une suite connue mais transformée. Par exemple, la suite des partages d'entiers N0244 de [Sl] est très facile à détecter. Il suffit de prendre la méthode d'Euler et le programme nous propose immédiatement un produit infini très simple. Mais si on effectue la translation a_n+3, le programme ne détectera pas ce produit infini. Pour une bonne raison car, si la suite ne commence pas naturellement à 1, alors l'opération d'Euler n'est pas valide et même si on l'effectue, les termes seront des nombres rationnels (non entiers). Donc afin de pouvoir isoler le plus possible de suites, on se sert, comme base de comparaison, de la table des suites qui en contient 4568. En prenant chaque suite transformée de façon élémentaire, on compare avec la table afin de voir s'il n'y aurait pas un croisement. En tout, nous avons répertorié 97 transformations élémentaires d'une suite susceptibles de se retrouver dans la table, soit 54 transformations avec la suite sous forme de série ordinaire et 43 avec la suite sous forme de série exponentielle.

Il serait fastidieux de les énumérer toutes, mais en voici quelques unes. Avec S(z) : la suite sous forme de série ordinaire par exemple, nous avons $S(z) + cz/(1-z)$ ou $c=\pm1,\pm2,\pm3$, $1/S(z)$, $S(z)^2$, $S(z)^3$, $S(z)/(1-z)$ ce qui équivaut à considérer la suite des sommes partielles de la suite. D'autres transformations sont plus simples encore, comme $\mathbf{N} \setminus \{a_n\}$, la différence ensembliste des entiers et de la suite. On ne tient pas compte ici de la multiplicité des termes. On a considéré aussi de prendre $a_n/\text{pgcd}\ (a_0, a_1, a_2,\ldots a_k)$ ou de prendre la suite avec les indices de rang pairs et impairs. L'idée est de prendre des transformations les plus simples possibles. La transformation d'Euler dans les 2 sens complète la liste.

On pourrait les classer en ces quelques catégories :

1) Translations : S(z) +/- cz/(1-z), avec c=1,2,3.

2) Inverses : $1/S(z), 1/S(z)^2, 1/S(z)^3$.

3) Puissances : $S(z)^k$ avec k=1,2,3.

4) Sommes et différences.

5) Transformation de type Euler (voir chapitre 3).

6) Transformations de type ensembliste comme $\mathbf{N} \setminus \{a_n\}$.

7) Transformations avec le p.g.c.d. .

Les autres sont données en considérant des combinaisons de ces dernières.

Par exemple, de la suite N0577 de [Sl] (les nombres de Catalan), on en obtient 97 autres et en comparant ces 97 suites avec la table, 6 autres suites au moins seraient liées à cette dernière. C'est donc que, si on connait déjà la fonction génératrice des nombres de Catalan obtenue avec d'autres méthodes, alors du même coup on obtient la fonction génératrice de ces 6 autres suites. C'est un avantage, parce que justement avec cet exemple, si l'on prend a_n-1 et que l'on compare avec la table, on retrouve la suite N1409 de [Sl]. Cette suite n'est pas hypergéométrique en vertu d'un critère assez simple de [GKP], elle ne commence pas par 1. De plus son inverse fonctionnel est impossible à effectuer pour le même genre de raisons; le premier terme est nul mais le deuxième terme n'est pas 1. Elle est cependant algébrique et c'est avec la méthode LLL (beaucoup plus lourde) que la fonction génératrice a été trouvée. En fait, elle est évidemment de la forme S(z) -1/(1-z) où S(z) est la fonction génératrice des nombres de Catalan. Mais ceci constitue un raisonnement a posteriori. Donc cette méthode des recoupements peut mener à des résultats très intéressants en autant que le traitement informatique des 97 transformations appliquées aux 4568 suites et comparées avec ces dernières à chaque fois ne soit pas trop lourd également.

Un détail ne doit cependant pas être oublié. La comparaison de 2 suites entre elles peut mener à des erreurs. On doit faire la comparaison à partir du deuxième terme, parce que souvent la suite est répertoriée mais les premiers termes peuvent être d'indices 0 ou 1. C'est-à-dire que la suite ne débute pas au terme de rang 0. Également on ne doit pas prendre toute la suite: il ne faut pas oublier que certaines suites de la table sont très courtes et ne contiennent que quelques termes. Elles ne sont pas moins importantes, par exemple la suite N0323 de [Sl]. Il y a un juste milieu et l'expérience montre que les

indices de rang 2 à 16 sont suffisants, c'est-à-dire les 15 premiers termes de la suite à partir du rang 2.

A cet effet un programme appelé HIS (Handbook of Integer Sequences) a été mis au point. Il n'est cependant pas public comme le programme gfun. Dans HIS se trouve la table numérique des suites et 2 procédures appelées "find" et "findhard". La première sert simplement à savoir si une suite se trouve dans la table et la deuxième fait une recherche dans la table après avoir effectué les 97 transformations en question. Le programme et la table sont entièrement contenus en Maple. Le programme est donc de cette façon transportable sur toute machine qui peut recevoir Maple.

La procédure "find" qui en principe ne fait que regarder si une suite se trouve dans la table emploie une procédure de recherche mise au point par Bruno Salvy de l'INRIA. Il était essentiel d'avoir à notre disposition un algorithme de recherche qui soit très rapide étant donné le nombre important de comparaisons à chaque opération. Une structure de données adaptée à ces besoins a été construite sous forme d'arbre binaire. En effectuant une boucle de calcul sur toute la table avec la procédure "findhard", une banque de données des croisements a été obtenue. En tout il y aurait 3800 croisements. Une proportion appréciable des ces croisements, soit environ 25% selon nous, est fortuite ou accidentelle. Ceci est relié à la décision de ne prendre qu'une partie de chaque suite pour comparer. Donc pour pouvoir retrouver la fonction génératrice, il y a un travail de vérification nécessaire.

Ce travail de vérification est très long, mais il en vaut la peine. Evidemment, beaucoup de croisements ne sont pas surprenants: à titre d'exemple, la suite de Fibonacci, qui est très connue et qui a une fonction génératrice assez simple croise avec une bonne centaine de suites. Aucun de ces croisements n'est vraiment nouveau. C'est lorsque la suite est intrinsèquement plus complexe que le jeu en vaut la chandelle. Sans exagérer, nous avons effectué patiemment des centaines d'heures de calcul et de vérification pour trouver ces résultats et il y en a beaucoup à faire encore, puisque cette table des 3000 bons croisements environ n'a pas été passée en revue au complet. Par ce procédé, 38 fonctions génératrices ont été obtenues. Elles sont répertoriées dans la table en appendice.

4.2 Les tableaux.

Le programme Maple manipule des données numériquement aussi bien que symboliquement. La procédure “ratpoly” est capable de trouver une fraction rationnelle de séries à une variable aussi bien qu’à 2 variables comme les tableaux à 2 dimensions. Un bon exemple est le triangle de Pascal. Il suffit de le mettre sous forme de tableau “carré” où chaque rangée sera un polynôme. En prenant les 5 premières rangées, on aura la suite

$$1,\ 1 + t,\ 1 + 2\,t + t^2,\ 1 + 3\,t + 3\,t^2 + t^3,\ 1 + 4\,t + 6\,t^2 + 4\,t^3 + t^4\ .$$

Si cette suite (de polynômes) est maintenant convertie en série de puissances en z et passée à la procédure “ratpoly”, elle retourne immédiatement

$1/(1 - t\,z - z)$. Si on développe en série par rapport à t, on obtient la fonction génératrice de chaque colonne et inversement, en développant par rapport à z, on obtient la fonction génératrice de chaque rangée (qui sont ici des polynômes). Notons que 4 termes suffisent pour trouver la fonction génératrice du tableau.

Contrairement aux autres méthodes, il n’existe pas de livre ou de catalogue de tels tableaux. Il y en a un bon nombre dans la littérature, mais ce qui a été fait plutôt est d’en générer de façon *ad hoc* . Il faut prendre un modèle de tableaux assez général, par exemple dans [GKP] ou [Théo], où on introduit les tableaux $A_{[n,k]}$ définis par la relation de récurrence

$$A_{[n+1,k+1]} = (r\,n+s\,k+t)\,A_{[n,k+1]} + (a\,n+b\,k+c)\,A_{[n,k]}$$

où a,b,c,r,s et t sont entiers. Il se trouve qu’une bonne partie des tableaux étudiés en combinatoire sont de ce type: les coefficients binomiaux, les nombres de Stirling de 1ère et de 2ème espèce, les nombres eulériens, les coefficients des polynômes de Tchébycheff, etc. On peut consulter [Théo] à ce sujet où une étude approfondie de ces tableaux a été menée. Il reste donc à en générer un bon nombre en prenant les entiers a,b,c,r,s et t compris entre -4 et 4 et de *tenter* de trouver la fonction génératrice. Sur des milliers tableaux générés de cette façon, 430 fonctions génératrices à deux variables ont été trouvées, couvrant la plupart des cas simples de ces tableaux. On obtient ainsi un échantillonnage assez important de formules, suffisamment important pour y trouver la fonction génératrice de centaines de suites de notre table. En tout, 20 nouvelles fonctions génératrices ont été isolées. Ces résultats sont

présentés dans la table en appendice.

CONCLUSION

On conclut que nos méthodes peuvent dans 23 % des cas donner la fonction génératrice d'une suite d'entiers "quelconque". Le mot quelconque signifie ici: ce qui est catalogué dans la table de suites [PlSl]. Nous croyons qu'il en est de même avec toute suite d'entiers qui se présente au mathématicien dans ses recherches, quel que soit son domaine. Nous souhaitons que ces méthodes deviennent des outils de travail.

Il reste cependant beaucoup à faire. Il faut trouver une explication raisonnable au fait que nous sommes passés à côté de 77% des suites. On pourrait peut-être étendre encore les méthodes en formulant d'autres modèles de fonctions génératrices. En fait, il en existe déjà. Par exemple, la fonction "plancher" ou partie entière permet de construire des suites très simples que nos méthodes n'ont pas détectées; la suite $[(3/2)^n]$ en est un bon représentant. On pourrait également mettre dans la même catégorie les suites définies avec des nombres irrationnels comme $[\sqrt{2}n]$. Un autre modèle pourrait être basé sur les récurrences quadratiques comme la suite 2,4,16,256,... (en mettant au carré à chaque fois). Elle est extrèmement simple mais indétectable par nos méthodes. Un autre serait basé sur les suites "doublement" récurrentes, là où il y a une fonction de l'indice comme $a_{a(n)}$. On pourrait multiplier les exemples de suites très simplement définies mais indétectables. Ce qui caractérise une table de suites comme [Sl] ou [PlSl], c'est la variété et c'est précisément ce qui nous passionne.

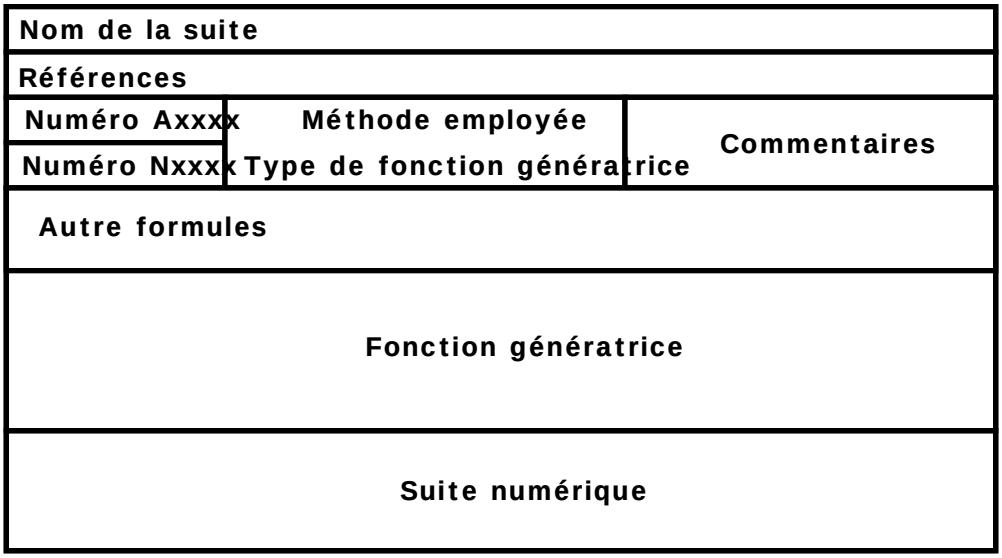
A.0 NOTES À L'UTILISATEUR DE LA TABLE

Chaque fonction génératrice trouvée à l'aide de l'une de nos méthodes est répertoriée dans la table qui suit sous forme de fiche. Chaque fiche contient les informations pertinentes à cette suite :

- Numéro séquentiel Axxxx et Nxxxx (s'il existe)
- Nom de la suite
- Les références bibliographiques avec dans l'ordre : Périodique Volume Page Année
- La méthode employée pour trouver la fonction génératrice
- Le type de fonction génératrice
- Commentaires additionnels
- Autres formules connues ou trouvées
- La fonction génératrice
- La suite numérique

Elles apparaissent selon le schéma suivant:



- Les références bibliographiques sont notées exactement comme dans le livre [Sl]. La liste des ouvrages se trouve dans une bibliographie séparée à la fin de la table.
- La fonction génératrice qui apparaît au centre est toujours une fonction génératrice ordinaire à moins qu'il en soit indiqué autrement (exponentielle ou double exponentielle).
- Les fiches ont été triées par ordre numérique sur les numéros Axxxx. Cette table est une pile Hypercard. On peut donc l'utiliser sur tout ordinateur Macintosh et la consulter comme une banque de donnée. Nous prévoyons un accès à Maple. De cette façon l'utilisateur pourra vérifier chaque formule.
- W(z) désigne la fonction Oméga, définie implicitement par W(z) exp(W(z)) = z. On la connait aussi sous

sa forme de série exponentielle dont les coefficients sont donnés, en valeur absolue, $|a_0| = 0$, $|a_n| = n^{n-1}$ pour $n>0$ (série alternante à terme constant nul). Son rayon de convergence est 1/e et elle est souvent utilisée pour le développement en série de certaines fonctions génératrices de structures arborescentes. Elle est très commode dans les calculs.

• La fonction génératrice qui apparaît au centre de chaque fiche est la plus simple ou plus élégante expression que nous connaissons donnant les termes de la suite.

• Le nom de chaque suite (s'il est présent) est tel qu'il apparaît dans [PlSl]. Quand il est omis c'est qu'il est d'une forme que nous jugeons redondante par rapport à la fonction génératrice.

• Les P-récurrences qui apparaissent dans la case "fonction génératrice" ou "autres formules" ont leur conditions initiales données par les premiers termes de la suite.

• La suite qui apparaît dans la case "suite numérique" est telle qu'elle apparaît dans [PlSl], plus de termes peuvent être évidemment obtenus avec la fonction génératrice.

• Certaines fiches ont été imprimées en format pleine grandeur pour plus de lisibilité

1031 Generating Functions

par
Simon Plouffe
August 1992
found using GFUN and other tools with a sample of the Encyclopedia of Integer Sequences (as of 1992)
with 4568 sequences.

Résumé

Nous décrivons ici une méthode expérimentale permettant de calculer de bons candidats pour une forme close de fonctions génératrices à partir des premiers termes d'une suite de nombres rationnels. La méthode est basée sur l'algorithme LLL[1] et utilise deux programmes de calcu symbolique, soit MapleV et Pari-GP. Quelques résultats sont présentés en appendice. Cette méthode a été testée sur toute la table de suites du livre , *The New book of Integer Sequences*, de N.J.A Sloane et S. Plouffe (en préparation). Ainsi, nous avons obtenu de cette façon la fonction génératrice,

$$\frac{z + (z+1)^{1/2} (1 - 3z)^{1/2} - 1}{2 (z^2 (z+1)^{1/2} (1 - 3z)^{1/2})}$$

pour la suite: 1, 2, 6, 16, 45, 126, 357, 1016, 2907, 8350, 24068, 69576, 201643, 585690,... qui apparaît en page 78 du livre de Louis Comtet, *Adanced Combinatorics*.

[1] Nommé ainsi à cause des travaux de Lenstra, Lenstra et Lovasz.

INTRODUCTION

Les suites P-récurrentes

On dit qu'une suite a_n d'entiers ou de nombres rationnels est P-récurrente si on a une récurrence de la forme :

(1) $$a_n P_0(n) = a_{n-1} P_1(n) + a_{n-2} P_2(n) + ..., + a_{n-k} P_k(n),$$

où les $P_i(n)$, $0 \le i \le k$, sont des polynômes à coefficients rationnels. D'un autre point de vue, (1) équivaut à dire que la fonction génératrice

$$A(x) = \sum_{n \ge 0} a(n) x^n$$

satisfait à une équation différentielle linéaire à coefficients polynômiaux. Il n'est donc pas possible d'espérer pouvoir trouver systématiquement une forme close pour A(x). Si l'on connait N termes d'une suite a_n satisfaisant (1) avec $N > \sum(\deg(P_i)+1)$, on peut déterminer les $P_i(x)$ par une approche de coefficients indéterminés.

Le programme [gfun] de la librairie "share" de MapleV procède ainsi via la commande "*listtorec*" pour obtenir une équation de la forme (1) pour une suite dont les N premiers termes sont :$[a_0, a_1, a_2, ..., a_N]$. Par exemple, la suite #1173 de [Sl,Tutte], relative aux cartes planaires, est une suite P-récurrente et on obtient:

Exemple 1

```
> suite:=[1, 1, 0, 1, 3, 12, 52, 241, 1173, 5929, 30880, 164796, 897380,
4970296,   27930828,   158935761,   914325657,   5310702819,   31110146416,
183634501753, 1091371140915]:

> recsuite:=listtorec(suite):

                    3         /                 59   2         3\
{(1/4 + 7/8 n - 9/8 n ) a(n) + |- 5/4 + 2/3 n + ---- n  - 13/3 n | a(n+1)
                               \                 12              /
                         2       3
       + (- 1 - 2/3 n + n  + 2/3 n ) a(n+2), a(1) = 1, a(2) = 1}.
```

On peut automatiquement traduire cette P-récurrence en programme avec la commande "rectoproc",

```
> Sl1173:=rectoproc(recsuite,a(n));

Sl1173 := proc(n) options remember;
if not type(n,nonnegint) then ERROR(`invalid arguments`) fi;
1/8*(27*procname(-2+n)*n^2+104*procname(n-1)*n^2-81*
procname(-2+n)*n-430*procname(n-1)*n+60*
procname(2+n)+414*procname(n-1))/(2*n^2-3*n+1)
end;
```

Notons que la procédure fournie permet de calculer autant de termes que l'on veut en temps linéaire par rapport à n. Cela nous servira par la suite. On dit de la P-récurrence précédente qu'elle est est de type (2,3), c'est à dire de degré 2 et à 3 termes. Lorsque la P-récurrence obtenue est de type (d,2) ou d est le degré, le rapport de deux termes successifs est une fraction rationnelle. On peut obtenir une expression hypergéométrique pour le terme général de la suite a_n.

Dans un même ordre d'idée, on peut s'intéresser au cas où la fonction génératrice A(z) est algébrique, i.e.:

$$\sum_{j=0}^{n} P_j(z) A(z)^j = 0$$

pour certains polynômes $P_j(z)$. Ce que nous proposons ici est une méthode expérimentale pour passer de la P-récurrence trouvée via [gfun] à l'équation algébrique.

Bien entendu on pourrait toujours tenter de résoudre le système

$$\sum_{0 \le j,k \le m} c_{j,k} S(z)^j z^k = 0$$

satisfait par la fonction génératrice, où S(z) est la série génératrice des a_n et les $c_{j,k}$ sont les indéterminées. C'est cette approche qu'utilise la procédure "*listtoalgeq*" de [gfun]. Ainsi pour la suite des nombres de Catalan, voir [Sl], [Comtet]

Exemple 2

```
> suite := [1, 1, 2, 5, 14, 42, 132, 429, 1430, 4862, 16796, 58786, 208012,
742900,  2674440,  9694845,  35357670,  129644790,  477638700,  1767263190,
6564120420];

> listtoalgeq(suite,S(z));

                                        2
                    1 - S(z) + z S(z)
```

En résolvant par rapport à S(z) et en prenant la racine positive on obtient,

```
> solve(",S(z));
                                    1/2
                          1 - (1 - 4 z)
                      1/2 ---------------
                                  z
```

Cependant cette approche est limitée pour deux raisons principales. D'abord le nombre d'équations et d'inconnues explose rapidement; de plus, comme les calculs s'effectuent en précision infinie et à l'aide d'un interprète, la résolution d'un gros système devient vite coûteuse en temps et en espace. L'expérience suggère qu'il est plus facile d'obtenir une P-récurrence explicite qu'une équation algébrique explicite. On peut donc penser rechercher d'abord une P-récurrence pour ensuite obtenir par un processus efficace une équation algébrique. C'est précisément ce genre

d'approche que nous allons décrire.

2. L'algorithme LLL.

L'algorithme LLL permet, étant donné une base d'un espace vectoriel de dimension finie qui génère un réseau, de trouver une base réduite de ce même espace. Si le réseau, engendré par les vecteurs de la base, est formé de vecteurs à coordonnées entières, celui-ci trouvera en temps polynômial, des vecteurs plus courts qui généreront le même réseau. L'algorithme existe également dans la version qui permet d'avoir des vecteurs à coordonnées rationnelles. On peut se référer aux articles originaux [LLL] et [Kannan]. Il permet, entre autres, de trouver numériquement un polynôme dont un nombre "réel" en virgule flottante est la racine.

Cet algorithme est implanté depuis la version V de Maple et porte le nom de "minpoly". Il fait appel à l'algorithme LLL. Disons simplement qu'il permet de résoudre, entre autres, numériquement le problème exactement inverse de trouver une racine d'un polynôme.

Le problème inverse étant : si un nombre réel est donné, que l'on suppose algébrique, de quel polynôme minimal est-il racine ? Mentionnons dès maintenant qu'on parle ici d'un nombreréel donné avec une certaine précision numérique. Ce nombre peut se convertir en nombre rationnel équivalent à la précision numérique voulue. On ne pourra (une fois l'opération réussie) qu'isolerun polynôme qui *semble* avoir ce nombre réel comme racine. Il serait un peu long de donner tous les détails qui font qu'aujourd'hui ce problème est pour ainsi dire *numériquement résolu*.

Mentionnons qu'au moins trois programmes de calcul symbolique ont implanté cet algorithme: soit Maple, Mathematica et Pari-GP. La meilleure implémentation de cet algorithme et la plus rapide nous semble être est celle de Pari-GP [Pari].

Cette procédure accepte donc en entrée un nombre décimal tronqué α et donne (selon la précision numérique en vigueur) un polynôme **minimal** P(x) dont α serait racine. La précision numérique en vigueur est celle que l'utilisateur demande. En pratique, elle est d'environ 500 chiffres décimaux avec Pari-GP. Le degré maximal du polynôme que l'on puisse demander dépend largement de cette précision. En pratique, la limite est un polynôme de degré 20. Ceci est tout de même suffisant pour obtenir des résultats intéressants.

Si la fonction génératrice S(z) correspondant à la suite est algébrique et si z=1/m, avec m entier, S(1/m) sera un nombre algébrique. C'est précisément ici que l'on utilise l'algorithme LLL. Avec la procédure "*rectoproc*" , on peut obtenir des milliers de termes qui serviront à évaluer S(z) en un point 1/m "très petit". Ainsi le résultat sera un nombre algébrique approché à une grande précision numérique. On calcule alors le polynôme dont S(1/m) est racine. On peut vérifier la vraisemblance du résultat en répétant ce calcul pour S(1/(m+1)), S(1/(m+2)), S(1/(m+3)), ... Il se trouve que la version de LLL du programme Pari-GP est extrêmement efficace. Non seulement la procédure (qui s'appelle "*algdep*") retourne en général le bon polynôme, mais de surcroît il est simplifié au maximum. De plus, les solutions trouvées sont *numériquement stables*; elles sont stables au point qu'elles permettent de reconstruire la fonction génératrice algébrique.

Voici donc l'algorithme correspondant. On utilise ici un interface qui permet de passer de Maple à Pari-Gp et vice versa dans la même session. Les commandes "listtorec,rectoproc listtoseries" font partie du programme [gfun], la commande ALGDEP du programme Pari-Gp; le reste des commandes, comme (evalf,interp,solve) font partie de MapleV en version standard. La commande "*interp*" de Maple permet simplement de calculer le polynôme d'interpolation de Newton

et utilise les différences finies.

1) listtorec(suite);
2) rec:=rectoproc(suite);
3) ser:=listtoseries(suite,z,ogf);
4) for i=1 from 1 to **nombre** do
v(i):=subs(z=1/(**m**+i-1),ser);
vf(i):=evalf(v(i),precision);
polynôme(i):=**PARI**(**ALGDEP**(vf(i),**degré**));
od;
5) eqalgébrique:=interp(polynôme(i),t,**m**);
6) alendroit:=subs(t=1/z,eqalgébrique);
7) solve(alendroit,t);

Illustrons cet algorithme en donnant un exemple. Nous prendrons une suite qui apparaît dans le Journal of Combinatorial Theory B, vol. 21 (1976) pp. 71-75, et qui est relative aux tournois. Article de J.W. Moon. Ici nous prendrons **nombre**=13, **degré**=2 et **m**=100. C'est à dire que l'on suppose ici que le degré de l'équation est 2, mais les coefficients sont de degré jusqu'à 12.

Exemple 3

```
> suite:=[1, 1, 1, 3, 16, 75, 309, 1183, 4360, 15783, 56750, 203929, 734722,
2658071, 9662093, 35292151, 129513736, 477376575, 1766738922, 6563071865,
24464169890];

> listtorec(suite,a(n));

[{a(2) = 1, a(1) =
                    2                      2
    (- 2/3 n - 4/3 n ) a(n) + (- 1 + n + n ) a(n + 1)

                            2                                  2       3
        + (1/2 - 1/3 n - 1/6 n ) a(n + 2) + 1/2 + 1/6 n - 1/6 n  + 1/2 n }]

> rec:=rectoproc(",a(n));

rec :=proc(n)
 options remember;
     if not type(n,nonnegint) then ERROR(`invalid arguments`) fi;
     (28*procname(n-2)*n-24*procname(n-2)-8*
     procname(n-2)*n^2+6*procname(n-1)-18*procname(n-1)*n+6*
     procname(n-1)*n^2-27+41*n-19*n^2+3*n^3)/(-3-2*n+n^2)
 end;
```

Voici la première valeur décimale, c'est la série S(z) évaluée en z=1/100. Le lecteur attentif reconnaîtra les premiers termes de la suite :1,1,3,16,... dans le développement décimal du nombre.

```

       + 26 t  z  - 44 t  z  + 41 t  z  - 20 t  z  + 4 t  z )  /  z
```

C’est l’équation algébrique recherchée; elle est de degré 2 en la variable t. Il ne reste qu’à résoudre cette équation et l’une des deux solutions (la positive) est,

$$\frac{- 1/2 \left(- 1 + 10\, z - 42\, z^{2} + 98\, z^{3} - 137\, z^{4} + 112\, z^{5} - 48\, z^{6} + 8\, z^{7}\right)}{\left(z^{2} \left(2\, z - 1\right)^{2} \left(z - 1\right)^{4}\right)}$$

$$\frac{\left(- \left(- 1 + 4\, z\right) \left(2\, z - 1\right)^{4} \left(z - 1\right)^{8\ 1/2}\right)}{\left(z^{2} \left(2\, z - 1\right)^{2} \left(z - 1\right)^{4}\right)}$$

En développant en série de Taylor cette fonction génératrice, on retrouve bien notre suite de départ. On en conclut que c'est *probablement* la fonction génératrice algébrique de cette suite.

Conclusion : notre méthode permet donc de trouver souvent une fonction génératrice algébrique de degré élevé en autant que l'on puisse trouver une P-récurrence. Les temps de calcul sont relativement peu élevés puisque ceux-ci ont été vérifiés avec un micro-ordinateur Macintosh SE/30. (4 mips). Dans [Plo], plus de 32 fonctions génératrices algébriques ont été trouvées grâce à cette méthode. Nous en présentons quelques unes en appendice.
