$$(class, \{ (class, \{ (class, \{ (class, \{ (class, \{Z_{10}, Z_{17}, (class, \{Z_{19}, (class, \{Z_{11}, Z_{12}\})\})\})\}), (class, \{Z_{15}, (class, \{ (class, \{Z_4, Z_7, (class, \{Z_3, Z_{13}\})\}), (class, \{Z_6, Z_{14}\}), (class, \{Z_{20}, Z_9\})\})\}), (class, \{Z_{18}, Z_{16}\})\}, Z_2\}), Z_5\}), Z_1, Z_8\})$$

The system determined by equations over bivariate generating functions can be solved by Maple:

```
> gfeqns(op(2..3,hier2),z,[[u,class]]);
```

$$[Z(z, u) = z, class(z, u) = u, H(z, u) = Z(z, u) + class(z, u)\,(e^{H(z,u)} - 1 - H(z, u))]$$

```
> H_zu:=solve(H=z+u*(exp(H)-1-H),H);
```

$$H\_zu := \frac{-\text{LambertW}\left(-\frac{u\,e^{\left(\frac{z-u}{1+u}\right)}}{1+u}\right) - \text{LambertW}\left(-\frac{u\,e^{\left(\frac{z-u}{1+u}\right)}}{1+u}\right) u + z - u}{1+u}$$

One gets averages by differentiation:

```
> H1_z:=subs(u=1,diff(H_zu,u));
```

$$H1\_z := 2\,\text{LambertW}\left(-\frac{1}{2}e^{(1/2\,z-1/2)}\right) \left(-\frac{1}{4}e^{(1/2\,z-1/2)} - \frac{1}{2}\left(-\frac{1}{4}-\frac{1}{4}z\right)e^{(1/2\,z-1/2)}\right) \Big/ \left(\left(1+\text{LambertW}\left(-\frac{1}{2}e^{(1/2\,z-1/2)}\right)\right)e^{(1/2\,z-1/2)} - \frac{1}{4} - \frac{1}{4}z\right)$$

Numerically, the mean number of nodes in a random classification tree of size n, when divided by n, is for $n = 1 .. 20$,

```
> Digits:=5: evalf(series(H1_z,z=0,22)): seq(coeff(",z,j)/count(hier,size=j)/j*j!,
j=1..20);
```

0, .50000, .58336, .63463, .66610, .68727, .70248, .71387, .72271, .72990, .73567, .74063, .74469, .74824, .75134, .75398, .75634, .75849, .76039, .76206

This suggests that a random classification may have about $.76\,n$ classification stages.

We can in fact analyse this rigorously, using the asymptotic method already employed for counts.

```
> H1_s:=subs(z=rho*(1-Delta^2),H1_z):
H1_sing:=map(simplify,series(H1_s,Delta=0,5));
H1_n_asympt:=n!*asympt(coeff(H1_sing,Delta,-1)*rho^(-n)*subs({cos(Pi*n)=1,O=0},
simplify(asympt(binomial(-1/2,n),n,2))),n);
```

$$H1\_sing := -\frac{1}{2}\frac{\ln(2)-1}{\sqrt{-1+2\ln(2)}}\Delta^{-1} + \left(-\frac{1}{6}\ln(2)-\frac{1}{3}\right) - \frac{1}{24}\frac{-15\ln(2)+2\ln(2)^2+7}{\sqrt{-1+2\ln(2)}}\Delta + O(\Delta^2)$$

$$H1\_n\_asympt := -\frac{1}{2}\frac{n!\,(\ln(2)-1)\sqrt{\frac{1}{n}}}{\sqrt{-1+2\ln(2)}\,\sqrt{\pi}\,(-1+2\ln(2))^n}$$

```
> C_classif:=asympt(H1_n_asympt/H_n_asympt,n,1); evalf(",20);
```

$$C\_classif := -\frac{(\ln(2)-1)\,n}{-1+2\ln(2)}$$

$$.79434972478104491547\,n$$

Thus, we have obtained (easily!) a new **Theorem** . *In a random classification tree, the number of classification stages (internal nodes) is asymptotic to*

$$-\frac{(\log(2)-1)\,n}{2\log(2)-1} = .794349724\,n\,.$$

Degrees in random classification trees

The corresponding generating functions are now outside of the range of implicit functions that Maple knows about. Thus, a separate mathematical analysis is needed. However, an empirical analysis based on small sizes is already quite informative. The following code builds a specification where nodes of degree k are marked. The principle is the obvious set-theoretic equation

$$\mathrm{Set}(X) = \mathrm{Union}(\mathrm{Set}(X, card < k), \mathrm{Set}(X, card = k), \mathrm{Set}(X, k \le card))\,.$$

The code uses combstruct[gfeqns] to generate the system of equations for each degree that is then expanded. In passing, it prints the corresponding generating function:

```
> deg_hier:=proc(k) local j,spec,n,dHH;
spec:=[H,{
H=Union(Z,Union(Set(H,card>k)),Prod(classif,Set(H,card=k)),seq(Set(H,card=j),j=2..
k-1)),
classif=Epsilon},labelled];
dHH:=subs(u=1,diff(RootOf(subs({Z(z,u)=z,classif(z,u)=u,H(z,u)=H},
H(z,u)=subs(gfeqns(op(2..3,spec),z,[[u,classif]]),H(z,u))),H),u));
print(dHH);
seq(evalf(coeff(series(subs(u=1,dHH),z,27),z,n)/count(spec,size=n)*n!/n,5),n=1..25)
end:
```

```
> deg_hier(2);
```

$$\frac{\mathrm{RootOf}(4\_Z - 2z - 2e^{-Z} + 2)^2}{4 - 2e^{\mathrm{RootOf}(4\_Z - 2z - 2e^{-Z} + 2)}}$$

0, .50000, .50000, .52885, .54661, .55875, .56754, .57419, .57940, .58358, .58702, .58989, .59233, .59442, .59623, .59782, .59922, .60047, .60159, .60260, .60351, .60434, .60510, .60580, .60644

```
> deg_hier(5);
```

$$\frac{\mathrm{RootOf}(240\_Z - 120z - 120e^{-Z} + 120)^5}{240 - 120e^{\mathrm{RootOf}(240\_Z - 120z - 120e^{-Z} + 120)}}$$

0, 0, 0, 0, .00084746, .0012718, .0015813, .0018135, .0019944, .0021393, .0022580, .0023570, .0024408, .0025127, .0025751, .0026297, .0026778, .0027207, .0027591, .0027936, .0028248, .0028533, .0028792, .0029030, .0029249

Thus a random classification on n elements seems to have on average about

about $.6n$ binary nodes;

about $.14\,n$ ternary nodes;

about $.02\,n$ quaternary nodes.

These results are consistent with the proved result that the total number of internal nodes is on average $.79\,n$. The simple pattern revealed by this computation suggests a formal proof (by singularity analysis) that the distribution of degrees in fact obeys a modified Poisson law. The following theorem, first found while developing this worksheet, appears to be new:

Theorem . *The probability that a random internal node in a random hierarchy of size* n *has degree* k *satisfies asymptotically a truncated Poisson law*

```
> tau:=sqrt(2*log(2)-1);
S:=expand(sum(exp(-tau)*tau^(k-1)/(k-1)!,k=2..infinity));
Pr(deg=k)=normal(1/S*exp(-tau)*tau^(k-1)/(k-1)!);
```

$$\tau := \sqrt{-1 + 2\ln(2)}$$

$$S := 1 - \frac{1}{e^{\left(\sqrt{-1 + 2\ln(2)}\right)}}$$

$$\Pr(deg = k) = \frac{e^{\left(\sqrt{-1 + 2\ln(2)}\right)} e^{\left(-\sqrt{-1 + 2\ln(2)}\right)} \left(\sqrt{-1 + 2\ln(2)}\right)^{(k-1)}}{\left(e^{\left(\sqrt{-1 + 2\ln(2)}\right)} - 1\right)(k-1)!}$$

Equivalently, the mean number of nodes of degree $2 \le k$ *is asymptotic to*

```
> C_classif/S*exp(-tau)*tau^(k-1)/(k-1)!;
```

$$-\frac{(\ln(2) - 1)\, n\, e^{\left(-\sqrt{-1 + 2\ln(2)}\right)} \left(\sqrt{-1 + 2\ln(2)}\right)^{(k-1)}}{(-1 + 2\ln(2))\left(1 - \frac{1}{e^{\left(\sqrt{-1 + 2\ln(2)}\right)}}\right)(k-1)!}$$

Numerically, this evaluates to

```
> evalf([seq('',k=2..10)]);
```

$$[.5729032234\,n, .1780370765\,n, .03688488077\,n, .005731226563\,n, .0007124210721\,n, .00007379801670\,n, .6552481970\,10^{-5}\,n, .5090671021\,10^{-6}\,n, .3515537274\,10^{-7}\,n]$$

These figures are consistent with what was found on sizes near 20. They show that nodes of degree 5 and higher have negligible chances of occurring.

Alternative models

Unlabelled hierarchies

A number of related models can be similarly analyzed. We examine here:

Unlabelled hierarchies: these represent the types of trees when one considers the elements to be classified as "indistinguishable". What we obtain is then reminiscent of chemical molecules (with an unrealistic element that would be capable of an arbitray valency).

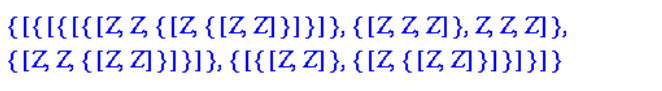
Planar hierarchies, where one distinguishes the order between decsendents of classification node.

For unlabelled, hierarchies, we just need to change the qualifier of specifications to "unlabelled".

```
> hier4:=[H,{H=Union(Z,Set(H,card>1))},unlabelled]:
```

```
> ureduce:=proc(e) eval(subs({Set=proc() {[args]} end,Prod=proc() ``(args) end, Sequence=proc() [args] end},e)) end:
```

```
> ureduce(draw(hier4,size=20));
```



Notice that internally, the setting up of counting tables is more complex as it involves a fragment of Polya's theory. The counting results grow much more slowly, since we distinguish fewer configurations.

```
> seq(count(hier4,size=j),j=0..30);
```

0, 1, 1, 2, 5, 12, 33, 90, 261, 766, 2312, 7068, 21965, 68954, 218751, 699534, 2253676, 7305788, 23816743, 78023602, 256738751, 848152864, 2811996972, 9353366564, 31204088381, 104384620070, 350064856815, 1176693361956, 3963752002320, 13378623786680, 45239588651121

```

{[Z, {[Z, {[Z, Z]}, {[Z, Z]}]}]},
{[{[Z, Z]}, {[Z, Z]}, {[Z, Z]}]},
{[{[Z, Z]}, {[{[Z, Z, Z]}, Z]}]},
{[Z, {[{[Z, Z, Z]}, Z, Z]}]}, {[Z, Z, Z, {[Z, {[Z, Z]}]}]},
{[Z, {[{[Z, Z, {[Z, Z]}]}, Z]}]}, {[Z, Z, Z, Z, Z, Z]},
{[Z, Z, {[Z, Z, Z, Z]}]}]

Planar hierarchies

We only need to change Set into Sequence to get the right classification:

```
> hier5:=[H,{H=Union(Z,Sequence(H,card>1))},unlabelled]:
```

```
> ureduce:=proc(e) eval(subs({Set=proc() {[args]} end,Prod=proc() ``(args) end,
Sequence=proc() [args] end},e)) end:
```

```
> ureduce(draw(hier5,size=50));
```

[[Z, Z, [Z, Z], Z, [[
Z, Z, [[Z, Z, [Z, Z, Z, [Z, Z]], Z, [[Z, Z], Z, [Z, Z, Z]]], Z, [Z, Z]]
], [[[Z, [Z, [[Z, Z], Z]]], [[[Z, Z, Z], [[Z, Z, Z], Z, Z, Z], Z, Z],
[[[Z, Z], [Z, Z]], [[Z, Z], Z]], Z]], Z]

The counting sequence is

```
> seq(count(hier5,size=j),j=0..30);
```

0, 1, 1, 3, 11, 45, 197, 903, 4279, 20793, 103049, 518859,
2646723, 13648869, 71039373, 372693519, 1968801519,
10463578353, 55909013009, 300159426963, 1618362158587,
8759309660445, 47574827600981, 259215937709463,
1416461675464871, 7760733824437545, 42624971294485657,
234643073935918683, 1294379445480318899,
7154203054548921813, 39614015909996567325

This is found as Sequence **M2898** in the *Encyclopedia of Integer Sequences* by Sloane and Plouffe and is known as Schroeder's second sequence.This sequence has a dignified history

and Stanley noticed recently that the element $\mathrm{count}(hier5, size = 10) = 103049$ already appears in Plutarch's [AD50- AD120 (!)] biographical notes on Hipparchus.

```
> gfsolve(op(2..3,hier5),z);
```

$$\{Z(z) = z, H(z) = \frac{1}{4} + \frac{1}{4}z - \frac{1}{4}\sqrt{1 - 6z + z^2}\}$$

```
> H5_z:=subs('',H(z));
```

$$H5\_z := \frac{1}{4} + \frac{1}{4}z - \frac{1}{4}\sqrt{1 - 6z + z^2}$$

```
> series(H5_z,z=0,11);
```

$$z + z^2 + 3z^3 + 11z^4 + 45z^5 + 197z^6 + 903z^7 + 4279z^8 + 20793$$
$$z^9 + 103049z^{10} + O(z^{11})$$

Here is finally one quick way to obtain a simple recurrence for these numbers: first guess the recurrence, then check your guess. This, and many alternatives are encapsulated in the Gfun package.

```
> with(gfun):
listtorec([seq(count(hier5,size=j),j=0..30)],u(n));
```

$$[\{(n - n^2)u(n) + (5n + 7n^2)u(n + 1)$$
$$+ (-18 - 23n - 7n^2)u(n + 2) + (6 + 5n + n^2)u(n + 3),$$
$$u(2) = 1, u(0) = 0, u(1) = 1\}, ogf]$$

```
> rectodiffeq(op(1,''),u(n),Y(z));
```

$$\{Y(0) = 0, D(Y)(0) = 1, -2Y(z) + (2z + 2)\left(\frac{\partial}{\partial z}Y(z)\right)$$
$$+ (z^3 - 7z^2 + 7z - 1)\left(\frac{\partial}{\partial z}\left(\frac{\partial}{\partial z}Y(z)\right)\right)\}$$

```
> dsolve('',Y(z));
```

$$Y(z) = \frac{1}{4} + \frac{1}{4}z - \frac{1}{4}\sqrt{1 - 6z + z^2}$$

Conclusion

Various models of random classification trees can be analysed both theoretically and empirically. Random generation is easy and the experiments lead to new conjectures (like the degree distribution) and even theorems (like the analysis of the number of classification stages). Returning to statistics, some properties of random trees appear to be present accross all models: for instance nodes of even moderately large degrees, $5 \leq deg$, are highly infrequent, and branching is predominantly binary. General observations of this type may be used to help distinguish classification trees without informational content ("random" trees) from meaningful ones.

Polya.mws

Enumerating alcohols and other classes of chemical moleculs,

an example of Polya theory

Frederic Chyzak
(Version of January 13, 1997)

Alkanes are a simple class of chemical compounds. They are generically described by the chemical formula $C_n H_{2n+2}$. First examples for small n are methane ($n = 1$), ethane ($n = 2$), propane ($n = 3$), butane ($n = 4$), a.s.o. For a given n however, there exist several different *isomers*, i.e., different structures of bonds between atoms. In chemistry, there is much interest in knowing the number, or better yet the list, of such isomers. Alcohols are obtained from alkanes by replacing a hydrogen atom by an OH group. It follows that they are isomorphic to carbon chains with a distinguished node, or again to alkyl radicals $C_n H_{2n+1}$, which are alkanes with a missing hydrogen atom. If we disregard geometrical constraints (i.e., if we consider *structural* isomers only, and not *conformational* isomers), this leads to a pure graph-theoretical problem: how many rooted trees are there with n internal nodes, where each internal node has degree 4?

In this session, we thus consider *rooted* trees, so that we count and enumerate alkyls, with generic formula $C_n H_{2n+1}$. The combinatorics also corresponds to simple alcohols $C_n H_{2n+1} O H$, organo-metalic compounds $C_n H_{2n+1} X$, and any other monosubstituted alkanes. We next treat the cases of disubstituted and trisubstituted alkanes. We develop the study of our models using the package Combstruct.

```
> with(combstruct);
```

```
[allstructs, count, draw, finished, gfeqns, gfseries, gfsolve, iterstructs,
nextstruct, prog_gfeqns, prog_gfseries, prog_gfsolve]
```

Enumerations of such classes of chemical compounds are part of Polya theory. We refer to the book by G. Polya and R. C. Read [*Combinatorial Enumeration of Groups, Graphs, and Chemical Compounds* , (1987), Springer-Verlag] for more extensive results.

Monosubstituted alkanes, $C_n H_{2n+1} X$

In this section, we study monosubstituted alkanes, i.e., *rooted* trees, first without any constraint, next according to the *height* .

General alkyls

Definition

An alkyl radical can be viewed as a carbon atom linked to at most 3 alkyl radicals. Thus, we only take into account hydrogen atoms implicitly. There is no loss of information, since hydrogen atoms can always be recovered from the carbon skeleton. This yields the class equation

$Alkyl = Carbon\,(\mathrm{E} + Alkyl + Alkyl^2 + Alkyl^3)$, which we map into the following grammar:

```
> gramm_Alkyl:=Alkyl=Prod(Carbon,Set(Alkyl,card<=3)),Carbon=Atom:
specs_Alkyl:=[Alkyl,{gramm_Alkyl},unlabelled]:
```

Note that since the Set construct denotes multisets, i.e., sets with repetitions, a carbon atom of an alkyl is allowed to be bound to two copies of the same subtree (but the order of the subtrees does not matter).

Define the size of an alkyl as the number of carbon atoms it contains. We compute the number of alkyls of a given size using combstruct[count] .

```
> seq(count(specs_Alkyl,size=i),i=0..50);
```

This series appears as the entry **M1146** ("quartic planted trees with n nodes") in the book by N. J. A. Sloane and S. Plouffe [*The Encyclopedia of Integer Sequences* , (1995), Academic Press].

Here is an example of an alkyl with 6 carbon atoms, obtained by the command combstruct[draw] .

```
> alk:=draw(specs_Alkyl,size=6);
```

$$alk := \mathrm{Prod}(Carbon, \mathrm{Set}(\mathrm{Prod}(Carbon, \mathrm{Set}(\mathrm{Prod}(Carbon, \mathrm{Set}(\mathrm{Prod}(Carbon, \mathrm{E}))), \mathrm{Prod}(Carbon, \mathrm{Set}(\mathrm{Prod}(Carbon, \mathrm{E})))))))$$

The following procedure rewrites an alkyl into a more readable way.

```
> nice:=proc(alk) eval(subs({Epsilon=NULL,Carbon=C,Prod=proc() global H;
[args] end,Set=proc() args end},alk)) end:
```

```
> nice(alk);
```

$$[C, [C, [C, [C]], [C, [C]]]]$$

The following procedure computes the size of a given alkyl.

```
> size:=proc(alk) option remember; 1+convert(map(size,op(2,alk)),`+`) end:
```

```
size(Prod(Carbon,Epsilon)):=1:
```

The following procedure computes the height of a given alkyl.

```
> height:=proc(alk) option remember; 1+max(op(map(height,op(2,alk)))) end:
height(Prod(Carbon,Epsilon)):=1:
```

Here is an alkyl with 50 carbon atoms, its nice representation and height.

```
> alk:=draw(specs_Alkyl,size=50):
```

```
> nice(alk);
```

$$[C, [C, [C, [C], [C, [C, [C, [C, [C],$$
$$[C, [C, [C], [C, [C], [C]]]], [C, [C, [C, [C]]],$$
$$[C, [C, [C]]], [C, [C, [C], [C], [C, [C], [C], [C, [C]]]],$$
$$[C, [C], [C, [C]]]]], [C, [C, [C, [C, [C]], [C, [C], [C]]]]],$$
$$[C, [C, [C, [C]]], [C, [C, [C]]]]]]]]$$

```
> height(alk);
```

$$13$$

Empirical study

Drawing

By drawing several random structures, we can study probabilistic properties of alkyls. For instance, the following is a probabilistic estimate of their height on average:

```
> for i to 10 do ho[i]:=height(draw(specs_Alkyl,size=50)) od;
```

$$ho_1 := 18$$

$$ho_2 := 15$$

$$ho_3 := 19$$

$$ho_4 := 13$$

$$ho_5 := 13$$

$$ho_6 := 15$$

$$ho_7 := 13$$

$$ho_8 := 16$$

$$ho_9 := 14$$

$$ho_{10} := 17$$

```
> add(ho[i],i=1..10)/10.;
```

$$15.30000000$$

In the same way, we get a probabilistic estimate of their standard deviation:

```
> sqrt(add((ho[i]-")^2,i=1..10)/10);
```

$$2.051828453$$

Exhaustive enumeration

The command combstruct[draw] permits us to draw *one* structure at random. We can also generate *all* alkyls of a given size, using combstruct[allstructs] , so as to compute the mean of a particular parameter exactly, or to count all those with a particular property. For instance, the height of trees cannot be represented in the class of combinatorial structures when using Combstruct . For instance, by computing all alkyls of size 5, we get the distribution of height for these alkyls (in their nice representation).

```
> allstructs(specs_Alkyl,size=5):

> map(nice,");
```

$$[[C, [C, [C], [C, [C]]]], [C, [C], [C], [C, [C]]],$$
$$[C, [C], [C, [C], [C]]], [C, [C, [C, [C, [C]]]]],$$
$$[C, [C, [C], [C], [C]]], [C, [C, [C, [C], [C]]]],$$
$$[C, [C], [C, [C, [C]]]], [C, [C, [C]], [C, [C]]]]$$

```
> sort(map(height,""));
```

$$[3, 3, 3, 3, 4, 4, 4, 5]$$

Here we count 4 alkyls of size 5 and height 3, 3 alkyls of size 5 and height 4, and 1 alkyl of size 5 and height 5.

By the same method, we get the exact mean and standard deviation of the height for small sizes.

```
> esd:=proc(n) local i,as,mean;
as:=map(height,allstructs(specs_Alkyl,size=n));
mean:=evalf(convert(as,`+`)/nops(as));
nops(as),mean,evalf(sqrt(add((i-mean)^2,i=as))/nops(as))
end:

> for i from 2 to 6 do i=esd(i) od;
```

$$2 = (1, 2., 0)$$

$$3 = (2, 2.500000000, .3535533906)$$

$$4 = (4, 3., .3535533905)$$

$$5 = (8, 3.625000000, .2460627461)$$

$$6 = (17, 4.117647059, .2017630413)$$

We could go up to $i = 9$ in less than 2 minutes.

Alkyls according to their height

Grammar

We define the class $Alkyl\_height_n$ to be the class of alkyls of height *at most* n .

An alkyl of height at most n can be viewed as a carbon atom linked to at most three alkyls of height at most $n-1$, according to the equation

$$Alkyl\_height_n = Carbon\ (\mathrm{E} + Alkyl\_height_{n-1} + Alkyl\_height_{n-1}^{2} + Alkyl\_height_{n-1}^{3}) .$$

```
> gramm_ltd_height:=proc(n) option remember;
Alkyl_height[n]=Prod(Carbon,Set(Alkyl_height[n-1],card<=3)),gramm_ltd_height
(n-1)
end:
gramm_ltd_height(1):=Alkyl_height[1]=Prod(Carbon,Epsilon),Carbon=Atom:
specs_ltd_height:=proc(n) option remember;
[Alkyl_height[n],{gramm_ltd_height(n)},unlabelled]
end:
```

The following procedure rewrites an alkyl into a more readable way.

```
> nice:=proc(alk) eval(subs({Epsilon=NULL,Carbon=C,Prod=proc() global H;
[args] end,Set=proc() args end},alk)) end:
```

The following procedures compute the size and height of a given alkyl.

```
> size:=proc(alk) option remember; 1+convert(map(size,op(2,alk)),`+`) end:
size(Prod(Carbon,Epsilon)):=1:
```

```
> height:=proc(alk) option remember; 1+max(op(map(height,op(2,alk)))) end:
height(Prod(Carbon,Epsilon)):=1:
```

For instance, we compute the height of a random alkyl of size 10 and height at most 5.

```
> alk:=draw(specs_ltd_height(5),size=10):
```

```
> nice(alk);
```

$$[C, [C], [C, [C]], [C, [C, [C], [C], [C, [C]]]]]$$

```
> size(alk),height(alk);
```

$$10, 5$$

In this section, we proceed to compute a table of the number of alkyls according to their size and height. The first method is by generating all structures. Next, we use generating functions to extend the table.

Generating all structures

The following procedure remembers all the alkyls of a given size and with bounded height.

```
> list_all_st:=proc(d,s) option remember; allstructs(specs_ltd_height(d),size=s)
end:
```

An alkyl of height h has a size at most $\frac{3^h - 1}{2}$. Therefore, to produce all alkyls with height at most h_{max}, we need to produce all alkyls with size up to $s_{max} = \frac{3^{h_{max}} - 1}{2}$.

```
> s[max]:=(3^h[max]-1)/2;
```

$$s_{max} := \frac{1}{2} 3^{h_{max}} - \frac{1}{2}$$

To begin with, we enumerate all alkyls with height at most 3.

```
> h[max]:=3;
```

$$h_{max} := 3$$

```
> for i from 1 to s[max] do i,nops(list_all_st(h[max],i)),map(nice,list_all_st(h[max],i)) od;
```

In this way, we have obtained the truncation of the bivariate generating function of alkyls with size marked by z and height by u.

> **enum_BGF:=map(series,series(convert(map(proc(s,z,u) z^size(s)*u^height(s) end,map(op,[seq(list_all_st(h[max],i),i=1..s[max])]),z,u),`+`),z,infinity),u,infinity);**

$$enum\_BGF := (u)\,z + (u^2)\,z^2 + (u^2 + u^3)\,z^3 + (u^2 + 2\,u^3)\,z^4 + (4\,u^3)\,z^5 + (4\,u^3)\,z^6 + (5\,u^3)\,z^7 + (4\,u^3)\,z^8 + (4\,u^3)\,z^9 + (3\,u^3)\,z^{10} + (2\,u^3)\,z^{11} + (u^3)\,z^{12} + (u^3)\,z^{13}$$

Generating functions

combstruct[gfeqns] returns a system of functional equations satisfied by the generating functions of related combinatorial structures. In the case of the alkyls with maximum height above, we get the following triangular system.

> **gfeqns(op(2..3,specs_ltd_height(4)),z);**

$$\left[\mathrm{Carbon}(z) = z,\ Alkyl\_height_2(z) = \mathrm{Carbon}(z)\left(1 + Alkyl\_height_1(z) + \frac{1}{2}Alkyl\_height_1(z^2) + \frac{1}{2}Alkyl\_height_1(z)^2 + \frac{1}{3}Alkyl\_height_1(z^3) + \frac{1}{2}Alkyl\_height_1(z)\,Alkyl\_height_1(z^2) + \frac{1}{6}Alkyl\_height_1(z)^3\right),\ Alkyl\_height_3(z) = \mathrm{Carbon}(z)\left(1\right.\right.$$

$$+ Alkyl\_height_2(z) + \frac{1}{2} Alkyl\_height_2(z^2)$$
$$+ \frac{1}{2} Alkyl\_height_2(z)^2 + \frac{1}{3} Alkyl\_height_2(z^3)$$
$$+ \frac{1}{2} Alkyl\_height_2(z)\, Alkyl\_height_2(z^2)$$
$$+ \frac{1}{6} Alkyl\_height_2(z)^3 \Big), \; Alkyl\_height_1(z) = \mathrm{Carbon}(z),$$
$$Alkyl\_height_4(z) = \mathrm{Carbon}(z) \Big(1 + Alkyl\_height_3(z)$$
$$+ \frac{1}{2} Alkyl\_height_3(z^2) + \frac{1}{2} Alkyl\_height_3(z)^2$$
$$+ \frac{1}{3} Alkyl\_height_3(z^3) + \frac{1}{2} Alkyl\_height_3(z)\, Alkyl\_height_3(z^2)$$
$$+ \frac{1}{6} Alkyl\_height_3(z)^3 \Big) \Big]$$

```
> gfsol:=gfsolve(op(2..3,specs_ltd_height(4)),z);
```

$$gfsol := \{ Alkyl\_height_3(z) = z + 5z^7 + 4z^9 + 3z^{10} + z^{13} + z^2$$
$$+ 2z^{11} + z^{12} + 4z^6 + 4z^8 + 2z^3 + 3z^4 + 4z^5,$$
$$Alkyl\_height_4(z) = 12z^6 + 31z^8 + 47z^9 + 137z^{12} + z$$
$$+ 184z^{13} + 70z^{10} + 99z^{11} + 7z^5 + 20z^7 + 300z^{15} + 498z^{18}$$
$$+ 594z^{20} + 453z^{26} + 570z^{24} + 369z^{16} + 614z^{21} + 378z^{27}$$
$$+ 181z^{30} + z^{39} + 56z^{33} + 12z^{36} + 624z^{22} + 239z^{14} + 3z^{38}$$
$$+ 6z^{37} + 37z^{34} + 20z^{35} + 128z^{31} + 312z^{28} + 238z^{29}$$
$$+ 89z^{32} + 601z^{23} + 514z^{25} + 432z^{17} + 551z^{19} + z^{40} + z^2$$
$$+ 2z^3 + 4z^4, \; Alkyl\_height_1(z) = z, \; \mathrm{Carbon}(z) = z,$$
$$Alkyl\_height_2(z) = z + z^2 + z^3 + z^4 \}$$

In particular, we have obtained a truncation of the bivariate generating function of all alkyls (i.e., with no constraint on height). In this series, u marks the height. It extends the previous truncation $enum\_BGF$.

```
> BGF:=map(series,series(eval(subs(Alkyl_height[0]=0,gfsol,add(u^h*
(Alkyl_height[h]-Alkyl_height[h-1])(z),h=1..4))),z,infinity),u,infinity);
```

$$BGF := (u)z + (u^2)z^2 + (u^2 + u^3)z^3 + (u^2 + 2u^3 + u^4)z^4$$
$$+ (4u^3 + 3u^4)z^5 + (4u^3 + 8u^4)z^6 + (5u^3 + 15u^4)z^7 +$$
$$(4u^3 + 27u^4)z^8 + (4u^3 + 43u^4)z^9 + (3u^3 + 67u^4)z^{10} +$$

$$(2u^3 + 97u^4)z^{11} + (u^3 + 136u^4)z^{12} + (u^3 + 183u^4)z^{13} + (239u^4)z^{14} + (300u^4)z^{15} + (369u^4)z^{16} + (432u^4)z^{17} + (498u^4)z^{18} + (551u^4)z^{19} + (594u^4)z^{20} + (614u^4)z^{21} + (624u^4)z^{22} + (601u^4)z^{23} + (570u^4)z^{24} + (514u^4)z^{25} + (453u^4)z^{26} + (378u^4)z^{27} + (312u^4)z^{28} + (238u^4)z^{29} + (181u^4)z^{30} + (128u^4)z^{31} + (89u^4)z^{32} + (56u^4)z^{33} + (37u^4)z^{34} + (20u^4)z^{35} + (12u^4)z^{36} + (6u^4)z^{37} + (3u^4)z^{38} + (u^4)z^{39} + (u^4)z^{40}$$

This is made explicit on the following normalized difference: each entry starts with a term in u^4, denoting alkyls with height at least 4.

```
> map(series,series(BGF-enum_BGF,z,infinity),u,infinity);
```

$$(u^4)z^4 + (3u^4)z^5 + (8u^4)z^6 + (15u^4)z^7 + (27u^4)z^8 + (43u^4)z^9 + (67u^4)z^{10} + (97u^4)z^{11} + (136u^4)z^{12} + (183u^4)z^{13} + (239u^4)z^{14} + (300u^4)z^{15} + (369u^4)z^{16} + (432u^4)z^{17} + (498u^4)z^{18} + (551u^4)z^{19} + (594u^4)z^{20} + (614u^4)z^{21} + (624u^4)z^{22} + (601u^4)z^{23} + (570u^4)z^{24} + (514u^4)z^{25} + (453u^4)z^{26} + (378u^4)z^{27} + (312u^4)z^{28} + (238u^4)z^{29} + (181u^4)z^{30} + (128u^4)z^{31} + (89u^4)z^{32} + (56u^4)z^{33} + (37u^4)z^{34} + (20u^4)z^{35} + (12u^4)z^{36} + (6u^4)z^{37} + (3u^4)z^{38} + (u^4)z^{39} + (u^4)z^{40}$$

Table of the number of alkyls according to size and height

Calculations with respect to different heights are much more efficient than the method of exhaustive enumeration. This makes it possible for us to set up the table of the number of alkyls according to size and height in a few minutes:

```
> h[max]:=5;
```

$$h_{max} := 5$$

```
> gfsol:=gfsolve(op(2..3,specs_ltd_height(h[max])),z);
```

$$gfsol := \{Alkyl\_height_5(z) = 16z^6 + 63z^8 + 121z^9 + 749z^{12} + z + 1344z^{13} + 225z^{10} + 415z^{11} + 8z^5 + 33z^7 + 39922778z^{93} + 552046535z^{84} + 261713408z^{87} + 12677964z^{96} + 4129z^{15} + 20354z^{18} + 55706z^{20} + 872727z^{26} + 364555z^{24} + 7106z^{16} + 90628z^{21}$$

$$+ 1328545\,z^{27} + 4393287\,z^{30} + 89755449\,z^{39}$$
$$+ 13204526\,z^{33} + 36095102\,z^{36} + 145729\,z^{22} + 2365\,z^{14}$$

A (huge) table for $h_{max} = 7$ could be computed in less than 10 minutes.

Disubstituted alkanes, $C_n H_{2n} X Y$

Enumerating disubstituted alkanes $C_n H_{2n} X Y$ is equivalent to enumerating monosubstituted alkyls $C_n H_{2n} X$. The latter can generically be viewed as a carbon atom linked to one monosubstituted alkyl and at least 2 nonsubstituted alkyls. This yields the class equation $S1\_Alkyl_X =$

$$Carbon\ S1\_Alkyl_X(\mathrm{E} + Alkyl) + Carbon\ X(\mathrm{E} + Alkyl + Alkyl^2).$$

```
> gramm_S1_Alkyl:=S1_Alkyl[X]=Union(Prod(Carbon,S1_Alkyl[X],Set(Alkyl,
card<=2)),Prod(Prod(Carbon,X),Set(Alkyl,card<=2))),X=Epsilon:

> specs_S1_Alkyl:=[S1_Alkyl[X],{gramm_S1_Alkyl,gramm_Alkyl},unlabelled]:

> seq(count(specs_S1_Alkyl,size=i),i=0..50);
```

This series appears as the entry **M1418** ("paraffins with n carbon atoms") in the book by N. J. A. Sloane and S. Plouffe [*The Encyclopedia of Integer Sequences* , (1995), Academic Press].

Of course, there are more monosubstituted alkyls than nonsubstituted ones. We give the ratios number of monosubstituted alkyls/number of alkyls for small sizes:

```
> seq([i=evalf(count(specs_S1_Alkyl,size=i)/count(specs_Alkyl,size=i))],i=1..50);
```

[1 = 1.], [2 = 2.], [3 = 2.500000000], [4 = 3.], [5 = 3.875000000],
[6 = 4.705882353], [7 = 5.384615385], [8 = 6.235955056],
[9 = 7.009478673], [10 = 7.808678501], [11 = 8.604200323],
[12 = 9.407916258], [13 = 10.19897892], [14 = 10.99859675],
[15 = 11.79210069], [16 = 12.58714553], [17 = 13.38032304],

Trisubstituted alkanes, $C_n H_{2n-1} X Y Z$

Enumerating trisubstituted alkanes $C_n H_{2n-1} X Y Z$ is equivalent to enumerating disubstituted alkyls $C_n H_{2n-1} X Y$. In this section, we assume X, Y and Z to be distinct. The grammar is more involved than in the disubstituted case: we have to distinguish several cases, according to which of X and Y go into subtrees, and into which subtrees. The corresponding class equation is

$$S2\_Alkyl_{X,Y} = Carbon\, S2\_Alkyl_{X,Y}(\mathrm{E} + Alkyl + Alkyl^2) + Carbon\,(X + S1\_Alkyl_X)(Y + S1\_Alkyl_Y)(\mathrm{E} + Alkyl).$$

```
> gramm_S2_Alkyl:=S2_Alkyl[X,Y]=Union(Prod(Carbon,S2_Alkyl[X,Y],Set
(Alkyl,card<=2)),Prod(Carbon,Union(S1_Alkyl[X],X),Union(S1_Alkyl[Y],Y),Set
(Alkyl,card<=1))):

> specs_S2_Alkyl:=[S2_Alkyl[X,Y],{gramm_S2_Alkyl,gramm_S1_Alkyl,op(subs
(X=Y,[gramm_S1_Alkyl])),gramm_Alkyl},unlabelled]:

> seq(count(specs_S2_Alkyl,size=i),i=0..50);
```

```

This series does not appear in the book by N. J. A. Sloane and S. Plouffe [*The*

Encyclopedia of Integer Sequences , (1995), Academic Press], nor do its first four differences. Comparing to the entry **M2838** ("tertiary alcohols with n carbon atoms") in this book, we check that there are always more compounds $C_n H_{2n-1} X_2 Y$ than compounds $C_n H_{2n-1} X_3$ (for $X \neq Y$).

Here is an example of a disubstituted alkyl with 6 carbon atoms, obtained by the command combstruct[draw] .

```
> alk:=draw(specs_S2b_Alkyl,size=6);
```

$$alk := \mathrm{Prod}(Carbon, \mathrm{Prod}(\mathrm{Prod}(Carbon, \mathrm{Prod}(\mathrm{Prod}(Carbon, X), \mathrm{Set}(\mathrm{Prod}(Carbon, E))), \mathrm{Set}(\mathrm{Prod}(Carbon, E), \mathrm{Prod}(Carbon, E))), X), E)$$

The following procedure rewrites a disubstituted alkyl into a more readable way.

```
> nice:=proc(alk) subs({[C,X]=CX,[C,X,X]=CX[2]},eval(subs({Epsilon=NULL,
Carbon=C,Prod=proc() [args] end,Set=proc() args end},alk))) end:
```

```
> nice(alk);
```

$$[C, [[C, [CX, [C]], [C], [C]], X]]$$

Here are the 9 disubstituted compounds $C_n H_{2n-1} X_2 Y$ for $n = 3$:

```
> map(nice,allstructs(specs_S2b_Alkyl,size=3));
```

$$[[C, [[CX], X], [C]], [C, [C, [X, X]], [C]], [C, [C, [X, X], [C]]], [C, [[CX, [C]], X]], [C, [[C, [CX]], X]], [C, [C, [C, [X, X]]]], [C, [C, [[CX], X]]], [C, [X, X], [C, [C]]], [C, [[CX], [CX]]]]$$

Conclusion: multiply substituted alkyls

In the previous sections, we have enumerated the substituted compounds $C_n H_{2n+1} X$, $C_n H_{2n} XY$, $C_n H_{2n-1} XYZ$ and $C_n H_{2n-1} X_2 Y$.

We could in principle enumerate the class $S_{p_1, \ldots, p_t}$ of compounds obtained after substituting p_1 hydrogen atoms by $X^{(1)}$ atoms, p_2 hydrogen atoms by $X^{(2)}$ atoms, ..., p_t hydrogen atoms by $X^{(t)}$ atoms, and one hydrogen atom by Y (so as to plant the trees). Doing so would require to define the class $S_{q_1, \ldots, q_t}$ for each $q_1 \leq p_1$, ..., $q_t \leq p_t$, and for each $q_1 \leq p_1$, ..., $q_t \leq p_t$, to write a recursion involving partitions into 4 parts of the multiset { $X^{(1)}$ (q_1 times), ..., $X^{(t)}$ (q_t times)}. When the q_i 's are given, those partitions can be computed by a call to combstruct[allstructs] . It follows that we would describe and generate the grammar for multiply substituted alkyls in terms of the grammar for partitions into 4 parts!

balls.mws

BALLS AND URNS, ETC.

Philippe Flajolet

(Version of December 14, 1996)

Balls and urns models are basic in combinatorics, statistics, analysis of algorithms, and statistical physics. These models are nicely decomposable and their basic properties can be explored using tools developed for the automatic manipulation of combinatorial models, like Combstruct .

As is well-known there are four types of models, depending on whether balls and urns are taken to be distinguishable or not.

The four basic models

We consider the placement of balls into urns in all possible ways. For definiteness, we examine only the situation of nonempty urns, so that the number of possible configurations of a fixed size (i.e., a fixed number of balls) is always finite. If the balls are distinguishable, we may assume them to be numbered consecutively by integers 1, 2, ..., n ; in this case, we are dealing with labelled structures, and balls are labelled atoms. If the balls are indistinguishable, then we simply regard them as anonymous unlabelled atoms (generically called Z , by a global convention of Combstruct). If the urns are distinguishable, we may view them as arranged in a row, so that we are dealing with a Sequence construction; otherwise, we have a Set construction. (The Set construction of Combstruct means a multiset, that is to say a set where repetitions are allowed.)

Balls are not ordered within an urn, so that an urn is a priori a Set of balls. This gives rise to four different models:

DBDU: distinguishable balls and distinguishable urns; we are dealing with Sequences of Sets, in a labelled universe;

DBIU: distinguishable balls and indistinguishable urns; we are dealing with Sets of Sets, in a labelled universe;

IBDU: indistinguishable balls and distinguishable urns; we are dealing with Sequences of Sets, in an unlabelled universe;

IBIU: indistinguishable balls and indistinguishable urns; we are dealing with Sets of Sets, in an unlabelled universe.

In combstruct, this is expressed by four different, but similar looking, specifications:

```
> with(combstruct);
```

```
[allstructs, count, draw, finished, gfeqns, gfseries, gfsolve,
iterstructs, nextstruct, prog_gfeqns, prog_gfseries, prog_gfsolve]
```

```
> DBDU:=[S,{S=Sequence(U),U=Set(Z,card>=1)},labelled]:

> DBIU:=[S,{S=Set(U),U=Set(Z,card>=1)},labelled]:

> IBDU:=[S,{S=Sequence(U),U=Set(Z,card>=1)},unlabelled]:

> IBIU:=[S,{S=Set(U),U=Set(Z,card>=1)},unlabelled]:

> for spec in DBDU,DBIU,IBDU,IBIU do draw(spec,size=10) od;
```

Sequence(Set(Z_4), Set(Z_3), Set(Z_5), Set(Z_9, Z_7), Set(Z_2),

$$\mathrm{Set}(\mathrm{Set}(Z_8), \mathrm{Set}(Z_1), \mathrm{Set}(Z_{10}, Z_6))$$

$$\mathrm{Set}(\mathrm{Set}(Z_5), \mathrm{Set}(Z_2, Z_8, Z_{10}), \mathrm{Set}(Z_3, Z_9, Z_7), \mathrm{Set}(Z_4, Z_1, Z_6))$$

$$\mathrm{Sequence}(\mathrm{Set}(Z, Z), \mathrm{Set}(Z, Z, Z, Z, Z, Z, Z), \mathrm{Set}(Z))$$

$$\mathrm{Set}(\mathrm{Set}(Z), \mathrm{Set}(Z), \mathrm{Set}(Z, Z), \mathrm{Set}(Z, Z), \mathrm{Set}(Z, Z, Z, Z))$$

The corresponding counting sequences satisfy natural domination conditions that one can summarize by the informal inequality: "Distinguishable>Indistinguishable"

```
> for spec in DBDU,DBIU,IBDU,IBIU do seq(count(spec,size=j),j=1..12) od;
```

1, 3, 13, 75, 541, 4683, 47293, 545835, 7087261, 102247563, 1622632573, 28091567595

1, 2, 5, 15, 52, 203, 877, 4140, 21147, 115975, 678570, 4213597

1, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, 2048

1, 2, 3, 5, 7, 11, 15, 22, 30, 42, 56, 77

In the sequel, it is convenient to represent objects by a more concise notation. We thus introduce "reduction" procedures for labelled and unlabelled objects:

```
> lreduce:=proc(e) eval(subs({Set=proc() {args} end, Sequence=proc() [args] end},e)) end:
ureduce:=proc(e) eval(subs({Set=proc() {[args]} end, Sequence=proc() [args] end},e)) end:
```

Since the set construction "{}" in Maple does not keep multisets, an unlabelled (multi) set will be represented as "{[...]}".

```
> for spec in DBDU,DBIU do lreduce(draw(spec,size=25)) od;
for spec in IBDU,IBIU do ureduce(draw(spec,size=25)) od;
```

$$[\{Z_{24}\}, \{Z_{11}\}, \{Z_{14}\}, \{Z_5\}, \{Z_{25}\}, \{Z_7, Z_{20}\}, \{Z_2\}, \{Z_4\}, \{Z_{13}\}, \{Z_{17}\}, \{Z_1\}, \{Z_3\}, \{Z_{18}\}, \{Z_{10}\}, \{Z_{23}\}, \{Z_9\}, \{Z_{21}\}, \{Z_{19}\}, \{Z_{22}\}, \{Z_8, Z_{15}\}, \{Z_{12}\}, \{Z_6\}, \{Z_{16}\}]$$

$$\{\{Z_2\}, \{Z_{19}\}, \{Z_9, Z_{21}\}, \{Z_1, Z_{11}\}, \{Z_4, Z_{20}\}, \{Z_{24}, Z_{12}\}, \{Z_3, Z_{10}, Z_{22}, Z_{15}\}, \{Z_{13}, Z_{23}\}, \{Z_8, Z_{17}, Z_{18}\}, \{Z_5, Z_7, Z_{14}, Z_{16}\}, \{Z_6, Z_{25}\}\}$$

$$[\{[Z, Z, Z, Z, Z, Z]\}, \{[Z]\}, \{[Z]\}, \{[Z]\}, \{[Z, Z, Z]\}, \{[Z, Z, Z]\}, \{[Z, Z]\}, \{[Z]\}, \{[Z]\}, \{[Z, Z, Z]\}, \{[Z, Z, Z]\}]$$

$$\{[\{[Z, Z, Z]\}, \{[Z, Z, Z]\}, \{[Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z]\}, \{[Z, Z]\}]\}$$

On such simulations, we see that there tends to be fewer urns in models of type IU, but more filled ones.

Distinguishable balls (labelled structures)

Distinguishable urns

In this model, we deal with distinguishable balls (labelled atoms) that go in all possible way into distinguishable urns corresponding to the specification:

```
> DBDU:=[S,{S=Sequence(U),U=Set(Z,card>=1)},labelled]:
```

Combinatorially, this model is the same as of Surjections from $[1 .. n]$ to an initial segment of the integers. It is the one that leads to larger cardinality counts.

```
> for j to 3 do j=map(lreduce,allstructs(DBDU,size=j)) od;
```

$$1 = [[\{Z_1\}]]$$

$$2 = [[\{Z_2\}, \{Z_1\}], [\{Z_1\}, \{Z_2\}], [\{Z_2, Z_1\}]]$$

$$3 = [[\{Z_3, Z_2, Z_1\}], [\{Z_1\}, \{Z_3\}, \{Z_2\}], [\{Z_2\}, \{Z_1\}, \{Z_3\}], [\{Z_3, Z_2\}, \{Z_1\}], [\{Z_3\}, \{Z_2, Z_1\}], [\{Z_3, Z_1\}, \{Z_2\}], [\{Z_1\}, \{Z_3, Z_2\}], [\{Z_2\}, \{Z_3, Z_1\}], [\{Z_3\}, \{Z_1\}, \{Z_2\}], [\{Z_3\}, \{Z_2\}, \{Z_1\}], [\{Z_2\}, \{Z_3\}, \{Z_1\}], [\{Z_2, Z_1\}, \{Z_3\}], [\{Z_1\}, \{Z_2\}, \{Z_3\}]]$$

```
> seq(count(DBDU,size=j),j=0..30);
```

1, 1, 3, 13, 75, 541, 4683, 47293, 545835, 7087261, 102247563, 1622632573, 28091567595, 526858348381, 10641342970443, 230283190977853, 5315654681981355, 130370767029135901, 3385534663256845323, 92801587319328411133, 2677687796244384203115, 81124824998504073881821, 2574844419803190384544203, 85438451336745709294580413, 2958279121074145472650648875, 106697365438475775825583498141, 4002225759844168492486127539083, 155897763918621623249276226253693, 6297562064950066033518373935334635, 263478385263023690020893329044576861, 11403568794011880483742464196184901963

Such tables are quite useful for checking various combinatorial conjectures. Here, we may verify that these numbers are the sequence **M2952** of the *Encyclopedia of Integer Sequences* by Sloane and Plouffe, where they are known as the numbers of preferential arrangements of n things.

The counting problem is solved automatically by combstruct[gfeqns] , combstruct [gfseries] (a series alternative to combstruct[count]) and combstruct[gfsolve] :

```
> gfeqns(op(2..3,DBDU),z);
```

$$\left[U(z) = e^{Z(z)} - 1,\ S(z) = \frac{1}{1 - U(z)},\ Z(z) = z \right]$$

```
> Order:=12: gfseries(op(2..3,DBDU),z);
```

$$\text{table}([$$

$$S(z) = 1 + z + \frac{3}{2}z^2 + \frac{13}{6}z^3 + \frac{25}{8}z^4 + \frac{541}{120}z^5 + \frac{1561}{240}z^6 + \frac{47293}{5040}z^7 + \frac{36389}{2688}z^8 + \frac{7087261}{362880}z^9 + \frac{34082521}{1209600}z^{10} + \frac{1622632573}{39916800}z^{11} + O(z^{12})$$

$$U(z) = z + \frac{1}{2}z^2 + \frac{1}{6}z^3 + \frac{1}{24}z^4 + \frac{1}{120}z^5 + \frac{1}{720}z^6 + \frac{1}{5040}z^7 + \frac{1}{40320}z^8 + \frac{1}{362880}z^9 + \frac{1}{3628800}z^{10} + \frac{1}{39916800}z^{11} + O(z^{12})$$

$$Z(z) = z\ ])$$

```
> gfsolve(op(2..3,DBDU),z);
```

$$\left\{ S(z) = -\frac{1}{-2 + e^z},\ Z(z) = z,\ U(z) = e^z - 1 \right\}$$

In particular, we have found the exponential generating function (EGF) explicitly:

```
> S_z:=subs(",S(z)); series(S_z,z=0,7);
```

$$S\_z := -\frac{1}{-2 + e^z}$$

$$1 + z + \frac{3}{2}z^2 + \frac{13}{6}z^3 + \frac{25}{8}z^4 + \frac{541}{120}z^5 + \frac{1561}{240}z^6 + O(z^7)$$

The EGF is singular with a pole at $z = \ln(2)$. This immediately gives an approximate expression for the coefficients:

```
> series(S_z,z=log(2),3);
```

$$-\frac{1}{2}(z - \ln(2))^{-1} + \frac{1}{4} + O(z - \ln(2))$$

```
> S_n_asympt:=1/2*n!*log(2)^(-n-1);
```

$$S\_n\_asympt := \frac{1}{2}n!\ln(2)^{(-n-1)}$$

As usual with meromorphic functions, the approximation is extremely good:

```
> for j from 0 by 5 to 30 do j,evalf(count(DBDU,size=j)/subs(n=j,
S_n_asympt),30); od;
```

This type of analysis can be easily generalized to determine for instance the expected number of urns in a random surjection. Such analyses may then be used to validate an a priori statistical model by comparing theoretical predictions against empirical data.

Indistinguishable urns (set partitions)

We are now dealing with indistinguishable urns. Equivalently, we consider the way n elements (the labels 1, ..., n) may be grouped into equivalence classes in all possible ways.

```
> DBIU:=[S,{S=Set(U),U=Set(Z,card>=1)},labelled]:
```

```
> for j to 4 do j=map(lreduce,allstructs(DBIU,size=j)) od;
```

$$1 = [\{\{Z_1\}\}]$$

$$2 = [\{\{Z_1\}, \{Z_2\}\}, \{\{Z_2, Z_1\}\}]$$

$$3 = [\{\{Z_1\}, \{Z_3, Z_2\}\}, \{\{Z_2, Z_1\}, \{Z_3\}\}, \{\{Z_3, Z_2, Z_1\}\}, \{\{Z_2\}, \{Z_3, Z_1\}\}, \{\{Z_1\}, \{Z_2\}, \{Z_3\}\}]$$

$$4 = [\{\{Z_3, Z_2, Z_1\}, \{Z_4\}\}, \{\{Z_2\}, \{Z_3\}, \{Z_1, Z_4\}\}, \{\{Z_1\}, \{Z_2\}, \{Z_3, Z_4\}\}, \{\{Z_2\}, \{Z_3, Z_1, Z_4\}\}, \{\{Z_1\}, \{Z_3, Z_2, Z_4\}\}, \{\{Z_1\}, \{Z_2\}, \{Z_3\}, \{Z_4\}\}, \{\{Z_2, Z_1\}, \{Z_3\}, \{Z_4\}\}, \{\{Z_1\}, \{Z_3\}, \{Z_2, Z_4\}\}, \{\{Z_3, Z_2, Z_1, Z_4\}\}, \{\{Z_2, Z_1\}, \{Z_3, Z_4\}\}, \{\{Z_3\}, \{Z_2, Z_1, Z_4\}\}, \{\{Z_3, Z_1\}, \{Z_2, Z_4\}\}, \{\{Z_1\}, \{Z_3, Z_2\}, \{Z_4\}\}, \{\{Z_3, Z_2\}, \{Z_1, Z_4\}\}, \{\{Z_2\}, \{Z_3, Z_1\}, \{Z_4\}\}]$$

```
> seq(count(DBIU,size=j),j=0..30);
```

1, 1, 2, 5, 15, 52, 203, 877, 4140, 21147, 115975, 678570, 4213597, 27644437, 190899322, 1382958545, 10480142147, 82864869804, 682076806159, 5832742205057, 51724158235372,

84674901451180933245014 7

Such tables are quite useful for checking various combinatorial conjectures. Here, we may verify that these numbers are the sequence **M1484** of the *Encyclopedia of Integer Sequences* by Sloane and Plouffe. They are the well-known Bell numbers of combinatorial theory that also appear as moments of the Poisson distribution, in the calculus of finite differences, etc.

We automatically obtain the exponential generating function as

```
> gfsolve(op(2..3,DBIU),z);
```

$$\{Z(z) = z,\ U(z) = e^{z} - 1,\ S(z) = e^{(e^{z} - 1)}\}$$

```
> P_z:=subs(',S(z));
```

$$P\_z := e^{(e^{z} - 1)}$$

```
> series(P_z,z=0,8);
```

$$1 + z + z^2 + \frac{5}{6}z^3 + \frac{5}{8}z^4 + \frac{13}{30}z^5 + \frac{203}{720}z^6 + \frac{877}{5040}z^7 + O(z^8)$$

```
> Order:=8: gfseries(op(2..3,DBIU),z);
```

table([$S(z) =$

$$1 + z + z^2 + \frac{5}{6}z^3 + \frac{5}{8}z^4 + \frac{13}{30}z^5 + \frac{203}{720}z^6 + \frac{877}{5040}z^7 + O(z^8)$$

$U(z) =$

$$z + \frac{1}{2}z^2 + \frac{1}{6}z^3 + \frac{1}{24}z^4 + \frac{1}{120}z^5 + \frac{1}{720}z^6 + \frac{1}{5040}z^7 + O(z^8)$$

$Z(z) = z$])

By expanding and truncating, we obtain excellent approximations (this is in fact a version of a formula found by Dobinski in 1877):

```
> P_n_asympt:=exp(-1)*Sum(k^n/k!,k=0..2*n);
for j by 3 to 20 do j,evalf(count(DBIU,size=j)/subs(n=j,P_n_asympt),30); od;
```

$$P\_n\_asympt := e^{(-1)}\left(\sum_{k=0}^{2n} \frac{k^n}{k!}\right)$$

19, 1.00000000000000000000000000001

Indistinguishable balls (unlabelled structures)

Distinguishable urns (integer compositions)

We start from the specification

> **IBDU:=[S,{S=Sequence(U),U=Sequence(Z,card>=1)},unlabelled]:**

In this particular case, as balls are indistinguishable, we may as well consider urns as Sequence of atoms. The reason for doing this is a simpler form of generating functions (as we do not have to go unnecessarily through Polya operators) as well as faster computations. We can check that this new version is equivalent to the earlier one, namely

> **IBDU_0:=[S,{S=Sequence(U),U=Set(Z,card>=1)},unlabelled]:**

> **seq(count(IBDU,size=j),j=0..20); seq(count(IBDU_0,size=j),j=0..20);**

1, 1, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, 2048, 4096, 8192, 16384, 32768, 65536, 131072, 262144, 524288

1, 1, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, 2048, 4096, 8192, 16384, 32768, 65536, 131072, 262144, 524288

Of course, here we recognize the powers of two: the result is combinatorially obvious since

a partition can be obtained by inserting arbitrary cuts in the integer interval 1, ..., n .

We can also check this with combstruct[gfsolve]

> **gfsolve(op(2..3,IBDU),z);**

$$\{Z(z) = z,\ S(z) = \frac{-1+z}{-1+2z},\ U(z) = -\frac{z}{-1+z}\}$$

> **SS_z:=subs('',S(z));**

$$SS\_z := \frac{-1+z}{-1+2z}$$

> **series(SS_z,z=0,10);**

$$1 + z + 2z^2 + 4z^3 + 8z^4 + 16z^5 + 32z^6 + 64z^7 + 128z^8 + 256z^9 + O(z^{10})$$

Indistinguishable urns (integer partitions)

We start from the specification

> **IBIU:=[S,{S=Set(U),U=Sequence(Z,card>=1)},unlabelled]:**

Combinatorially, we are specifying integer partitions that describe the occupancy profile of urns.

> **for j to 6 do j=map(ureduce,allstructs(IBIU,size=j)) od;**

$$1 = [\{[[Z]]\}]$$

$$2 = [\{[[Z], [Z]]\}, \{[[Z, Z]]\}]$$

$$3 = [\{[[Z, Z, Z]]\}, \{[[Z], [Z], [Z]]\}, \{[[Z, Z], [Z]]\}]$$

$$4 = [\{[[Z, Z], [Z, Z]]\}, \{[[Z, Z, Z], [Z]]\}, \{[[Z, Z], [Z], [Z]]\}, \{[[Z], [Z], [Z], [Z]]\}, \{[[Z, Z, Z, Z]]\}]$$

$$5 = [\{[[Z, Z, Z], [Z, Z]]\}, \{[[Z, Z], [Z, Z], [Z]]\}, \{[[Z, Z], [Z], [Z], [Z]]\}, \{[[Z, Z, Z, Z, Z]]\}, \{[[Z], [Z, Z, Z, Z]]\}, \{[[Z, Z, Z], [Z], [Z]]\}, \{[[Z], [Z], [Z], [Z], [Z]]\}]$$

$$6 = [\{[[Z], [Z], [Z], [Z], [Z], [Z]]\}, \{[[Z, Z, Z], [Z, Z, Z]]\}, \{[[Z, Z, Z], [Z], [Z], [Z]]\}, \{[[Z, Z], [Z, Z], [Z], [Z]]\}, \{[[Z, Z], [Z, Z], [Z, Z]]\}, \{[[Z], [Z], [Z, Z, Z, Z]]\}, \{[[Z, Z], [Z], [Z], [Z], [Z]]\}, \{[[Z, Z, Z], [Z, Z], [Z]]\}, \{[[Z], [Z, Z, Z, Z]]\}, \{[[Z, Z, Z, Z, Z]]\}, \{[[Z, Z], [Z, Z, Z]]\}]$$

Naturally, since we are dealing with sets of summands (the order does not count), we may as well regard these objects as an increasing sequence of summands that sum to the size n, or equivalently as "staircases" with size being the area below the staircase.

> **preduce:=proc(e) sort(eval(subs({Set=proc() [args] end, Sequence=proc() nargs end},e))) end:**

> **rand_part:=draw(IBIU,size=100): ureduce(rand_part); preduce(rand_part);**

$$\{[[Z, Z], [Z, Z], [Z, Z], [Z, Z], [Z, Z], [Z, Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z], [Z, Z, Z, Z, Z], [Z, Z, Z, Z, Z], [Z, Z, Z, Z, Z], [Z, Z, Z, Z, Z], [Z, Z, Z, Z, Z], [Z, Z, Z, Z, Z], [Z, Z, Z, Z, Z], [Z, Z, Z, Z, Z], [Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z], [Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z, Z]]\}$$

$$[1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 5, 5, 5, 5, 5, 5, 5, 14, 17]$$

There are much fewer structures than in previous models:

```
> seq(count(IBIU,size=j),j=0..30);
```

1, 1, 2, 3, 5, 7, 11, 15, 22, 30, 42, 56, 77, 101, 135, 176, 231, 297, 385, 490, 627, 792, 1002, 1255, 1575, 1958, 2436, 3010, 3718, 4565, 5604

The random generation process is nontrivial as one must generate objects up to certain symmetries. The first time, counting tables are set up on the fly, so that random generation takes a few seconds for size $n \leq 100$.

```
> for i from 0 by 20 to 100 do i,preduce(draw(IBIU,size=i)); od;
```

0, E

20, [1, 1, 1, 1, 1, 3, 4, 8]

40, [1, 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 4, 4, 6]

60, [1, 1, 2, 2, 2, 2, 2, 3, 4, 5, 5, 6, 12, 13]

80,
[1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 3, 3, 3, 3, 3, 3, 3, 4, 4, 5, 7, 13]

100, [1, 1, 1, 1, 1, 3, 3, 3, 3, 3, 3, 5, 5, 5, 10, 10, 11, 31]

Next, random generation becomes faster:

```
> for i to 10 do preduce(draw(IBIU,size=100)); od;
```

[1, 1, 1, 1, 1, 1, 1, 2, 6, 10, 12, 16, 22, 24]

[1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 3, 3, 3, 4, 4, 5, 9, 9, 17, 20]

[1, 1, 1, 1, 1, 1, 2, 3, 4, 4, 9, 11, 11, 18, 32]

[1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 4, 7, 7, 10, 12, 20, 25]

[1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 3, 3, 3, 3, 3, 3, 4, 4, 4, 4, 4, 4, 4, 4, 4, 10, 19]

[4, 4, 4, 4, 5, 6, 6, 9, 18, 20, 20]

[1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 3, 5, 5, 5, 5, 6, 6, 6, 6, 7, 14, 15]

[1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 3, 4, 5, 9, 10, 12, 13, 22]

[1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 3, 3, 4, 5, 5, 5, 7, 8, 12, 12, 18]

[1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 4, 4, 7, 14, 23, 28]

In this particular case, the random generation procedure that is automatically built by Combstruct coincides with a method especially designed by Wilf for integer partitions. By design, Combstruct accepts in full generality arbitrary compositions of Set and Cycle constructions (in addition to Union, Product, Sequence, etc).

The generating functions are now more complicated since they involve Polya operators.

> **gfeqns(op(2..3,IBIU),z);**

$$\left[U(z) = \frac{1}{1 - Z(z)} - 1,\ S(z) = e^{\left(\sum_{j_1 = 1}^{\infty} \frac{U\left(z^{j_1} \right)}{j_1} \right)},\ Z(z) = z \right]$$

> **gfsolve(op(2..3,IBIU),z);**

$$\left\{ Z(z) = z,\ U(z) = -\frac{z}{-1 + z},\ S(z) = e^{\left(\sum_{j_1 = 1}^{\infty} \left(-\frac{z^{j_1}}{\left(z^{j_1} - 1 \right) j_1} \right) \right)} \right\}$$

Such Polya operators are however known to combstruct[gfseries]

> **gfseries(op(2..3,IBIU),z);**

table([

$$S(z) = 1 + z + 2z^2 + 3z^3 + 5z^4 + 7z^5 + 11z^6 + 15z^7 + O(z^8)$$

$$U(z) = z + z^2 + z^3 + z^4 + z^5 + z^6 + z^7 + O(z^8)\ Z(z) = z\ ])$$

though they are not otherwise "known" to Maple

> **subs("",S(z)); series(",z=0);**

$$e^{\left(\sum_{j_1 = 1}^{\infty} \left(-\frac{z^{j_1}}{\left(z^{j_1} - 1 \right) j_1} \right) \right)}$$

Error, (in series/exp) unable to compute series

In such cases, one has to resort either to simplification by hand (not always possible) or to the literature. Here, it is very well known that the generating function of integer partitions is

> **PP_z:=Product(1/(1-z^k),k=1..infinity);**

$$PP\_z := \prod_{k=1}^{\infty} \frac{1}{1 - z^k}$$

> **Order:=12: series(subs(infinity=Order+2,PP_z),z=0);**

$$1 + z + 2z^2 + 3z^3 + 5z^4 + 7z^5 + 11z^6 + 15z^7 + 22z^8 + 30z^9 + 42z^{10} + 56z^{11} + O(z^{12})$$

Constrained models

Number of urns in surjections

The approach developed so far may be tuned to analyse a variety parameters. We explore here the way Combstruct may serve to analyse the number of urns as well as related situations with bounded urn capacity. We focus on counts and building numerical tables. Naturally, random generation and exhaustive listing are possible from any of these specifications.

We deal here with a fixed number of urns in the model DBDU that corresponds to surjections. Combinatorial specifications may actually be computed in Maple, then used by Combstruct.

The following procedure computes the specifications with r urns.

> **surj:=[S,{S=Sequence(U,card=r),U=Set(Z,card>=1)}, labelled]: subs(r=5,surj);**

$$[S, \{U = \mathrm{Set}(Z, 1 \le card), S = \mathrm{Sequence}(U, card = 5)\}, labelled]$$

In passing, this illustrates the use of cardinality modifiers for Sequence, Set, and Cycle constructions.

The following counts imply the first few values of the probability distribution of the number of urns in a random unconstrained surjection:

> **for i to 5 do seq(count(subs(r=i,surj),size=m),m=0..10) od;**

0, 1, 1, 1, 1, 1, 1, 1, 1, 1

0, 0, 2, 6, 14, 30, 62, 126, 254, 510, 1022

0, 0, 0, 6, 36, 150, 540, 1806, 5796, 18150, 55980

0, 0, 0, 0, 24, 240, 1560, 8400, 40824, 186480, 818520

0, 0, 0, 0, 0, 120, 1800, 16800, 126000, 834120, 5103000

and we may build tables of probability distributions automatically:

> **for i to 7 do seq(evalf(count(subs(r=i,surj),size=m)/count(DBDU,size=m),4), m=0..10) od;**

$$0, 1., .3333, .07692, .01333, .001848, .0002135, .00002114, .1832\,10^{-5}, .1411\,10^{-6}, .9780\,10^{-8}$$

$$0, 0, .6667, .4615, .1867, .05545, .01324, .002664, .0004653, .00007196, .9995\,10^{-5}$$

$$0, 0, 0, .4615, .4800, .2773, .1153, .03819, .01062, .002561, .0005475$$

$$0, 0, 0, 0, .3200, .4436, .3331, .1776, .07479, .02631, .008005$$

$$0, 0, 0, 0, 0, .2218, .3844, .3552, .2308, .1177, .04991$$

$$0, 0, 0, 0, 0, 0, .1537, .3197, .3509, .2688, .1607$$

$$0, 0, 0, 0, 0, 0, 0, .1066, .2585, .3285, .2898$$

Finally, we are led to rediscover the corresponding generating functions. Usually, this is done via recurrence computations, and what we obtain here is equivalent to the EGF of Stirling second kind (partition) numbers :

```
> for i to 5 do gfsolve(op(2,subs(r=i,surj)),labelled,z) od;
```

$$\{U(z) = e^z - 1, Z(z) = z, S(z) = e^z - 1\}$$

$$\{U(z) = e^z - 1, Z(z) = z, S(z) = (e^z)^2 - 2e^z + 1\}$$

$$\{U(z) = e^z - 1, Z(z) = z, S(z) = (e^z)^3 - 3(e^z)^2 + 3e^z - 1\}$$

$$\{U(z) = e^z - 1, Z(z) = z, S(z) = (e^z)^4 - 4(e^z)^3 + 6(e^z)^2 - 4e^z + 1\}$$

$$\{U(z) = e^z - 1, S(z) = (e^z)^5 - 5(e^z)^4 + 10(e^z)^3 - 10(e^z)^2 + 5e^z - 1, Z(z) = z\}$$

This suggests a pattern involving Pascal's triangle:

```
> Surj_z:=proc(k) local j; add(binomial(k,j)*(-1)^(k-j)*exp(z)^j,j=0..k) end:
```

```
> Surj_z(6); gfsolve(op(2,subs(r=6,surj)),labelled,z);
```

$$1 - 6e^z + 15(e^z)^2 - 20(e^z)^3 + 15(e^z)^4 - 6(e^z)^5 + (e^z)^6$$

$$\{U(z) = e^z - 1, Z(z) = z, S(z) = 1 - 6e^z + 15(e^z)^2 - 20(e^z)^3 + 15(e^z)^4 - 6(e^z)^5 + (e^z)^6\}$$

For coefficients finally, we have by straight expansion

$$\sum_{j=0}^{k} \text{binomial}(k,j)\,(-1)^{(k-j)}\,j^{n}.$$

```
> Surj_nk:=proc(n,k) local j; `if`(n<>0,add(binomial(k,j)*(-1)^(k-j)*j^n,j=0..
k),1) end:
```

The formula matches the values obtained by combstruct[gfseries]

```
> Order:=16: gfseries(op(2..3,subs(r=7,surj)),z);
```

$$\text{table}([$$

$$S(z) = z^{7} + \frac{7}{2}z^{8} + \frac{77}{12}z^{9} + \frac{49}{6}z^{10} + \frac{1939}{240}z^{11} + \frac{4753}{720}z^{12} + \frac{1249}{270}$$

$$z^{13} + \frac{77}{27}z^{14} + \frac{136111}{86400}z^{15} + O(z^{16})$$

$$U(z) = z + \frac{1}{2}z^{2} + \frac{1}{6}z^{3} + \frac{1}{24}z^{4} + \frac{1}{120}z^{5} + \frac{1}{720}z^{6} + \frac{1}{5040}z^{7} +$$

$$\frac{1}{40320}z^{8} + \frac{1}{362880}z^{9} + \frac{1}{3628800}z^{10} + \frac{1}{39916800}z^{11} +$$

$$\frac{1}{479001600}z^{12} + \frac{1}{6227020800}z^{13} + \frac{1}{87178291200}z^{14} +$$

$$\frac{1}{1307674368000}z^{15} + O(z^{16}) \quad Z(z) = z\ ])$$

```
> seq(Surj_nk(n,7)/n!,n=0..15);
```

$$1, 0, 0, 0, 0, 0, 0, 1, \frac{7}{2}, \frac{77}{12}, \frac{49}{6}, \frac{1939}{240}, \frac{4753}{720}, \frac{1249}{270}, \frac{77}{27}, \frac{136111}{86400}$$

Number of parts in integer compositions

This is the model IBDU.

```
> comp_r:=[S,{S=Sequence(U,card=r),U=Sequence(Z,card>=1)},unlabelled]:
```

```
> for i to 5 do seq(count(subs(r=i,comp_r),size=m),m=0..15) od;
```

$$0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1$$

$$0, 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14$$

$$0, 0, 0, 1, 3, 6, 10, 15, 21, 28, 36, 45, 55, 66, 78, 91$$

$$0, 0, 0, 0, 1, 4, 10, 20, 35, 56, 84, 120, 165, 220, 286, 364$$

$$0, 0, 0, 0, 0, 1, 5, 15, 35, 70, 126, 210, 330, 495, 715, 1001$$

```
> for i to 5 do subs(gfsolve(op(2,subs(r=i,comp_r)),labelled,z),S(z)) od;
```

$$-\frac{z}{-1+z}$$

$$\frac{z^2}{(-1+z)^2}$$

$$-\frac{z^3}{(-1+z)^3}$$

$$\frac{z^4}{(-1+z)^4}$$

$$-\frac{z^5}{(-1+z)^5}$$

The pattern is obvious and this corresponds to an explicit (and well-known!) binomial formula for the coefficients.

Number of parts in integer partitions

This is the model IBIU.

```
> part_r:=[S,{S=Set(U,card=r),U=Sequence(Z,card>=1)}, unlabelled]:
```

We can build tables, like before

```
> for i to 5 do seq(count(subs(r=i,part_r),size=m),m=0..15) od;
```

0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1

0, 0, 1, 1, 2, 2, 3, 3, 4, 4, 5, 5, 6, 6, 7, 7

0, 0, 0, 1, 1, 2, 3, 4, 5, 7, 8, 10, 12, 14, 16, 19

0, 0, 0, 0, 1, 1, 2, 3, 5, 6, 9, 11, 15, 18, 23, 27

0, 0, 0, 0, 0, 1, 1, 2, 3, 5, 7, 10, 13, 18, 23, 30

The generating functions are found by combstruct[gfsolve] to be rational:

```
> for i to 5 do gfsolve(op(2,subs(r=i,part_r)),unlabelled,z) od;
```

$$\{Z(z)=z,\ U(z)=-\frac{z}{-1+z},\ S(z)=-\frac{z}{-1+z}\}$$

$$\{Z(z)=z,\ U(z)=-\frac{z}{-1+z},\ S(z)=\frac{z^2}{z^3-z^2-z+1}\}$$

$$\{Z(z) = z,\ U(z) = -\frac{z}{-1+z},\ S(z) = -\frac{z^3}{z^6 - z^5 - z^4 + z^2 + z - 1}\}$$

$$\{Z(z) = z,\ U(z) = -\frac{z}{-1+z},$$
$$S(z) = \frac{z^4}{z^{10} - z^9 - z^8 + 2z^5 - z^2 - z + 1}\}$$

$$\{Z(z) = z,\ U(z) = -\frac{z}{-1+z},\ S(z) =$$
$$-\frac{z^5}{z^{15} - z^{14} - z^{13} + z^{10} + z^9 + z^8 - z^7 - z^6 - z^5 + z^2 + z - 1}\}$$

The form is then easily inferred from the factored representations, as one recognizes cyclotomic polynomials.

```
> S5_z:=subs(',S(z));
```

$$S5\_z := -\frac{z^5}{z^{15} - z^{14} - z^{13} + z^{10} + z^9 + z^8 - z^7 - z^6 - z^5 + z^2 + z - 1}$$

```
> factor(S5_z); series(',z=0,20);
```

$$-z^5 \Big/ ((-1+z)^5 (z+1)^2 (z^2+z+1)(z^2+1)$$
$$(z^4+z^3+z^2+z+1))$$

$$z^5 + z^6 + 2z^7 + 3z^8 + 5z^9 + 7z^{10} + 10z^{11} + 13z^{12} + 18z^{13} + 23$$
$$z^{14} + 30z^{15} + 37z^{16} + 47z^{17} + 57z^{18} + 70z^{19} + O(z^{20})$$

```
> z^5/mul(1-z^i,i=1..5); factor('); series(',z=0,20);
```

$$\frac{z^5}{(1-z)(1-z^2)(1-z^3)(1-z^4)(1-z^5)}$$

$$-z^5 \Big/ ((-1+z)^5 (z+1)^2 (z^2+z+1)(z^2+1)$$
$$(z^4+z^3+z^2+z+1))$$

$$z^5 + z^6 + 2z^7 + 3z^8 + 5z^9 + 7z^{10} + 10z^{11} + 13z^{12} + 18z^{13} + 23$$
$$z^{14} + 30z^{15} + 37z^{16} + 47z^{17} + 57z^{18} + 70z^{19} + O(z^{20})$$

Bounded capacity in the DBDU model (hashing)

We now consider configurations where the number of urns is a fixed number r, so that one can relax the constraint that urns need to be nonempty. We are thus dealing with the collection of the r^n functions of $[1 .. r]$ to $[1 .. r]$, not necessarily surjections. Such specifications also describe words (size being length) on an alphabet of cardinality r and this may be used to model hashing sequences in a table of length r. The set of all possible sequences (r fixed) is specified by

```
> hash_r:=[S,{S=Prod(U$r),U=Set(Z)},labelled]: subs(r=10,hash_r);
```

$$[S, \{S = \mathrm{Prod}(U \$ 10), U = \mathrm{Set}(Z)\}, \mathit{labelled}]$$

Here, we use a hack, with Prod instead of "Sequence" with fixed cardinality, since the current version of Combstruct does not accept Sequence applied to an argument that leads to an Epsilon structure, even in the case of a bounded cardinality modifier.

We change the reduction procedure to take this new construct into account.

```
> lreduce:=proc(e) eval(subs({Set=proc() {args} end, Prod=proc() [args] end},e)) end:
ureduce:=proc(e) eval(subs({Set=proc() {[args]} end, Sequence=proc() [args] end,
Prod=proc() [args] end},e)) end:
```

The number of objects of size n is, as predicted, 10^n.

```
> seq(count(subs(r=10,hash_r),size=j),j=0..10);
```

$$1, 10, 100, 1000, 10000, 100000, 1000000, 10000000, 100000000, 1000000000, 10000000000$$

Next, we consider urns with a bounded maximum capacity b:

```
> hash_br:=[S,{S=Prod(U$r),U=Set(Z,card<=b)}, labelled]: subs({r=5,b=3},
hash_br);
```

$$[S, \{S = \mathrm{Prod}(U \$ 5), U = \mathrm{Set}(Z, \mathit{card} \le 3)\}, \mathit{labelled}]$$

Such specifications also describe words (size being length) on an alphabet of cardinality r, given that no letter is used more than b times. This models hashing sequences in a table of length r when pages have capacity b.

```
> lreduce(draw(subs(r=10,hash_r),size=30));
```

$$[\{Z_{25}, Z_{28}\}, \{Z_9, Z_{17}, Z_5, Z_{30}, Z_{23}\}, \{Z_{29}, Z_6, Z_{13}\}, \{Z_7\}, \{Z_{14}, Z_1, Z_{18}, Z_{24}, Z_{22}\}, \{Z_{21}, Z_{10}, Z_{11}\}, \mathrm{E}, \{Z_{19}, Z_2, Z_{16}, Z_{26}, Z_{27}\}, \{Z_4, Z_{20}, Z_{12}\}, \{Z_3, Z_{15}, Z_8\}]$$

```
> lreduce(draw(subs({r=10,b=4},hash_br),size=30));
```

$$[\{Z_{14}, Z_9, Z_{24}\}, \{Z_{19}, Z_5, Z_{22}, Z_{15}\}, \{Z_2, Z_6, Z_{16}, Z_{27}\},$$

$$\{Z_{23}, Z_{26}\}, \{Z_{29}, Z_{25}\}, \{Z_{21}, Z_7, Z_{30}, Z_{18}\}, \{Z_1, Z_4, Z_{17}\},$$
$$\{Z_3, Z_{12}\}, \{Z_{10}, Z_{11}, Z_{20}\}, \{Z_{28}, Z_{13}, Z_8\}]$$

The following command automatically creates a table of maximum urn occupancy: the j -th entry in the b -th line is the probability that j balls thrown into 10 urns fit into urns of capacity b .

```
> for i 1 to 6 do seq(evalf(count(subs({r=10,b=i},hash_br),size=j)/count(subs
(r=10,hash_r),size=j),4),j=0..20); od;
```

Syntax error, unexpected number

Naturally, Combstruct automatically recognizes "impossible" configurations:

```
> draw(subs({r=10,b=3},hash_br),size=31);
```

Error, (in combstruct/drawgrammar) there is no structure of this size

Bounded capacity in the IBDU model (bosons)

This is a model of integer compositions. (A more sophisticated example that is related to submarine detection is treated below.) We consider here a fixed number r of urns and this is exactly the so-called "Bose-Einstein" model of statistical physics, where the corresponding objects are called bosons.

Mark Kobrak, a chemist at the University of Chicago wrote to us (December 13, 1996):

The basic problem is this: I am interested in simulating a problem in laser spectroscopy. A molecule has n modes, and I need to generate every possible combination which places up to m quanta in each mode. As I go through each one, I will analyze its energy.
This is exactly like a problem where, given n jars, you may put up to m marbles in each jar. The marbles are indistinguishable. I know how to count the number of combinations, but I need a good way to program a computer to go through all these combinations.

We let again r denote the number of urns and b the bucket capacity, i.e., the maximum number of urns that may fit into any given urn. We have the model of integer compositions:

```
> boson_br:=[S,{S=Prod(U$r),U=Sequence(Z,card<=b)}, unlabelled]: subs({r=5,
b=3},boson_br);
```

$$[S, \{U = \text{Sequence}(Z, card \le 3), S = \text{Prod}(U\ \$\ 5)\}, unlabelled]$$

For instance, here are all the 95 possible ways of putting j marbles ($j \le 4$) into $r = 5$ jars, each jar being of maximum capacity $b = 2$.

```
> seq(count(subs({r=5,b=2},boson_br),size=j),j=1..4);
```

$$5, 15, 30, 45$$

```
> for j to 4 do j=map(ureduce,allstructs(subs({r=5,b=2},boson_br),size=j)) od;
```

Stack polyominoes

Polyominoes are familiar objects of combinatorial mathematics. A stack polyomino or *stack* is a piling up of nonempty integer intervals, each interval being included in the previous one. The number of intervals comprising a stack are called the height; the total length of the intervals is called the size. For instance, the collection

```
> [1,12],[3,8],[4,7],[4,7],[6,7];
```

$$[1, 12], [3, 8], [4, 7], [4, 7], [6, 7]$$

is a stack of height 5 and size

```
> (12-1)+(8-3)+(7-4)+(7-4)+(7-6);
```

$$23$$

We may assume stacks to be left justified, starting at 1. Stacks of height exactly r are specified by ($r = 5$ in the example)

```
> stack:=[st,{st=Prod(left,right),left=Set(U,card=r),right=Set(U,card<r),
U=Sequence(Z,card>=1)},unlabelled]: subs(r=5,stack);
```

$$[st, \{left = \mathrm{Set}(U, card = 5), right = \mathrm{Set}(U, card < 5), st = \mathrm{Prod}(left, right), U = \mathrm{Sequence}(Z, 1 \le card)\}, unlabelled]$$

Combinatorially, we view a stack as an ascending staircase (the left part) of height r followed by a descending staircase (the right part) of height at most r. Staircases of fixed height are defined as partitions into bounded summands.

The distribution of height in stacks is for small height:

```
> for i to 6 do seq(count(subs(r=i,stack),size=m),m=0..20) od;
```

0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1

0, 0, 1, 2, 4, 6, 9, 12, 16, 20, 25, 30, 36, 42, 49, 56, 64, 72, 81, 90, 100

0, 0, 0, 1, 2, 5, 9, 16, 25, 39, 56, 80, 109, 147, 192, 249, 315, 396, 489, 600, 726

0, 0, 0, 0, 1, 2, 5, 10, 19, 32, 54, 84, 129, 190, 275, 386, 536, 726, 973, 1282, 1672

0, 0, 0, 0, 0, 1, 2, 5, 10, 20, 35, 61, 99, 159, 244, 369, 541, 784, 1109, 1551, 2131

0, 0, 0, 0, 0, 0, 1, 2, 5, 10, 20, 36, 64, 106, 174, 274, 425, 640, 952, 1384, 1989

The total number of stacks is:

```
> for i to 6 do for m from 0 to 10 do stnum[i,m]:=count(subs(r=i,stack),size=m)
od od: for m to 6 do m,convert([seq(stnum[i,m],i=1..6)],`+`) od;
```

1, 1

2, 2

3, 4

4, 8

5, 15

6, 27

This is **M1102** of the *Encyclopedia of Integer Sequences* . The table given there is incomplete. However, from an earlier computation of generating functions, we have a formula for the generating function of all stacks:

```
> Q:=Product(1-z^k,k=1..n); Stack_z:=1+Sum(z^r/subs(n=r,Q)/subs(n=r-1,Q),
r=1..infinity);
```

$$Q := \prod_{k=1}^{n} (1 - z^k)$$

$$Stack\_z := 1 + \left(\sum_{r=1}^{\infty} \frac{z^r}{\left(\prod_{k=1}^{r} (1 - z^k) \right) \left(\prod_{k=1}^{r-1} (1 - z^k) \right)} \right)$$

```
> Order:=30: series(value(subs(infinity=Order+3,Stack_z)),z=0);
```

$$1 + z + 2z^2 + 4z^3 + 8z^4 + 15z^5 + 27z^6 + 47z^7 + 79z^8 + 130z^9 + 209z^{10} + 330z^{11} + 512z^{12} + 784z^{13} + 1183z^{14} + 1765z^{15} + 2604z^{16} + 3804z^{17} + 5504z^{18} + 7898z^{19} + 11240z^{20} + 15880z^{21} + 22277z^{22} + 31048z^{23} + 43003z^{24} + 59220z^{25} + 81098z^{26} + 110484z^{27} + 149769z^{28} + 202070z^{29} + O(z^{30})$$

A problem in submarine detection

Problem 68-16 that appeared in the 1968 volume of *SIAM Review* reads as follows:

Problem 68-16. A combinatorial Problem, by Melda Hayes (Ocean Technology Inc.).

In how many ways can n *identical balls be distributed in* r *boxes in a row such that each pair of adjacent boxes contains at least 4 balls? This problem arose in some work on submarine detection.*

The problem is thus relative to integer compositions with constrained summands. The constraints are reminiscent of maximum capacity problems but they concern

successive summands. For pedagogical reasons, we decompose the solution in two phases:

a problem of counting words over a 5-letter alphabet that translates the succession contraint;

the original problem.

The word counting problem

Consider an alphabet comprising letters

```
> A=seq(a.j,j=0..4);
```

$$A = (a0, a1, a2, a3, a4)$$

There $a.j$, for $j < 4$ represents symbolically a summand of size j ; the quantity $a4$ represents a summand of cardinality *at least* 4. The first grammar specifies words over the alphabet A such that the sum of indices of any two consecutive letters is at least 4.

```
> grammar1:=[Q4,{
seq(Q.i=Union(Epsilon,seq(Prod(a.j,Q.j),j=4-i..4)),i=0..4),
seq(a.j=Z,j=0..4)
},unlabelled];
```

$$grammar1 := [Q4, \{Q0 = \mathrm{Union}(\mathrm{E}, \mathrm{Prod}(a4, Q4)), Q1 = \mathrm{Union}(\mathrm{E}, \mathrm{Prod}(a3, Q3), \mathrm{Prod}(a4, Q4)), Q2 = \mathrm{Union}(\mathrm{E}, \mathrm{Prod}(a2, Q2), \mathrm{Prod}(a3, Q3), \mathrm{Prod}(a4, Q4)), a1 = Z, a3 = Z, a2 = Z, a4 = Z, a0 = Z, Q4 = \mathrm{Union}(\mathrm{E}, \mathrm{Prod}(a0, Q0), \mathrm{Prod}(a1, Q1), \mathrm{Prod}(a2, Q2), \mathrm{Prod}(a3, Q3), \mathrm{Prod}(a4, Q4)), Q3 = \mathrm{Union}(\mathrm{E}, \mathrm{Prod}(a1, Q1), \mathrm{Prod}(a2, Q2), \mathrm{Prod}(a3, Q3), \mathrm{Prod}(a4, Q4))\}, unlabelled]$$

The grammar above is just a translation of the finite automaton that recognizes the language of symbolic constraints. We can solve the counting problem easily.

```
> seq(count(grammar1,size=j),j=0..20);
```

$$1, 5, 15, 55, 190, 671, 2353, 8272, 29056, 102091, 358671, 1260143, 4427294, 15554592, 54648506, 191998646, 674555937, 2369942427, 8326406594, 29253473175, 102777312308$$

```
> gfsolve(op(2..3,grammar1),z);
```

$$\{Z(z) = z, Q4(z) = -\frac{-z^3 + 1 + 2z + z^4 - 3z^2}{-1 + 3z^2 - z^4 - 4z^3 + 3z + z^5}, a3(z) = z,$$

$$a4(z) = z, Q3(z) = \frac{-1 - z + z^2}{-1 + 3z^2 - z^4 - 4z^3 + 3z + z^5}, a2(z) = z,$$

$$Q2(z) = -\frac{1}{-1 + 3z^2 - z^4 - 4z^3 + 3z + z^5}, a0(z) = z,$$

$$Q0(z) = -\frac{1 - z^2 + z^3 - 2z}{-1 + 3z^2 - z^4 - 4z^3 + 3z + z^5},\ a1(z) = z,$$

$$Q1(z) = \frac{-1 + z}{-1 + 3z^2 - z^4 - 4z^3 + 3z + z^5}\}$$

The generating function of all words has been found to be

```
> Q_z:=factor(subs('',Q4(z)));
```

$$Q\_z := -\frac{(-1 + z)(z^3 - 3z - 1)}{-1 + 3z^2 - z^4 - 4z^3 + 3z + z^5}$$

```
> series(Q_z,z=0,20);
```

$$1 + 5z + 15z^2 + 55z^3 + 190z^4 + 671z^5 + 2353z^6 + 8272z^7 + 29056z^8 + 102091z^9 + 358671z^{10} + 1260143z^{11} + 4427294z^{12} + 15554592z^{13} + 54648506z^{14} + 191998646z^{15} + 674555937z^{16} + 2369942427z^{17} + 8326406594z^{18} + 29253473175z^{19} + O(z^{20})$$

The asymptotics results from locating the dominant pole:

```
> Digits:=30: fsolve(denom(Q_z),z);
```

$$-1.68250706566236233772362329784,$$
$$-.83083002600377285105854829 8459,$$
$$.28462967654657028088758533 7233,$$
$$1.30972146789057012811385014493,$$
$$1.91898594722899477978073611413$$

```
> rho:=fsolve(denom(Q_z),z,0..1);
```

$$\rho := .28462967654657028088758533 7233$$

```
> c:=-subs(z=rho,numer(Q_z)/diff(denom(Q_z),z))/rho;
```

$$c := 1.25170169910163367947646373163$$

```
> Q_n_asympt:=proc(n) round(c*rho^(-n)) end:
```

```
> count(grammar1,size=30); Q_n_asympt(30); evalf("/"");
```

$$29450689289430149$$

$$29450689289430243$$

$$1.00000000000000319177588939273$$

The integer composition problem

For the original problem, we only need to interpret a,j for $j < 4$ as meaning a summand of value j, that is to say Z repeated j times, and $a4$ as a summand of value at least 4.

```
> grammar2:=[Q4,{
seq(Q.i=Union(Epsilon,seq(Prod(a.j,Q.j),j=4-i..4)),i=0..4),
seq(a.j=Sequence(Z,card=j),j=0..3),a4=Sequence(Z,card>=4)
},unlabelled];
```

$$grammar2 := [Q4, \{Q0 = \mathrm{Union}(E, \mathrm{Prod}(a4, Q4)), a4 = \mathrm{Sequence}(Z, 4 \le card), a0 = \mathrm{Sequence}(Z, card = 0), a3 = \mathrm{Sequence}(Z, card = 3), a2 = \mathrm{Sequence}(Z, card = 2), a1 = \mathrm{Sequence}(Z, card = 1), Q1 = \mathrm{Union}(E, \mathrm{Prod}(a3, Q3), \mathrm{Prod}(a4, Q4)), Q2 = \mathrm{Union}(E, \mathrm{Prod}(a2, Q2), \mathrm{Prod}(a3, Q3), \mathrm{Prod}(a4, Q4)), Q4 = \mathrm{Union}(E, \mathrm{Prod}(a0, Q0), \mathrm{Prod}(a1, Q1), \mathrm{Prod}(a2, Q2), \mathrm{Prod}(a3, Q3), \mathrm{Prod}(a4, Q4)), Q3 = \mathrm{Union}(E, \mathrm{Prod}(a1, Q1), \mathrm{Prod}(a2, Q2), \mathrm{Prod}(a3, Q3), \mathrm{Prod}(a4, Q4))\}, unlabelled]$$

```
> seq(count(grammar2,size=j),j=0..30);
```

2, 1, 1, 1, 7, 11, 17, 25, 51, 94, 165, 280, 496, 887, 1576, 2770, 4880, 8630, 15276, 26990, 47656, 84183, 148781, 262921, 464528, 820699, 1450091, 2562250, 4527272, 7999104, 14133456

We then get the generating function as before.

```
> gr2_sys:=gfsolve(op(2..3,grammar2),z);
```

$$gr2\_sys := \{Z(z) = z, a0(z) = 1, a4(z) = -\frac{z^4}{-1+z},$$
$$Q4(z) = \frac{-z^4 - z^2 + 2 + z^6 - 2z^3 + z}{z^9 + z^8 - z^6 - 3z^5 - 3z^4 - z^3 - z^2 + 1}, a3(z) = z^3,$$
$$Q3(z) = -\frac{z^3 - z - 1}{z^9 + z^8 - z^6 - 3z^5 - 3z^4 - z^3 - z^2 + 1}, a2(z) = z^2,$$
$$Q2(z) = \frac{1}{z^9 + z^8 - z^6 - 3z^5 - 3z^4 - z^3 - z^2 + 1},$$
$$Q0(z) = \frac{z^6 - z^4 - z^3 - z^2 + 1}{z^9 + z^8 - z^6 - 3z^5 - 3z^4 - z^3 - z^2 + 1},$$
$$Q1(z) = -\frac{-1+z}{z^8 - z^5 - 2z^4 - z^3 - z + 1}, a1(z) = z\}$$

```
> QQ_z:=factor(subs(",Q4(z)));
```

$$QQ\_z := \frac{(-1+z)(z^5+z^4-2z^2-3z-2)}{(z+1)(z^8-z^5-2z^4-z^3-z+1)}$$

```
> series(QQ_z,z=0,31);
```

$$2+z+z^2+z^3+7z^4+11z^5+17z^6+25z^7+51z^8+94z^9+165z^{10}+280z^{11}+496z^{12}+887z^{13}+1576z^{14}+2770z^{15}+4880z^{16}+8630z^{17}+15276z^{18}+26990z^{19}+47656z^{20}+84183z^{21}+148781z^{22}+262921z^{23}+464528z^{24}+820699z^{25}+1450091z^{26}+2562250z^{27}+4527272z^{28}+7999104z^{29}+14133456z^{30}+O(z^{31})$$

```
> rho:=fsolve(denom(QQ_z),z,0..1);
```

$$\rho := .56596494435075135442678159 3907$$

```
> QQ_n_asympt:=proc(n) round(subs(z=rho,-1/diff(denom(QQ_z),z)/rho*numer(QQ_z))*rho^(-n)) end: QQ_n_asympt(n);
```

$$\text{round}(.54192208153603168933727338 2179 .56596494435075135442678159 3907^{\langle -n \rangle})$$

```
> count(grammar2,size=40); QQ_n_asympt(40); evalf("/");
```

4191365486

4191365824

.99999991935802929331706074 4350

This solves the original problem. A detailed solution involving reduction of infinite matrices was submitted by D. R. Breach, University of Toronto.

Fixing the number of boxes

The published solution by D. R. Breach also provided detailed tables for number of balls (size) $n \leq 20$ and number of boxes $r \leq 10$. Like before, we could generate specifications for each given value of r. However, it is possible to solve simultaneously *all* such problems by means of bivariate generating functions. Roughly, Combstruct makes it possible to insert marks (in the form of Epsilons that do not modify the counting results).

The specification $grammar1$ generates objects where all atoms are anonymously labelled Z.

```
> allstructs(grammar1,size=2);
```

[Prod(Z, Prod(Z, E)), Prod(Z, Prod(Z, E)),
Prod(Z, Prod(Z, E)), Prod(Z, Prod(Z, E)),

Prod(Z, Prod(Z, E)), Prod(Z, Prod(Z, E)),
Prod(Z, Prod(Z, E)), Prod(Z, Prod(Z, E)),
Prod(Z, Prod(Z, E)), Prod(Z, Prod(Z, E)),
Prod(Z, Prod(Z, E)), Prod(Z, Prod(Z, E)),
Prod(Z, Prod(Z, E)), Prod(Z, Prod(Z, E)),
Prod(Z, Prod(Z, E))]

If we wish to keep track of additional informations, we can just take products with suitable structures of size 0 (Epsilons). This is a general programming technique of Combstruct. Here we use b.j to mark an occurrence of an a.j.

```
> grammar1bis:=[Q4,{
seq(Q.i=Union(Epsilon,seq(Prod(a.j,Q.j),j=4-i..4)),i=0..4),
seq(a.j=Prod(Z,b.j),j=0..4),
seq(b.j=Epsilon,j=0..4)
},unlabelled];
```

grammar1bis := [Q4, {Q0 = Union(E, Prod(a4, Q4)),
Q1 = Union(E, Prod(a3, Q3), Prod(a4, Q4)),
Q2 = Union(E, Prod(a2, Q2), Prod(a3, Q3), Prod(a4, Q4)),
Q4 = Union(E, Prod(a0, Q0), Prod(a1, Q1), Prod(a2, Q2),
Prod(a3, Q3), Prod(a4, Q4)), Q3 = Union(E, Prod(a1, Q1),
Prod(a2, Q2), Prod(a3, Q3), Prod(a4, Q4)), b1 = E, b2 = E,
b3 = E, b4 = E, b0 = E, a0 = Prod(Z, b0), a1 = Prod(Z, b1),
a2 = Prod(Z, b2), a3 = Prod(Z, b3), a4 = Prod(Z, b4)},
unlabelled]

```
> subs({Prod=``,Epsilon=NULL},allstructs(grammar1bis,size=2));
```

[((Z, b3), ((Z, b3))), ((Z, b2), ((Z, b3))),
((Z, b4), ((Z, b2))), ((Z, b4), ((Z, b4))),
((Z, b2), ((Z, b4))), ((Z, b4), ((Z, b1))),
((Z, b4), ((Z, b0))), ((Z, b3), ((Z, b1))),
((Z, b3), ((Z, b4))), ((Z, b1), ((Z, b4))),
((Z, b1), ((Z, b3))), ((Z, b2), ((Z, b2))),
((Z, b0), ((Z, b4))), ((Z, b3), ((Z, b2))),
[Maple Math]

Likewise, we may insert a generic marker [N M] f or each summand in the compositions described by [Maple Math] :

```
> grammar2bis:=[Q4,{
seq(Q.i=Union(Epsilon,seq(Prod(a.j,Q.j),j=4-i..4)),i=0..4),
seq(a.j=Prod(b,Sequence(Z,card=j)),j=0..3),a4=Prod(b,Sequence(Z,card>=4)),
b=Epsilon
},unlabelled];
```

[Maple Math]

[Maple Math]

[Maple Math]

The functions combstruct[gfeqns] and combstruct[gfsolve] respect such marks and allow for the possibility of assigning auxiliary variables for such marks. Thus, one can determine multivariate generating functions. Here [Maple Math] is the variable associated to mark [Maple Math].

> **gfeqns(op(2..3,grammar2bis),z,[[u,b]]);**

[Maple Math]

[Maple Math]

[Maple Math]

[Maple Math]

[Maple Math]

[Maple Math]

[Maple Math]

[Maple Math]

[Maple Math]

[Maple Math]

[Maple Math]

Solving for [Maple Math], we find:

> **QQ_zu:=(-u^2*z^2-2*u^2*z^3+u^4*z^6+u+1-u^3*z^4+u*z)*(-1+z)/(u*z^2-1)/(u^4*z^8-u^2*z^5-2*u^2*z^4-u*z^3-z+1);**

[Maple Math]

[Maple Math]

We then automatically obtained the main table in the solution published by *SIAM Review* . We can even detect errors: for instance, in the last line we must have 1261 (instead of 1211) and 4756 (instead of 4762)!

> **map(series,series(QQ_zu,z=0,21),u,infinity);**

Les nombres hyperharmoniques et la fratrie du collectionneur de vignettes

Résumé. Le problème traditionnel du collectionneur de vignettes est prolongé au cas où le collectionneur fait partager sa moisson avec les membres de sa fratrie. Il reste le seul acheteur, mais donne à ses frères les images qu'il obtient en double. Quand son album est fini, les albums de ses frères ont un certain nombre d'emplacements vides. En moyenne, combien ? Nous apportons une réponse à cette question et obtenons, en outre, une expression pour la fonction génératrice multivariée des variables aléatoires en question. Le problème fait apparaî tre les nombres hyperharmoniques, qu'il faut étudier sous certains aspects, comme solutions d'équations aux différences notamment.

Abstract. The traditional coupon collector's problem is extended to the case where the collector shares his harvest with his own phratry. He remains the only coupon provider, but gives his brothers the coupons that have already appeared in his picture-book. When his book is completed, the books of the other brothers have certain numbers of empty spots. On the average, how many ? We bring an answer to this question and also derive the multivariable generating function for the random variables involved. The problem gives rise to the hyperharmonic numbers that are to be studied under various aspects, in particular as solutions of finite-difference equations.

``The graphical major index'' (with Dominique Foata), (appeared in J. Comput. Applied Math (special issue on q-series) 68(1996) 79-101.

Dominique Foata's bijective proof of MacMahon's result that the number of inversions and the major index are equi-distributed is one of my all-time-favorites. In this paper we define a generalization of both notions, parameterized by an arbitrary graph, and characterize those graphs that have the `mahonian' property of being equi-distributed.

``A Classic Proof of a Recurrence for a Very Classical Sequence'' by Dominique Foata and Doron Zeilberger

(Appeared in J. Comb. Theory-Ser.A 80(1997), 380-384.)

When Dominique Foata and I were working on our `main project' we reached a stage where we desperately needed a distraction. Then arrived Richard Stanley's message advertising his latest parking paper. When we downloaded it, we also found in his home page the delightful and erudite historical paper about the Schroeder-Hipparchus numbers, that contained a challenge: to supply a "direct combinatorial proof" for the three-term linear recurrence for these numbers.

This paper is dedicated to the memory of our great master Marco Schutzenberger (20 Oct. 1920- 30 July 1996).

MetaMix:

Between Unity and Collaboration

Jason Freeman

October 2002 (revised March 2003)

In this paper, I describe *MetaMix* (2002) and I analyze its ambivalent relationship to modern and postmodern thought. I offer neither a complete analysis of the work nor a deep exploration of relevant theory. Rather, I focus on the two key aspects of *MetaMix* which best exemplify its ambivalence towards modernism and postmodernism: its approach to form, and its transformation of the roles of composer, performer, and listener.

Reading this paper is no substitute for experiencing *MetaMix* directly. The accompanying CD-ROM is an install disc for Mac OS X 10.1.x/10.2.x and Windows 98/NT/2000/Me/XP. (*MetaMix* is *not* compatible with Mac OS 9 and earlier or with Windows 95 and earlier.) The disc also includes some audio examples of *MetaMix*'s output, accessible through any audio compact disc player.

1. Overview of *MetaMix*

MetaMix is algorithmic audio remixing software for Mac OS X and Windows. It is a musical composition in that it creates original music, but it consists entirely of direct quotations, and the source of those quotations is not even predetermined. It is a software tool in that it manipulates audio files, but its functionality is too narrowly focused to be of practical use, and it lacks even the built-in ability to save or record its creations. It is a digital audio player in that it plays compact discs and MP3 files, but it would take longer than the age of the universe for it to reach the end of a five-minute audio track. It is an interactive experience in that musical output is dependent on user input, but users are encouraged to set a few parameters, press play, and then let the software run without further intervention — for hours or even days at a time. And it is a work of conceptual art in that it is the stubborn realization of a single simple idea, but its intent is to communicate musical structure more than to communicate a concept.

How MetaMix Works[1]

The concept behind *MetaMix* is simple. Take an audio file. Divide it into equal-length chunks. Label those chunks with the natural numbers: `0, 1, 2, 3,….` Rearrange those chunks as dictated by an interesting (and usually self-similar[2]) infinite integer sequence. Essentially, *MetaMix* superimposes a new musical form onto pre-existing musical material.

Chunks are the basic building blocks of audio which *MetaMix* manipulates. Figure 1 shows how *MetaMix* divides an audio file into chunks by beginning a new chunk every four seconds in the audio track, which is the default setting.

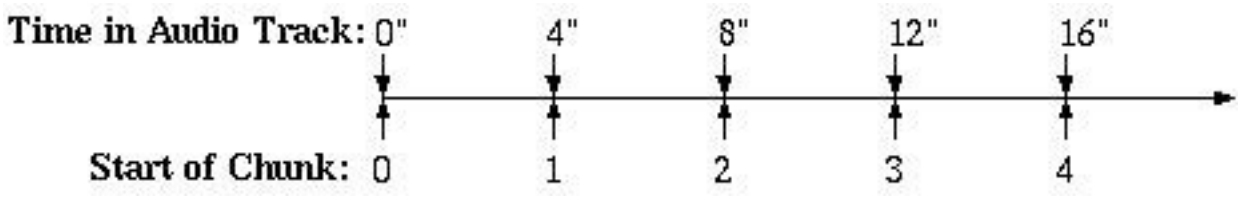

Figure 1: Division of audio track into chunks.

These chunks then have a straightforward mapping onto the numbers of one of the program's twelve integer sequences.[3] For example, the default integer sequence begins like this:

---

[1] Parts of this section, and all of the figures, have been adapted from the *MetaMix* documentation. See Jason Freeman, *MetaMix* (2002), available on the accompanying CD-ROM or online at http://www.jasonfreeman.net.

[2] A self-similar integer sequence is an infinite sequence which contains infinitely many copies of itself. One example is the Thue-Morse sequence, which begins:

`0, 1, 1, 2, 1, 2, 2, 3, 1, 2, 2, 3, 2, 3, 3, 4…`

Taking every other term from the sequence produces:

`0, 1, 1, 2, 1, 2, 2…`

which is, of course, the same sequence. For a nice discussion of self-similar sequences (including a slight variation on this example), see Manfred Schroeder, *Fractals, Chaos, Power Laws: Minutes from an Infinite Paradise* (New York: W. H. Freeman and Company, 1991): 264-268.

[3] These "interesting" integer sequences are all taken from N. J. A. Sloane, editor (2002), *The On-Line Encyclopedia of Integer Sequences*, available at

0, 1, 1, 2, 1, 2, 2, 3, 1, 2, 2, 3, 2, 3, 3, 4, …

Figure 2 shows how *MetaMix* triggers the corresponding chunks from the audio track for the first four integers of this sequence:

Number in Integer Sequence	**0**	**1**	**1**	**2**
***MetaMix* triggers chunk number:**	**0**	**1**	**1**	**2**
Playback starts at:	**0"**	**4"**	**4"**	**8"**
Elapsed time:	**0"**	**4"**	**8"**	**16"**

Figure 2: Realization of integer sequence by triggering corresponding chunks.

MetaMix also overlaps chunks to make transitions between them smooth. As a new chunk gradually fades in, an older chunk gradually fades out.

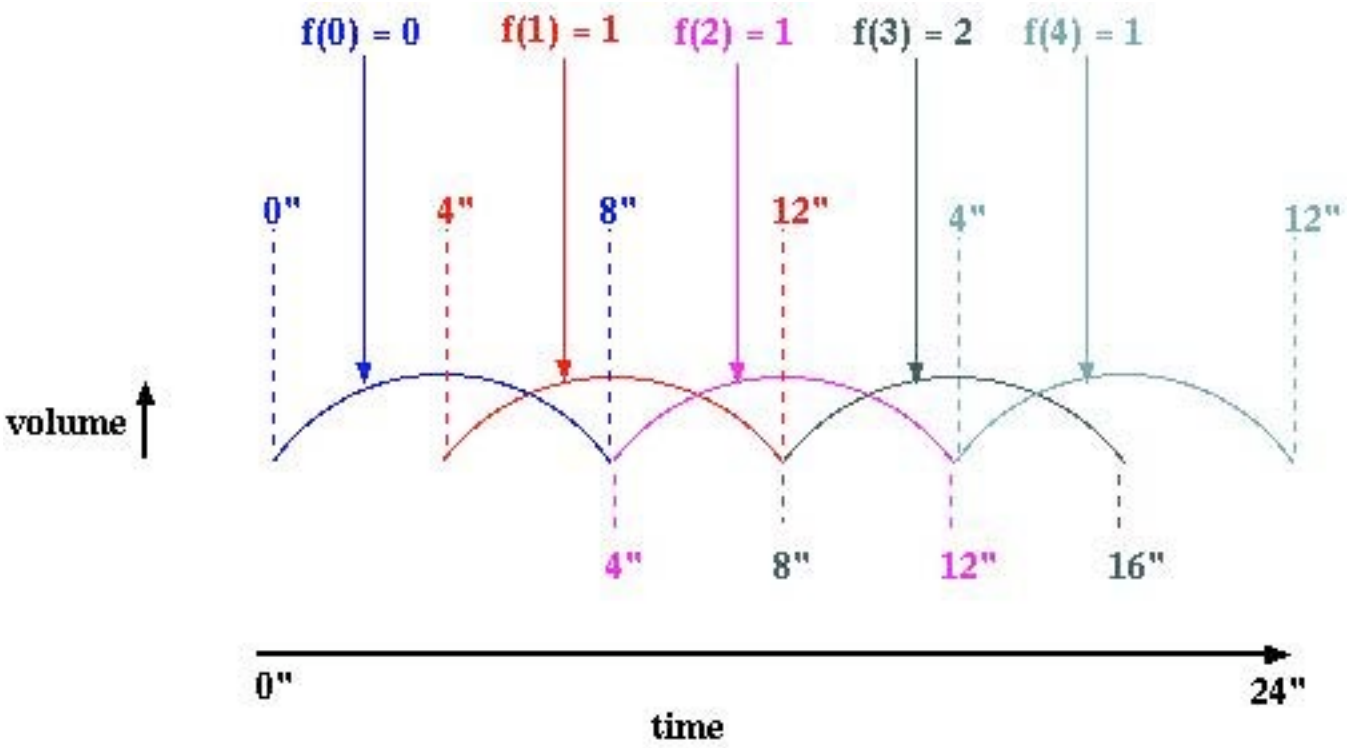

Figure 3: Layering chunks.

Figure 3 shows how this layering process works with two simultaneous layers, which is the

---

http://www.research.att.com/~njas/sequences/.

default setting. (Up to six simultaneous layers are possible.) Each arc represents a single chunk: the higher the curve, the louder the chunk. Labels of the form `f(n) = v` show how each chunk maps to a successive number from the integer sequence: `n` is the index in the sequence, and `v` is the value at that index in the sequence. Because two layers play simultaneously, *MetaMix* plays each chunk for eight seconds but triggers a new chunk every four seconds. Each chunk fades in during the first four seconds it plays and fades out during the last four seconds it plays.

While these explanations of *MetaMix*'s algorithms may seem complicated, the process itself is actually quite simple. *MetaMix* makes no attempt to analyze the audio track or to intelligently divide it into meaningful chunks. *MetaMix* makes no effort to relate musical form to musical content. In fact, it is quite strange and wonderful that the music *MetaMix* produces often seems so fluid and continuous in spite of (or because of?) the blind process to which it stubbornly adheres.[4]

User Interaction[5]

While *MetaMix* is not meant to be constantly manipulated, it does require initial user input to set an audio source file and some basic parameters. The user imports an audio source via a standard open file dialog box, and he or she may also specify a specific starting point within the file. The user chooses the integer sequence. (Each sequence is accompanied by a brief description.) Several parameters of the algorithm have default settings but may also be modified: the number of simultaneous layers; the rate at which new chunks are triggered to play; and the

---

[4] For an interesting perspective on the role continuity and discontinuity play in a similarly simple process in Steve Reich's *Piano Phase*, see Paul Epstein, "Pattern structure and process in Steve Reich's Piano phase," *The Musical Quarterly* LXXII/4 (1986): 494-502.

[5] Please see the appendix for screen shots of the three main windows of the *MetaMix* graphical user interface.

circumstances under which chunks play backwards (e.g. a negative integer value).

Additional controls and displays emphasize *MetaMix*'s connection to traditional audio playback equipment. There are tape-style "transport" buttons: play, stop, pause, fast-forward, and rewind. (The fast-forward and rewind buttons instruct *MetaMix* to skip forward or backward in the integer sequence by a factor which varies according to the structure of each sequence.) *MetaMix* also has an enhanced counter display which shows all currently playing chunks, their positions in the audio source track, and their relative volumes as they fade in and out.

2. Form in *MetaMix*

Motivations

One of my primary motivations for creating *MetaMix* was to aurally render an interesting process as clearly as possible. I have long been fascinated with using integer sequences to generate large-scale musical forms. The sequences usually originate from strict poetic forms with interlocking repetitive patterns[6] and from infinite, self-similar integer sequences. But using these sequences as large-scale forms in my instrumental compositions was often problematic. It was difficult to maintain coherence between sections while keeping each section unique and easily recognizable. And it was also difficult to vary repeated sections enough to maintain linear momentum while also maintaining the identity of each recurring section over the course of the piece.[7] In short, my compositional goals were often at odds with the compositional forms I

---

[6] The sestina, the pantoum, and many other such poetic forms are described in John Hollander, *Rhyme's Reason: A Guide to English Verse* (New Haven: Yale University Press, 1989). Other books are more comprehensive than this, but none are as much fun to read.

[7] This issue is fairly easily addressed in a traditional theme and variations form, since there is usually only one theme. But it is much more problematic here, where there are many

wanted to use, and one or the other often had to be compromised a bit.

MetaMix, in its own twisted way, manages to circumvent many of these problems. Because the user chooses the source material, each chunk (section) of material is familiar and recognizable. Thus the large number of different chunks demanded by the integer sequences is not problematic. Since all of the chunks are extracted from the same audio source, *MetaMix*'s output also has a certain inherent coherence; in fact, *MetaMix* often serendipitously exposes unexpected relationships between distant chunks in the source file.[8] And since *MetaMix* is intended for a causal (and often background) listening experience rather than for a performance in a concert hall, the exact, static repetitions are not problematic for me. In a sense, *MetaMix* is more successful at realizing these integer sequences than my instrumental compositions because it expresses pure structure with no "interference" from the composer.[9]

Interpretations

While some of the ways in which *MetaMix* employs musical form go against the grain of modernist thought, the legacy of modernism is clear: the scientific approach to creating a logical and systematic musical form, the centrality of that form to the work, and the assumption that the perception of that form is proof that something meaningful has been communicated by the

---

different themes and variations intertwined with each other.

[8] For example, one chunk may prolong, embellish, or change the harmony of another; it may create a syncopated metrical relationship; it may add a new contrapuntal voice to the texture; or it may serve as a new consequent to an antecedent phrase which was cut short.

[9] This does not mean that *MetaMix* makes better music; it just means that *MetaMix* is more successful in its attempt to depict the integer sequences.

composer to the listener.[10]

A favorite story of mine exemplifies the preoccupation of many modernist composers with the creation and perception of form. A "modernist" teacher at a summer festival once told me that he often sat down with his daughter and analyzed rhythmic processes at work in songs by RadioHead. When I asked him if knowing about these structures made him enjoy the music more, he said no: he did not enjoy the music more, but he felt more *justified* in enjoying it. By discovering that there was something subtle, logical, and systematic about the music, he proved to himself that it had been constructed with care and that he was listening to it with care. Since he could explain a plausible method by which one aspect of the music had been constructed, he believed that something important had been communicated between the composer and the listener. No matter that he could describe no effect that the transmission of this abstract information had had on the rest of his understanding of the music. Its only purpose for him was to justify that this popular music was indeed worthwhile to listen to at all.

Like postwar serialism, the approach to form in *MetaMix* is scientific, systematic, and logical. It presumes that the listener can perceive the forms it creates; it even assists the listener in this task, both with its included descriptions of each of the integer sequences and with its counter display, which visually shows exactly what chunks are playing and how they relate to the sequence. And *MetaMix* is built on the assumption that the perception of these musical forms is essential to understanding the work. While the presumed line of communication from composer

---

[10] For a discussion of communication and modernism, see Jonathan D. Kramer, *Postmodern Music, Postmodern Listening* (Unpublished manuscript, 6/14/01): 110-111. For a good, brief discussion of Babbitt and the connection between scientific study and postwar modernism, see Georgina Born, *Rationalizing Culture: IRCAM, Boulez, and the Institutionalization of the Musical Avant-Garde* (Berkeley: University of California Press, 1995): 47-56.

to listener is not as clear as in a RadioHead song or a Babbitt piano piece (an issue I will return to in the next section), there is an implicit belief that the decisions made by all the creators (myself, the user, and the creator(s) of the source material) deeply affect the listener's perception of the music and its meaning.

But unlike postwar serialism, *MetaMix* is neither efficient nor subtle. The slow, extremely repetitive processes in *MetaMix* could never be described in terms such as Babbitt uses; there is no "increase in efficiency [which] necessarily reduces the 'redundancy' of the language."[11] In fact, *MetaMix* actually does the opposite; it takes existing music and *decreases* the efficiency and *increases* the redundancy of its language. How else could one explain the transformation of a five-minute song into a result which lasts longer than the age of the universe?[12]

By purely realizing a slow and simple process, *MetaMix* is more closely aligned with some early minimalist music than with postwar serialism. Like modernists, early minimalists rigorously used musical structures, and they believed it was essential for listeners to hear these structures. But as Reich explains, they created their music in a way which made it as easy as possible for listeners to perceive these structures:

> I am interested in perceptible processes. I want to be able to hear processes happening throughout the sounding music. To facilitate closely detailed listening, a musical process

---

[11] Milton Babbitt, "Who Cares If You Listen?" *High Fidelity* VIII, no. 2 (February 1958). Reprinted in Piero Weiss and Richard Taruskin, eds., *Music in the Western World: A History in Documents* (New York: Schirmer Books, 1984), 529-534.

[12] MetaMix may be based on infinite integer sequences, but its music is nevertheless finite. Sooner or later the sequence will reach a chunk number which points to a location past the end of the audio file. But this usually takes an extremely long time. With the default parameters and a five-minute audio source, this takes about 10^{15} years. The age of the universe is about 10^{10} years.

should happen extremely gradually.[13]

And they also seemed less preoccupied with communicating meaning to the listener via that structure. For example, Reich is interested in the "mysteries" of the phasing process: "the impersonal, *unintended* [italics mine], psycho-acoustic by-products of the intended process." [14] Such aspects of the music clearly cannot have been communicated to a listener from the composer. *MetaMix* relishes in this kind of unintended meaning as well, as unexpected chance juxtapositions and connections emerge in its transformation of source material.

There is also a connection between *MetaMix*'s self-similar structures, which distort any normal sense of time,[15] and an experimentalist view of time. Georgina Born writes:

> Against the serial view of time as linear, "duration" as mathematically quantifiable, experimental composers viewed time as noncumulative, nondirectional, static, and rhythm as cyclical, repetitive, and processual…This approach is well expressed in the minimalist, process, or systems music of composers such as Terry Riley, Philip Glass, and Steve Reich, which developed out of the experimental tradition…the music sets up repetitive and cyclic rhythmic structures that permutate as the performance unfolds: a ritual process set in motion. Performances might last for twenty-four hours, and music was stripped to minimal simplicity.[16]

These connections to modernism and experimentalism are at once genuine and ironic, just as *MetaMix* itself can seem at once modern and postmodern. In writing *MetaMix*, I expressed a heartfelt belief that fascinating integer sequences could be perceived aurally and that

---

[13] Steve Reich, "Music as a Gradual Process," reprinted in *Steve Reich: Writings about Music* (Halifax: The Press of the Nova Scotia College of Art and Design, 1974): 9-11.

[14] Ibid.

[15] Because self-similar sequences are invariant under scaling, they do not clearly mark progress through musical time. At any point, the sequence could be twice (or half or four times or one fourth, etc.) as far along as the listener may think.

[16] Born, 57.

the work could draw its power almost entirely from them. But within the software itself, this genuine mission is often treated a bit whimsically. Detailed mathematical descriptions accompany each sequence, explaining its derivation and meaning. But occasionally, these descriptions include a sentence or two which deliberately undermine the whole endeavor. For instance, in the description of "Palindrome I," I write: "The sequence is actually based on the 'weight of balanced ternary representation of n.' I must confess I have no idea what that means."[17] With this flippant remark, I suggest that it may not be so important to understand the mathematical roots of *MetaMix* after all. If I can be fascinated by an integer sequence without understanding the mathematics behind its derivation, then why can't a listener be fascinated by a musical result without grasping its structure? Are the integer sequences really even the essential element of the work? If not, then what is?

I also assigned playful names to each of the mathematical sequences. For instance, a group of related sequences all have names based on "Exponential Slow," because the sequences' momentum slow down exponentially over time. One of the more chaotic sequences in that group is named "Not Quite So Exponential Slow," poking fun at the minimalist nature of all of these structures. Carefully chosen source material could also lead to humorous and ironic transformations: consider a recording of Satie's *Vexations*. Examples such as this last one, though, are merely possibilities for user interaction — which leads us nicely into the next section…

---

[17] Freeman.

3. The Developer and the User in *MetaMix*

Motivations

Another primary motivation for creating *MetaMix* was to make possible a meaningful interactive musical experience accessible to both musicians and non-musicians. Inevitably, this necessitated a transformation of the traditional art music roles — composer, performer, and listener. These roles continue to exist, but they do not have direct, one-to-one mappings to people or groups; the tasks traditionally associated with each of these roles are divided amongst several people, and some people take on tasks from multiple roles.[18] Some terminology from the software industry more clearly identifies the roles people play in relation to the work: developer and user. (I have already been using these terms informally throughout this paper.)

Creating such an interactive experience also requires a new presentation format; *MetaMix* transforms the experience of listening to recorded music into a format which better suits its goals. Traditionally, a listener hears a recorded performance, digitally edited to near perfection and identical on each successive hearing. Even under the best circumstances, the excitement, the risks, and the surprises of a live concert performance are gone. But by rearranging and remixing a recording in real time, *MetaMix* tries to inject some of that excitement back into recorded music. The surprise with *MetaMix* comes not from the recorded performance, but rather from the manner in which chunks of the recording are repeated and rearranged to reveal new connections and relationships. *MetaMix* encourages users to listen afresh by extracting new meaning out of familiar sounds.

---

[18] This is the opposite of a famous Cage quote: “Composing’s one thing, performing’s another, listening’s a third. What can they have to do with each other?” in John Cage, *Silence* (Middletown: Wesleyan University Press, 1961): 15.

One of the strangest and most wonderful experiences I have had as a *MetaMix* user occurred with a transformation of a jazz piano recording. I instructed the software to begin from a passage near the end of the track. After a few hours, I suddenly heard momentary but uproarious applause creeping in from the end of this live recording. As the music continued, the applause returned for increasingly long periods of time and with increasing frequency. Each time it came back, it forced me to reconsider the music around it. Was the applause highlighting a cadence? Or was it echoed by an arpeggiation in the lower octaves of the piano? Or was it an enthusiastic reaction to a little flourish? Of course, the applause was not originally any of these things. But these strange juxtapositions forced me to reconsider what made moments in the recording special. And I began to eagerly anticipate (and even try to predict) where and when the next moment marked by applause would come.

Interpretations

With this change in roles comes a transformation or even destruction of a meta-narrative[19] of art music recordings: a composer writes the music, a performer plays it, and a listener absorbs it. In *MetaMix*, this paradigm is still important, but it no longer functions as a meta-narrative. The software, not the listener, directly absorbs the music, and it then serves as an interface through which the user accesses the music. Two different paradigms function only together, and the second happens to be a meta-narrative in the software industry: a developer creates software with which a user then interacts.

MetaMix does not fully embrace either of these meta-narratives. The recorded music meta-narrative implies that the listener is merely a passive spectator and plays no role in the

---

[19] See Kramer, 45-48 for a definition and discussion of meta-narratives.

musical result, but the software meta-narrative implies that the user continuously interacts with the software and deserves primary credit for the musical result. Neither of these implications make sense under the circumstances.

Such an ambivalence towards meta-narratives links *MetaMix* to postmodern thought. Jean-François Lyotard writes: "Simplifying to the extreme, I define postmodern as incredulity toward metanarratives."[20] *MetaMix* still believes in other meta-narratives. For instance, its rigorous formal structure betrays an interest in unity and thus a link to modernism. But Lyotard's remark is relevant to the work's self-conscious treatment of the meta-narratives of recorded music and of software, incorporating them as flexible paradigms which can be reshaped and combined at will.

Reshaping these particular meta-narratives makes it difficult to identify the creator of the work. When a composer engraves a musical score with *Finale*, Coda (its developer) takes no credit for the work.[21] But when a user creates a transformation of Erik Satie's *Vexations* in *MetaMix*, many people deserve some credit: me (as developer), the user (for picking the source material and setting the parameters), Satie (for writing the original piece), the pianist (for performing it), and perhaps even the engineer or producer of the original recoding (for mixing and editing the performance). And it is equally difficult to define the work itself, since no

---

[20] Jean-François Lyotard, "Answering the Question: What is Postmodernism?" in *The Post-Modern Reader*, ed. Charles Jencks (London: Academy Editions, 1992): 138-150. See also Kramer, 45, which begins its exploration of meta-narratives with Lyotard.

[21] Actually, it is not quite that simple. Coda's license agreement reads: "…MakeMusic! [the company which recently purchased Coda] retains all ownership and rights in the Software, including all rights in any portion(s) of the Software present in any output of the Software." This wording is deliberately ambiguous, and it is doubtful the company could ever legally claim ownership to a score engraved in *Finale*. But it does demonstrate that even in a seemingly clear example, legal ownership can be ambiguous. See *Finale Notepad 2003*. Coda Music Technology, Eden Prairie, Minnesota. Available at http://www.codamusic.com.

element of the work is original. The source material is a digitally exact quotation. The musical structures are taken directly from the work of mathematicians at AT&T. The graphical user interface is somewhat original, but it is more of a necessary facilitator of interaction than a meaningful component in itself.

These problematic identities of the work and its creator(s) point to another link with postmodern thought, particularly in it relationship to technology. Steve Holtzman summarizes the connection nicely in an explanation of why interactive digital technology is well-suited for postmodern expression:

> The digital experience is interactive, not passive. Digital worlds respond to you, pull you in, demand your participation. The unique creation that results is not simply a "work" produced by an artist held high on a pedestal, but the interaction between you and the possibilities defined by the artist…Two experiences created from a broad field of possibilities may bear little resemblance to each other. As in jazz improvisation or the live performance of music, it's the uniqueness of each interpretation that is the essence of the digital aesthetic.[22]

Holtzman makes an interesting comparison to live musical performances, but it is important to remember that interactive works tend to create much more problematic definitions of the "work" and the "creator" than conventional musical performances (even in jazz). Jonathan Impett focuses on this problematic identity of the work itself and offers a suggestion:

> In the case of interactive music, the blurring of the boundaries between composition and performance, work and environment, is an essential characteristic. It could even be considered…the material itself.[23]

But *MetaMix* does not go as far as many postmodernist thinkers. Andreas Huyssen, though speaking neither of music nor of technology in specific, argues that even asking questions

---

[22] Steve Holtzman, *Digital Mosaics* (New York: Simon and Schuster, 1997): 128.

[23]Jonathan Impett, "Situating the Invention in Interactive Music," *Organised Sound* Vol 5, No. 1 (April 2000): 27-34.

like “Who is writing?” is no longer relevant, because these questions are “tied by mere reversal to the very ideology that invariably glorifies the author as genius…” [24] By retaining the idea of a primary creator, even if that creator’s role is diminished, and by retaining the recorded music paradigm, even if it is no longer a meta-narrative, *MetaMix* keeps itself within both postmodernist and modernist worlds without quite fitting in either.

4. Connections

So *MetaMix* incorporates a strange duality — a unified (modernist) structure combined with a disjunct (postmodernist) creative process. The formal structure and the interface are predetermined, while the specific content and some parameters of the algorithms are decided at the moment of interaction. Content is completely divorced from form, but the work attempts nonetheless to be coherent and unified.

A similar approach has found its way into other works of mine. For instance, in *The Locust Tree in Flower* (2000), an interactive gallery installation, users read phonemes which become the inputs into a complex digital signal processing algorithm, and the resulting sounds are mixed, layered, and repeated according to a predetermined formal layout. In *Telephone Etude #1: Shakespeare Cuisinart* (2001), a telephone caller’s voice is transformed into a piece of *musique concrete*; the piece is created via a complex hierarchy of random decisions, structured in such a way that the overall shape of the music follows one of a few different possibilities. And in *peopletank* (2001), a work for dancers with live electronics and floor sensors, the rhythms of dancers’ feet act as gates to prerecorded sound files, creating rhythmic gestures which are looped, layered, and transformed according to a predetermined form. In all of these works, the

---

[24] Andreas Huyssen, “Mapping the Postmodern,” in *The Post-Modern Reader*, ed. Charles Jencks (London: Academy Editions, 1992): 40-72.

structure is mostly fixed, and the interaction or performance consists of "filling in" structure with content.

There are many similar examples beyond my own work. In John Cage's *Imaginary Landscape No.5* (1952), a graphical score specifies precisely how to assemble the work from forty-two phonograph records but leaves the choice of records up to the "user." The result is a short work for electronic tape.[25] Alvin Lucier's *I Am Sitting In A Room* (1970), for voice and electromagnetic tape, is based on a simple but rigorous process: playing and re-recording a spoken voice recording again and again until the voice eventually gives way to "the natural resonant frequencies of the room." While this piece is best known in a version which Lucier recorded himself, the score leaves virtually all elements of the work (except the process itself) up to the performer. It directs the performer to "choose a room the musical qualities of which you would like to invoke;" to "use the following [supplied] text or any other text of any length;" and to "continue this process through *many* [italics mine] generations." Lucier even suggests possible variations to the "parameters" of the process: moving the location of the microphone within the room for each successive recording; moving to a different room for each successive recording; or using multiple readers with texts in multiple languages. He even suggests different methods of dissemination: the work may be documented as a piece for tape or may be produced as a live performance.[26]

While there are certainly examples of this approach in instrumental compositions as well, the particular combination of rigorous structure with the uncertainty of "user" interaction seems

---

[25] John Cage, *Imaginary Landscape No. 5* (New York: Henmar Music, 1961).

[26] Alvin Lucier, *I Am Sitting In A Room*, reprinted in *Sound By Artists*, ed. Dan Lander and Micah Lexier (Toronto: Art Metropole and Walter Phillips Gallery, 1990): 191-192.

particularly well suited to works which employ technology in unusual ways.

5. Conclusions

Though I have identified an approach which is important in many of my recent works, it nonetheless carries with it contradictions and limitations with which I constantly struggle. I want to open up the possibility for systems to be used in ways I could not imagine, but I also want to ensure that even "inept" users can create something interesting. I want each experience to be unique, yet I also want each to be recognizable as something for which I was the principal creator. In short, I am fascinated with giving up control because I am a control freak at heart.

In *MetaMix* and other similar works of mine, the development process is a natural extension of traditional composition; just as an instrumental composer must imagine how his notation will sound when performed by other people, so I must imagine how my systems will sound when used by other people. This element of prediction, guesswork, and uncertainty continually fascinates me and renews my interest in composition.[27] As composers, our ability to mentally bridge this gap between conception and performance improves as we gain more experience and learn from past mistakes, but the uncertainty never completely vanishes.

In the future, I hope to extend this approach to works which provide deeper, more meaningful interactive experiences. To do so involves many risks: it may become yet harder to identify the work and its creator(s); the risk of "bad" results may increase; and the work may even be viewed by some as a tool rather than as a work of art. But continuing to search for the best balance between developer and user could also lead to works which are increasingly meaningful, engaging, and creative experiences.

---

[27] In fact, it is the *lack* of such an element when writing works "for tape" which has discouraged me from pursuing that medium.

A method for the compact and efficient encoding of ordinal primes

W. Freeman
Department of Computer Science
University of York
York YO10 5DD U.K.

wf@cs.york.ac.uk

28 April (revised 10 June) 2000

Submitted as a YCS Report 26 March 2003

Indexing terms: ordinal prime numbers, compact encoding, Ada aggregates.

Consider the following two questions. (1) Given *v*, what is the *v*-th prime? (2) Given *p*, then, if *p* is the *v*-th prime, what is *v*? The method described allows these questions to be answered efficiently in real time, and compactly in space, for a range of primes of significant size. We call primes in the range in which the system can deliver their order in this way, *ordinal* primes.

(Note that we are *not* concerned here with simple primality, prime factorisation, etc., which can be determined by investigating the prime in question only.)

Practicalities and implementation issues are addressed. The method has been implemented in Ada95 and tested using GNAT. Some Ada95 code is included, which was used to give fast and compact access to ordinal primes up to 20999999 (the 1329943-th prime).

A method for the compact and efficient encoding of ordinal primes.

Introduction.

By *ordinal primes*, we mean primes recorded in such a way that we can tell (1) what is the v-th prime, given v; and (2) what is v, given prime p and supposing it to be the v-th prime. We shall call the ordinal numbers of such primes, *primals*. As a guide to the magnitudes concerned, it was required to deal with ordinal primes at least 19999999 (primal 1270607). But, the bigger the better.

We are required to answer questions (1) and (2), within the range implemented, compactly in space and efficiently in real time. Clearly, the table concerned must be pre-computed, with the possibilities then that (a) it could be an aggregate, statically compiled in the program, (b) it could be an array loaded in one go, at run-time, from a LAN fileserver, or (c) it could be a set of buffers loaded at run-time on demand. The structure of a wider system of practically usable software, of which this was a part, gave a very strong preference for (a) over (b) or (c), while the elapsed time on demand would always make (c) the least preferable whenever real time is important. This note is concerned in particular with exploring how far option (a) could be developed. Clearly, compactness and efficiency are always important, but are most important for (a). The method developed here is, though, generally applicable, including to cases (b) and (c).

(Note that we are here concerned with ordinal primes and primals, and *not* with simple primality, prime factorisation, etc., since these latter can be determined by investigating the prime in question only.)

Table 1. Primals and ordinal primes.

v	p_v	v	p_v	v	p_v	v	p_v
0	1	1000	7919	1000000	15485863	1270608	2000003
1	2	1001	7927	1000001	15485867	1270609	2000029
2	3	1002	7933	1000002	15485917	1270610	2000039
3	5	1003	7937	1000003	15485927	1270611	2000081
4	7	1004	7949	1000004	15485933	1270612	2000083
5	11	1005	7951	1000005	15485941	1270613	2000093
6	13	1006	7963	1000006	15485959	1270614	2000107
7	17	1007	7993	1000007	15485989	1270615	2000113
8	19	1008	8009	1000008	15485993	1270616	2000143
9	23	1009	8011	1000009	15486013	1270617	2000147

We could set up a simple bit map of all the natural numbers up to some limit forced by the resources available. This could have ‘0’ for composite and ‘1’ for non-composite (i.e. unit or prime†). Such a table, up to the 20 millionth natural number (19999999) would occupy 2500000 8-bit bytes, or 625000 32-bit words. It would flag primes up to 19999999, which is the 1270607-th prime. This table would be pre-computed, as also would a table of the running count of the number of primes so far (primals). On the assumption that as much space as is feasible should be allocated to the primality bit-map, this running count would be held only at regular intervals in the bit-map. Using these data to answer either of the questions (1) and (2) above could be efficient in time, but the bit-map would not be very compact.

---

† To allow a simple dichotomy, composite/prime, the unit is counted as the zeroth prime, throughout.

There is an obvious way of making it more compact: at the very least, the bit-map could be halved in size by storing the primality of odd numbers only. The prime 2 (or its primal, 1) would first be dealt with as a special case; thereafter, the method would proceed as before. A further improvement would be to take out all numbers divisible by 2 or by 3, and map only those that remain. The primes 2 and 3 (or their primals, 1 and 2) would first be dealt with as special cases. The map would now contain two bit positions for every six natural numbers (indicating the primality of those with remainders 1 or 5 on division by 6), so it would now be only one third of its original size.

How can this method be generalised? And, when does further such effort and complication cease to be cost-effective? We now address these questions.

The general method.

We define $\pi(s)$, the *primorial* function of *s*, in the usual way, as the product of the first *s* primes

$$\pi(s) \triangleq \prod_{i=1}^{s} p_i$$

where p_i is the *i*-th prime. See sequence M1691 in Sloane and Plouffe (1995), and Table 2 here. We define $\mathbf{Z}_m$, the *ring of integers* modulo *m*, in the usual way, as the set of remainders from integer division by *m*

$$\mathbf{Z}_m \triangleq \{r: 0 \le r \le m-1\} = \{0, 1, \ldots, m-1\}$$

and similarly Φ_m, the *reduced set of residues* modulo *m*, as the subset of $\mathbf{Z}_m$ that contains those elements that are relatively prime to *m*

$$\Phi_m \triangleq \{r: 0 \le r \le m-1 \wedge \gcd(r, m)=1\}$$

and recall that $\#\Phi_m = \phi(m)$, where $\phi(m)$ is *Euler's totient function* defined in terms of the canonical prime factorisation of *m* as

$$\phi(m) = \phi(\prod_i p_i^{\alpha_i}) \triangleq \prod_{\substack{i \\ \alpha_i \neq 0}} p_i^{\alpha_i - 1}(p_i - 1)$$

where p_i is the *i*-th prime number. See sequence M0299 in Sloane and Plouffe (1995), and Table 2 here. For number-theoretic matters discussed here, see e.g. Burn (1997).

Any natural number *n* can be expressed uniquely as $q.\pi(s)+r$, where $r \in \mathbf{Z}_{\pi(s)}$, and given fixed *s*. That is, $q = n \text{ div } \pi(s)$ and $r = n \bmod \pi(s)$, where 'div' and 'mod' are integer division and remainder in the sense usual in computer science. Now, it is a necessary (but not sufficient) condition for *n* to be prime, that either $n \le p_s$ or $r \in \Phi_{\pi(s)}$. So, leaving cases $n \le p_s$ to be dealt with separately, and regarding cases $n > p_s$ as *mapped* numbers, we can say of a mapped *n* that if $r \notin \Phi_{\pi(s)}$ then *n* is certainly composite, while if $r \in \Phi_{\pi(s)}$ then we need to refer to the appropriate one of a number of bits (actually, $\phi(\pi(s))$ bits) that have been pre-computed to decide its primality.

The set of $\pi(s)$ consecutive numbers, from $q.\pi(s)$ to $(q+1).\pi(s)-1$, will be called the *q*-th *Z-block*. The string of $\phi(\pi(s))$ bits, from the $q.\phi(\pi(s))$-th to the $(q+1).\phi(\pi(s))-1$-th of the primality bit-map, whose values encode the primality of the numbers in the corresponding Z-block, will be called the *q*-th Φ-*block*. Accordingly, we define the *compaction factor*, κ_s, of the encoding, for given *s*, as the ratio between the size

of a Φ-block (#Φ) and the size of a Z-block (#*Z*)

$$\kappa_s \triangleq \frac{\#\Phi}{\#Z} = \frac{\phi(\pi(s))}{\pi(s)}$$

Before drawing up Table 2, we incorporate one simplification of notation. First, we note that $\pi(s)$ is, by construction, always square-free; then, defining

$$\pi'(s) \triangleq \prod_{i=1}^{s} (p_i - 1)$$

we always have $\phi(\pi(s)) = \pi'(s)$.

Table 2. Z-block sizes, Φ-block sizes, and compaction factors.

s	p_s	$\#Z = \pi(s)$	$\Phi_{\pi(s)}$	$\#\Phi = \pi'(s)$	$\kappa_s = \frac{\#\Phi}{\#Z}$	$\frac{\kappa_{s-1} - \kappa_s}{\kappa_{s-1}}$
0	1	1	{0}	1	1.000	
1	2	2	{1}	1	0.500	50.0%
2	3	6	{1, 5}	2	0.333	16.7%
3	5	30	{1, 7, 11, 13, 17, 19, 23, 29}	8	0.266	6.7%
4	7	210	{1, 11, . . ., 199, 209}	48	0.228	3.8%
5	11	2310	{1, 13, . . ., 2297, 2309}	480	0.207	2.1%
6	13	30030	{1, 17, . . ., 30013, 30029}	5760	0.191	1.6%
7	17	510510	{1, 19, . . ., 510491, 510509}	92160	0.180	1.1%

Table 3. Φ-block sizes that are multiples of a byte.

s	p_s	$\pi(s)$	$p_s - 1$	$\pi'(s)$	$\frac{t.\pi'(s)}{8}$	t	$\#\Phi = t.\pi'(s)$	$\#Z = t.\pi(s)$
0	1	1	0	1	1	8	(8)	(8)
1	2	2	1	1	1	8	8	16
2	3	6	2	2	1	4	8	24
3	5	30	4	8	1	1	8	30
4	7	210	6	48	6	1	48	210
5	11	2310	10	480	60	1	480	2310
6	13	30030	12	5760	720	1	5760	30030
7	17	510510	16	92160	11520	1	92160	510510

Table 4. Φ-block sizes that are multiples of a word.

s	p_s	$\pi(s)$	$p_s - 1$	$\pi'(s)$	$\frac{t.\pi'(s)}{32}$	t	$\#\Phi = t.\pi'(s)$	$\#Z = t.\pi(s)$
0	1	1	0	1	1	32	(32)	(32)
1	2	2	1	1	1	32	32	64
2	3	6	2	2	1	16	32	96
3	5	30	4	8	1	4	32	120
4	7	210	6	48	3	2	96	420
5	11	2310	10	480	15	1	480	2310
6	13	30030	12	5760	130	1	5760	30030
7	17	510510	16	92160	2880	1	92160	510510

We suppose that Φ-blocks have been computed and recorded for all values of q from 0 up to a maximum value, $q_{\max} = Q - 1$, so that the primality bit-map contains $Q.\#\Phi$ bits altogether, recording the primality of those natural numbers from 0 to $Q.\#Z - 1$ which, when reduced mod $\#Z$, are relatively prime to $\#Z$. Similarly, the cumulative count of primes will have been computed and recorded in a separate table, at intervals of h bits in the bit-map. There will be $\frac{Q.\#\Phi}{h}$ numbers in this count table (where this ratio is assumed to be a whole number).

Clearly, in practice, it would be more efficient if $\#\Phi$ were a round number of bytes. Further, even if some table look-up (etc.) operations are carried out byte-wise, there will be aspects of the representation that would be better carried out word-wise. So we explore the consequences, first, of requiring that $\#\Phi$ be a multiple of 8 (see Table 3); and, second, of requiring it to be a multiple of 32 (see Table 4). (Extension to other powers of 2 is obvious.) If each Φ-block is to be made larger by the smallest necessary positive integral factor t that will ensure the required divisibility by 8 or by 32, then the Z-block must be made larger by the same factor. We could, in general, say that the new Φ-block and the new Z-block each represent t consecutive copies of the original (i.e. $t = 1$) Φ-block and Z-block, respectively: but it would be less awkward to explain and to code if we could say that $\Phi_{t.\pi'(s)}$ was the reduced set of residues of the ring $\mathbf{Z}_{t.\pi(s))}$; and, so, that each new Φ-block was the residue primality map of the corresponding new Z-block. It is easy to show that this is so for s at least 1. (When $s = 0$, t-fold replication remains a valid explanation.) If $\gamma(m)$ is the greatest square-free divisor of m, we have in general $\gamma(m)|n \Rightarrow \phi(m.n) = m.\phi(n)$; and so, in particular,

$$\gamma(t) \mid \pi(s) \quad \Rightarrow \quad \phi(t.\pi(s)) = t.\phi(\pi(s))$$

Consequently, if t contains no prime divisors that are not also divisors of $\pi(s)$, then $\phi(t.\pi(s)) = t.\phi(\pi(s)) = t.\pi'(s)$ as required. Since t is here always a power of 2, and $\pi(s)$ is even for s at least 1, the result follows for s at least 1.

The algorithms.

In what follows, $\rho(u)$ is the value of the u-th smallest element of the reduced set of residues modulo $\pi(s)$, so $u \in \mathbf{Z}_{\pi(s)}$ and $\rho(u) \in \Phi_{\pi(s)}$. Also, $\rho^{-1}(r)$ is the partial inverse of ρ defined over $\Phi_\pi(s)$, so that $\rho^{-1}(\rho(u)) = u$.

The procedure for pre-computing the tables is as follows.

(1) Choose a small positive integer, s. This will determine that the first s primes are to be treated as special cases. Let $\#Z = \pi(s)$, and $\#\Phi = \pi'(s)$.

(2) Choose a value for the eventual size of the entire primality bit-map that is to be available to any main program using the tables at run-time. Let this size be $Q.\#\Phi$ bits. Each successive Φ-block will be used to record the actual primality of those $\#\Phi$ numbers whose primality is in question, among each successive Z-block of natural numbers.

(3) Choose an interval, h, so that a cumulative count of '1' bits will be kept prior to every $h.\#\Phi$-th bit position in the bit-map.

(4) Find the primality of all numbers n, $0 \le n \le Q.\#Z - 1$. For each n such that n mod $\#Z$ is relatively prime to $\#Z$, use one bit in the bit-map to record its primality ('1' for prime). For every $h.\#\Phi$ such bits, use one word in the count table to record

the cumulative count of such '1' bits that applies prior to the start of the interval.

To find the v-th prime, proceed as follows.

(1) If $v \le s$, deal with this specially (in an obvious way). Otherwise, continue.

(2) Search the count table (in logarithmic time) for the greatest count, c, such that $c < v$. Suppose that this c is found at entry i in the count table: then the interval number in the bit-map is i, and the zeroth bit position in that interval is the $h.i.\#\Phi$-th bit position in the whole map.

(3) Scan through the i-th interval of the bit-map, accumulating k, the count of '1' bits, starting with $k = c$, until k first reaches the value n at (say) the j-th bit position within the interval.

(4) Then we have $p_v = (h.i + j \text{ div } \#\Phi).\#Z + \rho(j \bmod \#\Phi)$. So the answer returned is $(h.i + j \text{ div } \#\Phi).\#Z + \rho(j \bmod \#\Phi)$.

To find primal v, given p and that p is the v-th prime, proceed as follows.

(1) If $p \le p_s$, deal with this specially (in an obvious way). Otherwise, continue.

(2) Let $i = p \text{ div } (h.\#Z)$. Take the i-th count from the count table, and let it be c.

(3) Scan through the i-th interval of the primality bit-map, accumulating k, the count of '1' bits, starting with $k = c$, until the next bit position would be the zeroth bit of the $p \text{ div } \#Z$-th Φ-block of the entire map. Retain the resulting value of k.

(4) Let $u = \rho^{-1}(p \bmod \#Z)$. If u is not defined, there must have been an error in the value of p supplied, since it has been found to be composite. Otherwise, let b be the u-th bit of the $(p \text{ div } \#Z)$-th Φ-block of the primality bit-map.

If $b = 0$, there must have been an error in the value of p supplied, since it has been found to be composite. Otherwise, increase k by the number of '1' bits from the zeroth bit position to the u-th bit position (inclusive) within the $(p \text{ div } \#Z)$-th Φ-block of the primality bit-map. So p is p_k, and so the answer returned is k.

Implementation choices and practicalities.

The original implementation, in Ada83 compiled under the York Ada compiler, used $s = 2$ and (effectively) $t = 1$, and held the bit-map in the lower 31 bits of each 32-bit signed integer, giving $\kappa = \frac{32}{31} \times \frac{2}{6} = 0.344$. This arrangement was forced by the lack of unsigned 32-bit or 8-bit types and bitwise operators in Ada83, and by the fact that the York compiler generated Boolean vectors with — astoundingly — one byte, rather than one bit, per element. There were sufficient complications with $s = 2$, without going to $s = 3$, especially since $s = 2$ enabled a primality table of adequate size to be compiled.

In re-coding for Ada95, it was decided that the bit-map would be expressed as a sequence of 32-bit unsigned numbers (using package ada.interfaces). It was hoped that this would enable a larger table to be used. Each 32-bit number (containing four juxtaposed bytes) was output (in decimal, for compactness) by the pre-computation program and incorporated into the ordinal prime package. It was decided initially to use $s = 3$ and $t = 1$, giving $\#Z = 30$, $\#\Phi = 8$ and $\kappa = 0.266$.

The Ada95 was compiled using GNAT 3.11p. The size of aggregate that this compiler could cope with turned out to be much smaller than that possible with the York compiler

for Ada83, for a given ceiling on the virtual memory available during compilation. If the bit-map table were merely to be declared statically, and then the aggregate loaded dynamically, there would be no problem; but on this occasion a static aggregate solution was sought, so as to be accessible simply through the Unix execution path. (That does not mean that the general idea of the compact encoding of ordinal primes, as described from the start of this note, is restricted to such an implementation: it is of course usable generally.)

Each of the two tables (bit-map and count) was held on its own in a package specification (see below), but, even if these were forcibly pre-compiled individually, that would be to no avail because the virtual memory limit would be exceeded (only) when there was a demand for code generation and linking, during the first compilation of a main program employing the package. It was decided to explore the setting $s = 4$ and $t = 2$, giving $\#Z = 420$, $\#\Phi = 96$ and $\kappa = 0.228$. (The code given below is for this case.) Then, a bit-map of 150000 words would encode up to 20999999, the 1329943-th prime.

It will be appreciated, from Table 2, that there would be a small further improvement with $s = 5$; while, with $s = 6$ and $s = 7$, the auxiliary tables would have grown to a size that countervailed any further compaction of the bit-map table. (For an example showing the necessary auxiliary tables, see the code given below for $s = 4$ and $t = 2$.)

Actual figures for sizes of virtual memory available, speeds of processors and times required for compilation are not given above, nor in Figure 5, since they became out of date (and were not of historical interest) even during the writing of this note.

Table 5. Implementation characteristics.

Language	Compiler	Words in bit map	Bits used per word	s	t	$\#\Phi$	$\#Z$	κ	$v_{\max}$	$p_{\max}$
Ada 83	York	150000	31	2	–	(64)	(186)	0.344	907101	13949989
Ada 83	York	450000	31	2	–	(64)	(186)	0.344	2539186	41849999
Ada 95	GNAT	50000	32	4	2	96	420	0.228	476606	6999299
Ada 95	GNAT	150000	32	4	2	96	420	0.228	1329943	20999999

APPLICATIONS OF THE CLASSICAL UMBRAL CALCULUS

IRA M. GESSEL

Dedicated to the memory of Gian-Carlo Rota

Abstract. We describe applications of the classical umbral calculus to bilinear generating functions for polynomial sequences, identities for Bernoulli and related numbers, and Kummer congruences.

1. Introduction

In the nineteenth century, Blissard developed a notation for manipulating sums involving binomial coefficients by expanding polynomials and then replacing exponents with subscripts. For example, the expression $(a+1)^n$ would represent the sum $\sum_{i=0}^{n}\binom{n}{i}a_i$. Blissard's notation has been known variously as Lucas's method, the symbolic method (or symbolic notation), and the umbral calculus. We shall use Rota and Taylor's term "classical umbral calculus" [37] to distinguish it from the more elaborate mathematical edifice that the term "umbral calculus" has come to encompass [32, 33, 35].

The goal of this article is to show, by numerous examples, how the classical umbral calculus can be used to prove interesting formulas not as easily proved by other methods. Our applications are in three general areas: bilinear generating functions, identities for Bernoulli numbers and their relatives, and congruences for sequences such as Euler and Bell numbers.

The classical umbral calculus is intimately connected with exponential generating functions; thus $a^n = a_n$ is equivalent to

$$e^{ax} = \sum_{n=0}^{\infty} a_n \frac{x^n}{n!},$$

and multiplication of exponential generating functions may be expressed compactly in umbral notation:

$$\left(\sum_{n=0}^{\infty} a_n \frac{x^n}{n!}\right)\left(\sum_{n=0}^{\infty} b_n \frac{x^n}{n!}\right) = \sum_{n=0}^{\infty} c_n \frac{x^n}{n!}$$

is equivalent to $(a+b)^n = c^n$.

Key words and phrases. classical umbral calculus, exponential generating function, bilinear generating function, Hermite polynomial, Charlier polynomial, Bernoulli number, Bell number, Kummer congruence.

This research was supported by NSF grant DMS-9972648.

When I first encountered umbral notation it seemed to me that this was all there was to it; it was simply a notation for dealing with exponential generating functions, or to put it bluntly, it was a method for avoiding the use of exponential generating functions when they really ought to be used. The point of this paper is that my first impression was wrong: none of the results proved here (with the exception of Theorem 7.1, and perhaps a few other results in section 7) can be easily proved by straightforward manipulation of exponential generating functions. The sequences that we consider here are defined by exponential generating functions, and their most fundamental properties can be proved in a straightforward way using these exponential generating functions. What is surprising is that these sequences satisfy additional relations whose proofs require other methods. The classical umbral calculus is a powerful but specialized tool that can be used to prove these more esoteric formulas. The derangement numbers, for example, have the well-known exponential generating function $\sum_{n=0}^{\infty} D_n x^n/n! = e^{-x}/(1-x)$ from which their basic properties can be derived; umbral calculus gives us the more interesting but considerably more recondite formula $\sum_{n=0}^{\infty} D_n^2 x^n/n! = e^x \sum_{k=0}^{\infty} k!\, x^k/(1+x)^{2k+2}$.

We begin in the next section with a description of the classical umbral calculus, following Rota [34] and Rota and Taylor [36, 37], and point out some of the minor ways in which we differ from their approach. Next, in sections 3 through 5, we consider bilinear and related generating functions for Charlier and Hermite polynomials, and some variations. In section 6 we derive a bilinear generating function for the Rogers-Szegő polynomials, which are related to q-Hermite polynomials. In section 7 we apply the umbral calculus to identities for Bernoulli and related numbers. Sections 8 through 10 deal with Kummer congruences and with analogous congruences for Bell numbers.

The next section contains a formal description of the classical umbral calculus as used in this paper. The reader who is not interested in these technicalities may wish to go directly to section 3.

2. The classical umbral calculus

Most users of Blissard's symbolic notation have viewed it as simply a notational convenience, requiring no formal justification. Thus Guinand [23], in explaining the interpretation of umbral symbols, writes: "In general, any step in manipulation is valid if and only if it remains valid when interpreted in non-umbral form." However, in 1940 E. T. Bell [5] attempted to give an axiomatic foundation to the umbral calculus. To the modern reader, Bell's approach seems ill-conceived, if not completely incomprehensible. A much more successful explanation was given by G.-C. Rota in 1964 [34]: When we interpret $(a+1)^n$ as $\sum_{i=0}^{n} \binom{n}{i} a_i$, we are applying the linear functional on the algebra of polynomials in a that takes a^i to a_i. In retrospect, Rota's idea seems almost obvious, but we must remember that in Bell's day the concept of a linear functional was not the familiar notion that it is in ours. The seemingly mysterious "umbral variable" a is just an ordinary variable; it is in the invisible, but otherwise unremarkable, linear functional that the meaning of the umbral calculus resides. The "feeling of witchcraft" that Rota and Taylor [37] observe hovering about the umbral calculus comes from the attribution to umbrae of properties that really belong to these linear functionals. As in stage illusion, misdirection is essential to the magic.

Rota and Taylor's recent works [36, 37] expanded on Rota's original insight and introduced new concepts that help to resolve some of the ambiguities that may arise in applications of the traditional notation. However, I shall use the traditional notation in this paper. What follows is a short formal description of the classical umbral calculus as used here, based on Rota and Taylor's formulation, but with some modifications.

In the simplest applications of the classical umbral calculus, we work in the ring of polynomials in one variable, e.g., $R[a]$, where R is a ring of "scalars" (R is often a ring of polynomials or formal power series containing the rationals), and we have a linear functional $\mathrm{eval} : R[a] \to R$. (This notation was introduced by Rota and Taylor [36].) The variable a is called an umbral variable or *umbra*. There is nothing special about it other than the fact that the linear functional eval is defined on $R[a]$. We will often use the same letter for the umbra and the sequence; thus we would write a_n for $\mathrm{eval}(a^n)$. It is traditional, and convenient, to omit eval and to write $a^n = a_n$ instead of $\mathrm{eval}(a^n) = a_n$. However when following this convention, we must make clear where eval is to be applied. The rule that we shall follow in this paper is that eval should be applied to any term in an equation that contains a variable that has been declared to be umbral. It should be emphasized that this is a syntactic, not mathematical rule, so the formula $a^n = n$ is to be interpreted as $\mathrm{eval}(a^n) = n$ for all n, even though for $n = 0$, a does not "appear" on the left side. One important difference between our approach and that of Rota and Taylor [36, 37] is that they require that $\mathrm{eval}(1) = 1$, but we do not, and in sections 7 and 9 we shall see several examples where $\mathrm{eval}(1) = 0$. This involves some notational subtleties discussed below; nevertheless, there is no reason why a linear functional on polynomials cannot take 1 to 0, and there are are interesting applications where this happens.

We shall often have occasion to deal with several umbrae together. It should be pointed out that although we use the symbol eval for whatever linear functional is under discussion, there are really many different such functionals. When we write $a^n = a_n$ and $b^n = b_n$ we are really talking about two different linear functionals, $\mathrm{eval}_1 : R[a] \to R$ and $\mathrm{eval}_2 : R[b] \to R$, where $\mathrm{eval}_1(a^n) = a_n$ and $\mathrm{eval}_2(b^n) = b_n$. The meaning of $\mathrm{eval}(a^m b^n)$ might be determined by a completely different linear functional on $R[a, b]$, but traditionally one takes the linear functional eval_3 defined by $\mathrm{eval}_3(a^m b^n) = \mathrm{eval}_1(a^m)\,\mathrm{eval}_2(b^n)$. In this case, we say that the umbrae a and b are *independent* (even though we are really dealing with a property of the linear functional eval_3 rather than a property of the variables a and b). In fact, applications of umbrae that are not independent in this sense are uncommon and do not seem to be have been considered before, and we shall assume that our umbrae are independent except where we explicitly state otherwise. Nevertheless we give an example in section 5 of an application of umbrae that are not independent.

Eschewing the requirement that $\mathrm{eval}(1) = 1$ entails an additional interpretative issue that must be mentioned. We cannot assume that there is a "universal" evaluation functional that applies to every term in a formula; instead we may need a different functional for each term, corresponding to the variables that appear in that term. In section 9, for example, we have the formula

$$F^n = 2A^n - (4B + C)^n,$$

involving the umbrae F, A, B, and C, which must be interpreted as

$$\mathrm{eval}_1(F^n) = \mathrm{eval}_2(2A^n) - \mathrm{eval}_3\big((4B + C)^n\big),$$

where eval_1 is defined on $\mathbf{Q}[F]$, eval_2 is defined on $\mathbf{Q}[A]$, and eval_3 is defined on $\mathbf{Q}[B, C]$. Although the rule may seem unnatural when stated this way, in practice the interpretation is exactly what one would expect.

We will often find it useful to work with power series, rather than polynomials, in our umbrae. However, if $f(u)$ is an arbitrary formal power series in u and a is an umbra then $\mathrm{eval}(f(a))$ does not make sense. Let us suppose that R is a ring of formal power series in variables $x, y, z, \ldots$. Then we call a formal power series $f(u) \in R[[u]]$ *admissible* if for every monomial $x^i y^j z^k \cdots$ in R, the coefficient of $x^i y^j z^k \cdots$ in $f(u)$ is a polynomial in u. Then if $f(u) = \sum_i f_i u^i$ is admissible, we define $\mathrm{eval}(f(a))$ to be $\sum_i f_i \,\mathrm{eval}(a^i)$; admissibility of f ensures that this sum is well defined as an element of R. More generally, we may define admissibility similarly for a formal power series in any finite set of variables with coefficients involving other variables.

3. Charlier polynomials

In the next three sections we apply the classical umbral calculus to find bilinear generating functions. More specifically, we find explicit expressions for generating functions of the form $\sum_n a_n b_n x^n/n!$, where there are simple expressions for the generating functions $\sum_n a_n x^n/n!$ and $\sum_n b_n x^n/n!$. Although it is not obvious *a priori* that such explicit expressions exist, they do, and they have important applications in the theory of orthogonal polynomials (see, e.g., Askey [3]). The method that we use can be translated into a traditional analytic computation, since in all cases that we consider in these three sections, eval can be represented by a definite integral (though in some cases the radius of convergence of the series is 0). For example, in this section we consider the umbra A evaluated by $\mathrm{eval}(A^n) = \alpha(\alpha+1)\cdots(\alpha+n-1)$. We could define eval analytically by

$$\mathrm{eval}\big(f(A)\big) = \frac{1}{\Gamma(\alpha)} \int_0^\infty f(x) x^{\alpha-1} e^{-x}\, dx$$

and do all our calculations with integrals. In fact this idea has been used, in a significantly more sophisticated setting, by Ismail and Stanton [25, 26, 27] to obtain bilinear generating functions much more complicated than those we deal with here.

The rising factorial $(\alpha)_n$ is defined to be $\alpha(\alpha+1)\cdots(\alpha+n-1)$. The Charlier polynomials $c_n(x; a)$ are defined by

$$c_n(x; a) = \sum_{k=0}^{n} \binom{n}{k} (-x)_k\, a^{-k}$$

(see, for example, Askey [3, p. 14]), but it is more convenient to work with differently normalized versions of these polynomials, which we define as

$$C_n(u, \alpha) = u^n c_n(-\alpha; u) = \sum_{i=0}^{n} \binom{n}{i} (\alpha)_i u^{n-i}.$$

Let us define the umbra A by $A^n = (\alpha)_n$. Then

$$C_n(u, \alpha) = (A + u)^n. \tag{3.1}$$

Now

$$e^{Ax} = \sum_{n=0}^{\infty} A^n \frac{x^n}{n!} = \sum_{n=0}^{\infty} (\alpha)_n \frac{x^n}{n!} = (1-x)^{-\alpha}, \tag{3.2}$$

by the binomial theorem. So

$$\sum_{n=0}^{\infty} C_n(u,\alpha)\frac{x^n}{n!} = e^{(A+u)x} = e^{ux}e^{Ax} = \frac{e^{ux}}{(1-x)^{\alpha}}. \tag{3.3}$$

Our goal in this section is to prove the bilinear generating function for the Charlier polynomials,

$$\sum_{n=0}^{\infty} C_n(u,\alpha)C_n(v,\beta)\frac{x^n}{n!} = e^{uvx}\sum_{k=0}^{\infty} \frac{(\alpha)_k}{(1-vx)^{k+\alpha}}\frac{(\beta)_k}{(1-ux)^{k+\beta}}\frac{x^k}{k!}.$$

To do this we first prove some properties of the umbra A.

Lemma 3.1. *For any admissible formal power series f,*

$$e^{Ay}f(A) = \frac{1}{(1-y)^{\alpha}} f\left(\frac{A}{1-y}\right).$$

Proof. First we prove the lemma for the case $f(z) = e^{zw}$. We have

$$\begin{aligned} e^{Ay}e^{Aw} = e^{A(y+w)} &= \frac{1}{(1-y-w)^{\alpha}} \\ &= \frac{1}{(1-y)^{\alpha}} \frac{1}{\left(1-\dfrac{w}{1-y}\right)^{\alpha}} \\ &= \frac{1}{(1-y)^{\alpha}} \exp\left(\frac{A}{1-y}w\right). \end{aligned} \tag{3.4}$$

by (3.2). Equating coefficients of $w^k/k!$ shows that the lemma is true for $f(z) = z^k$. The general case then follows by linearity.

Alternatively, we could have introduced an umbra F with $e^{Fz} = f(z)$ and replaced w with F in (3.4). □

As a first application of Lemma 3.1, we prove the following little-known result.

Theorem 3.2.

$$\sum_{m=0}^{\infty} C_{2m}(u,\alpha)\frac{x^m}{m!} = e^{u^2x}\sum_{k=0}^{\infty} \frac{(\alpha)_{2k}}{(1-2ux)^{2k+\alpha}}\frac{x^k}{k!}.$$

Proof. We have

$$\begin{aligned}\sum_{m=0}^{\infty} C_{2m}(u,\alpha)\frac{x^m}{m!} &= \sum_{m=0}^{\infty}(A+u)^{2m}\frac{x^m}{m!} = e^{(A+u)^2x}\\ &= e^{(A^2+2Au+u^2)x} = e^{u^2x}e^{2Aux}e^{A^2x}\\ &= \frac{e^{u^2x}}{(1-2ux)^{\alpha}}\exp\left[\left(\frac{A}{1-2ux}\right)^2 x\right] \quad \text{by Lemma 3.1}\\ &= e^{u^2x}\sum_{k=0}^{\infty}\frac{(\alpha)_{2k}}{(1-2ux)^{2k+\alpha}}\frac{x^k}{k!}.\end{aligned}$$

□

By a similar computation we can prove a generalization given by the next theorem. We leave the details to the reader.

Theorem 3.3.

$$\sum_{m,n=0}^{\infty} C_{2m+n}(u,\alpha)\frac{x^m}{m!}\frac{y^n}{n!} = e^{u^2x+uy}\sum_{k=0}^{\infty}\frac{(\alpha)_{2k}}{(1-2ux-y)^{2k+\alpha}}\frac{x^k}{k!}. \quad \square$$

Next we prove the bilinear generating function for Charlier polynomials. An equivalent formula can be found in Askey [3, p. 16, equation (2.47)] with a minor error; a and b must be switched on one side of the formula as given there for it to be correct. A combinatorial proof of our Theorem 3.4 has been given by Jayawant [28], who also proved a multilinear generalization.

Theorem 3.4.

$$\sum_{n=0}^{\infty} C_n(u,\alpha)C_n(v,\beta)\frac{x^n}{n!} = e^{uvx}\sum_{k=0}^{\infty}\frac{(\alpha)_k}{(1-vx)^{k+\alpha}}\frac{(\beta)_k}{(1-ux)^{k+\beta}}\frac{x^k}{k!}.$$

Proof. Let A and B be independent umbrae with $A^n = (\alpha)_n$ and $B^n = (\beta)_n$. Then there is an analogue of Lemma 3.1 with B replacing A and β replacing α.

We have

$$\begin{aligned}\sum_{n=0}^{\infty} C_n(u,\alpha)C_n(v,\beta)\frac{x^n}{n!} &= e^{(A+u)(B+v)x}\\ &= e^{uvx}e^{Avx}e^{(Bu+AB)x}\\ &= e^{uvx}\frac{1}{(1-vx)^{\alpha}}\exp\left(Bux+\frac{A}{1-vx}Bx\right) \quad \text{by Lemma 3.1}\\ &= \frac{e^{uvx}}{(1-vx)^{\alpha}}e^{Bux}\exp\left(\frac{A}{1-vx}Bx\right)\\ &= \frac{e^{uvx}}{(1-vx)^{\alpha}}\cdot\frac{1}{(1-ux)^{\beta}}\exp\left(\frac{A}{1-vx}\cdot\frac{B}{1-ux}x\right) \quad \text{by Lemma 3.1}\end{aligned}$$

$$= e^{uvx} \sum_{k=0}^{\infty} \frac{(\alpha)_k}{(1-vx)^{k+\alpha}} \frac{(\beta)_k}{(1-ux)^{k+\beta}} \frac{x^k}{k!}.$$

□

The polynomials $C_n(u, \alpha)$ have a simple interpretation in terms of permutation enumeration: the coefficient of $\alpha^i u^j$ in $C_n(u-\alpha, \alpha)$ is the number of permutations of $\{1, 2, \ldots, n\}$ with j fixed points and i cycles of length at least 2. This follows easily from the exponential generating function

$$e^{ux} \left(\frac{e^{-x}}{1-x} \right)^{\alpha} = \sum_{n=0}^{\infty} C_n(u-\alpha, \alpha) \frac{x^n}{n!}.$$

(See, for example, Stanley [39, chapter 5].) In particular, $C_n(-1, 1)$ is the derangement number D_n, the number of permutations of $\{1, 2, \ldots, n\}$ with no fixed points, and Theorems 3.2 and 3.4 give the formulas

$$\sum_{m=0}^{\infty} D_{2m} \frac{x^m}{m!} = e^x \sum_{k=0}^{\infty} \frac{(2k)!}{(1+2x)^{2k+1}} \frac{x^k}{k!}$$

and

$$\sum_{n=0}^{\infty} D_n^2 \frac{x^n}{n!} = e^x \sum_{k=0}^{\infty} \frac{k!}{(1+x)^{2k+2}} x^k.$$

Theorem 3.4 can be generalized to a formula involving 3-line Latin rectangles. See [21] for a combinatorial proof that also uses umbral methods. A more general result was given using the same technique by Zeng [45], and using very different techniques by Andrews, Goulden, and Jackson [2].

4. Hermite polynomials

We now prove some similar formulas for Hermite polynomials. Perhaps surprisingly, the proofs are a little harder than those for Charlier polynomials. We first define the umbra M by

$$e^{Mx} = e^{-x^2}, \tag{4.1}$$

so that

$$M^n = \begin{cases} (-1)^k \dfrac{(2k)!}{k!}, & \text{if } n = 2k \\ 0, & \text{if } n \text{ is odd.} \end{cases}$$

(The reason for the minus sign in this definition is so that we can obtain formulas for the Hermite polynomials in their usual normalization.) There are two basic simplification formulas for M:

Lemma 4.1.

(i) $e^{M^2 x} = \dfrac{1}{\sqrt{1+4x}}$.

(ii) *For any admissible formal power series f, we have*

$$e^{My} f(M) = e^{-y^2} f(M - 2y).$$

Proof. For (i), we have

$$e^{M^2 x} = \sum_{k=0}^{\infty} (-1)^k \frac{(2k)!}{k!} \frac{x^k}{k!} = \frac{1}{\sqrt{1+4x}}.$$

For (ii), as in the proof of Lemma 3.1, it is sufficient to prove that the formula holds for $f(z) = e^{zw}$. In this case we have

$$e^{My} e^{Mw} = e^{M(y+w)} = e^{-y^2-2yw-w^2} = e^{-y^2} e^{-2yw} e^{Mw} = e^{-y^2} e^{(M-2y)w}.$$

□

Lemma 4.2.

$$e^{Mx+M^2 y} = \frac{e^{-x^2/(1+4y)}}{\sqrt{1+4y}}.$$

Although Lemma 4.2 can be proved directly by showing that both sides are equal to

$$\sum_{i,j} (-1)^{j+k} \frac{(2j+2k)!}{(j+k)!} \frac{x^{2j}}{(2j)!} \frac{y^k}{k!},$$

we give instead two proofs that use Lemma 4.1

First proof. If we try to apply Lemma 4.1 directly, we find that the linear term in M does not disappear, so we need to use a slightly less direct approach. We write e^{Mx+M^2y} as $e^{M(x+z)} e^{M^2 y - Mz}$, where z will be chosen later. Now applying Lemma 4.1 gives

$$\begin{aligned} e^{M(x+z)} e^{M^2 y - Mz} &= e^{-(x+z)^2} e^{(M-2x-2z)^2 y - (M-2x-2z)z} \\ &= e^{-(x+z)^2} e^{M^2 y - 4M(x+z)y + 4(x+z)^2 y - Mz + (2x+2z)z}. \end{aligned}$$

We now choose z so as to eliminate the linear term in M on the right; i.e., we want $-4(x+z)y - z = 0$. So we take $z = -4xy/(1+4y)$, and on simplifying we obtain $e^{Mx+M^2y} = e^{-x^2/(1+4y) + M^2 y}$. Then applying Lemma 4.1 (i) gives the desired result. □

Second proof. Let us fix y and set $g(x) = e^{Mx+M^2y}$. Applying Lemma 4.1 directly gives

$$\begin{aligned} g(x) = e^{Mx+M^2y} &= e^{-x^2} e^{(M-2x)^2 y} \\ &= e^{-x^2+4x^2y} e^{-4Mxy+M^2y} = e^{-x^2(1-4y)} g(-4xy). \end{aligned}$$

Iterating and taking a limit yields

$$\begin{aligned} g(x) &= e^{-x^2(1-4y) - 4^2 x^2 y^2 (1-4y) - \cdots} = e^{-x^2(1-4y+4^2y^2-4^3y^3+\cdots)} g(0) \\ &= e^{-x^2/(1+4y)} g(0) = e^{-x^2/(1+4y)} / \sqrt{1+4y} \end{aligned}$$

by Lemma 4.1 (i). □

Now we define the Hermite polynomials $H_n(u)$ by the generating function

$$\sum_{n=0}^{\infty} H_n(u)\frac{x^n}{n!} = e^{2ux-x^2} = e^{(2u+M)x} \tag{4.2}$$

so that $H_n(u) = (2u+M)^n$.

First we prove a well-known analogue of Theorem 3.2, a special case of a result of Doetsch [10, equation (10)].

Theorem 4.3.

$$\sum_{n=0}^{\infty} H_{2n}(u)\frac{x^n}{n!} = \frac{1}{\sqrt{1+4x}}\exp\left(\frac{4u^2x}{1+4x}\right).$$

Proof. We have

$$\begin{aligned}\sum_{n=0}^{\infty} H_{2n}(u)\frac{x^n}{n!} &= e^{(2u+M)^2x} = e^{4u^2x}e^{4Mux+M^2x} \\ &= \frac{1}{\sqrt{1+4x}}e^{4u^2x}\exp\left(\frac{-16u^2x^2}{1+4x}\right) \quad \text{by Lemma 4.2} \\ &= \frac{1}{\sqrt{1+4x}}\exp\left(\frac{4u^2x}{1+4x}\right).\end{aligned}$$

□

By the same reasoning we can prove the following generalization of Theorem 4.3.

Theorem 4.4.

$$\sum_{m,n=0}^{\infty} H_{2m+n}(u)\frac{x^m}{m!}\frac{y^n}{n!} = \frac{1}{\sqrt{1+4x}}\exp\left(\frac{4u^2x+2uy-y^2}{1+4x}\right). \quad \square$$

Equating coefficients of $y^n/n!$ in both sides of Theorem 4.4, and using (4.2) yields

$$\sum_{m=0}^{\infty} H_{2m+n}(u)\frac{x^m}{m!} = (1+4x)^{-(n+1)/2}H_n\left(\frac{u}{\sqrt{1+4x}}\right)\exp\left(\frac{4u^2x}{1+4x}\right),$$

which is the general form of Doetsch's result [10].

We state without proof a "triple" version of Theorem 4.3 that can be proved by the same technique. See Jayawant [28], where umbral and combinatorial proofs are given.

Theorem 4.5.

$$\sum_{n=0}^{\infty} H_{3n}(u)\frac{x^n}{n!} = \frac{e^{8v^3x+144v^4x^2}}{(1+48ux)^{1/4}}\sum_{n=0}^{\infty}\frac{(-1)^n(6n)!}{(3n)!\,(1+48ux)^{3n/2}}\frac{x^{2n}}{(2n)!},$$

where $v = \left(\sqrt{1+48ux}-1\right)/(24x)$. □

Next we prove Mehler's formula, which gives a bilinear generating function for the Hermite polynomials. An elegant combinatorial proof of this formula has been given by Foata [13], and generalized to the multilinear case by Foata and Garsia [14, 15].

Theorem 4.6.

$$\sum_{n=0}^{\infty} H_n(u)H_n(v)\frac{x^n}{n!} = \frac{1}{\sqrt{1-4x^2}}\exp\left(4\frac{uvx-(u^2+v^2)x^2}{1-4x^2}\right).$$

Proof. We use two independent umbrae, M and N, with M as before and $N^n = M^n$ for all n. (In the terminology of Rota and Taylor [37, 36], M and N are "exchangeable" umbrae.) Then

$$\begin{aligned}
\sum_{n=0}^{\infty} H_n(u)H_n(v)\frac{x^n}{n!} &= e^{(2u+M)(2v+N)x} \\
&= e^{2u(2v+N)x}e^{M(2v+N)x} \\
&= e^{2u(2v+N)x}e^{-(2v+N)^2x^2} \quad \text{by (4.1)} \\
&= e^{4vx(u-vx)}e^{2Nx(u-2vx)-N^2x^2} \\
&= \frac{e^{4vx(u-vx)}}{\sqrt{1-4x^2}}\exp\left(-\frac{4x^2(u-2vx)^2}{1-4x^2}\right) \quad \text{by Lemma 4.2} \\
&= \frac{1}{\sqrt{1-4x^2}}\exp\left(4\frac{uvx-(u^2+v^2)x^2}{1-4x^2}\right).
\end{aligned}$$

□

5. Carlitz and Zeilberger's Hermite polynomials

Next we consider analogues of the Hermite polynomials studied by Carlitz [8] and Zeilberger [44]. Carlitz considered the "Hermite polynomials of two variables"

$$H_{m,n}(u,v) = \sum_{k=0}^{\min(m,n)} \binom{m}{k}\binom{n}{k} k!\, u^{m-k}v^{n-k},$$

with generating function

$$\sum_{m,n} H_{m,n}(u,v)\frac{x^m}{m!}\frac{y^n}{n!} = e^{ux+vy+xy}$$

and proved the bilinear generating function

$$\begin{aligned}
&\sum_{m,n=0}^{\infty} H_{m,n}(u_1,v_1)H_{m,n}(u_2,v_2)\frac{x^m}{m!}\frac{y^n}{n!} \\
&\qquad = (1-xy)^{-1}\exp\left(\frac{u_1u_2x+v_1v_2y+(u_1v_1+u_2v_2)xy}{1-xy}\right). \quad (5.1)
\end{aligned}$$

Independently, Zeilberger considered the "straight Hermite polynomials"

$$H_{m,n}(w) = \sum_{k=0}^{\min(m,n)} \binom{m}{k}\binom{n}{k} k!\, w^k,$$

with generating function

$$\sum_{m,n} H_{m,n}(w)\frac{x^m}{m!}\frac{y^n}{n!} = e^{x+y+wxy},$$

and gave a combinatorial proof, similar to Foata's proof of Mehler's formula [13], of the bilinear generating function

$$\sum_{m,n=0}^{\infty} H_{m,n}(u)H_{m,n}(v)\frac{x^m}{m!}\frac{y^n}{n!} = (1-uvxy)^{-1}\exp\left(\frac{x+y+(u+v)xy}{1-uvxy}\right). \tag{5.2}$$

It is easy to see that Carlitz's and Zeilberger's polynomials are related by $H_{m,n}(u,v) = u^m v^n H_{m,n}(1/uv)$, and that (5.1) and (5.2) are equivalent. We shall prove (5.2), since it involves fewer variables. Our proof uses umbrae that are not independent.

We define the umbrae A and B by

$$A^m B^n = \delta_{m,n} m!,$$

where $\delta_{m,n}$ is 1 if $m = n$ and 0 otherwise. Equivalently, A and B may be defined by

$$e^{Ax+By} = e^{xy}. \tag{5.3}$$

Then Zeilberger's straight Hermite polynomials are given by $H_{m,n}(u) = (1+A)^m(1+Bu)^n$. Two of the basic properties of these umbrae are given in the following lemma.

Lemma 5.1.

(i) *If $f(x,y)$ is an admissible power series then $e^{Ar+Bs}f(A,B) = e^{rs}f(A+r,B+s)$.*

(ii) $e^{Ax+By+ABz} = \dfrac{1}{1-z}e^{xy/(1-z)}$.

Proof. As in the proof of Lemma 3.1, it is sufficient to prove (i) for the case $f(x,y) = e^{xu+yv}$, and for this case we have

$$e^{Ar+Bs}f(A,B) = e^{Ar+Bs}e^{Au+Bv} = e^{A(r+u)}e^{B(s+v)} = e^{(r+u)(s+v)},$$

by (5.3), and

$$\begin{aligned} e^{rs}f(A+s,B+r) &= e^{rs}e^{(A+s)u+(B+r)v} = e^{rs+rv+su}e^{Au+Bv} \\ &= e^{rs+rv+su}e^{uv} = e^{(r+u)(s+v)}. \end{aligned}$$

We can prove (ii) by using (i) to reduce it to the case $x = y = 0$, but instead we give a direct proof. We have

$$\begin{aligned} e^{Ax+By+ABz} &= \sum_{i,j,k} A^{i+k}B^{j+k}\frac{x^i}{i!}\frac{y^j}{j!}\frac{z^k}{k!} \\ &= \sum_{j,k}(j+k)!\,\frac{(xy)^j}{j!^2}\frac{z^k}{k!} = \sum_{j,k}\binom{j+k}{j}\frac{(xy)^j}{j!}z^k \\ &= \sum_j \frac{1}{(1-z)^{j+1}}\frac{(xy)^j}{j!} = \frac{1}{1-z}e^{xy/(1-z)}. \end{aligned}$$

□

Now we prove Zeilberger's bilinear generating function (5.2). We introduce two independent pairs of umbrae A_1, B_1 and A_2, B_2 such that each pair behaves like A, B; in other words,

$$A_1^k B_1^l A_2^m B_2^n = \delta_{k,l}\delta_{m,n} k!\, m!.$$

Then

$$\begin{aligned}\sum_{m,n=0}^{\infty} H_{m,n}(u)H_{m,n}(v)\frac{x^m}{m!}\frac{y^n}{n!} &\\ &= \sum_{m,n}(1+A_1)^m(1+B_1u)^n(1+A_2)^m(1+B_2v)^n\frac{x^m}{m!}\frac{y^n}{n!}\\ &= e^{(1+A_1)(1+A_2)x+(1+B_1u)(1+B_2v)y}\\ &= e^{(1+A_2)x+(1+B_2v)y}e^{A_1(1+A_2)x+B_1(1+B_2v)uy}.\end{aligned}$$

Applying (5.3) with A_1 and B_1 for A and B yields

$$e^{(1+A_2)x+(1+B_2v)y+(1+A_2)(1+B_2v)uxy} = e^{x+y+uxy}e^{A_2x(1+uy)+B_2vy(1+ux)+A_2B_2uvxy}.$$

Then applying Lemma 5.1 (ii) yields (5.2).

By similar reasoning, we can prove a generating function identity equivalent to the Pfaff-Saalschütz theorem for hypergeometric series [22]. In terms of Carlitz's Hermite polynomials of two variables, this is the evaluation of

$$\sum_{m,n} H_{m,n+j}(0,1)H_{m+i,n}(0,1)\frac{x^m}{m!}\frac{y^n}{n!}.$$

Theorem 5.2. *Let i and j be nonnegative integers. Then*

$$\sum_{m,n=0}^{\infty}\binom{m+i}{n}\binom{n+j}{m}x^m y^n = \frac{(1+x)^j(1+y)^i}{(1-xy)^{i+j+1}}. \tag{5.4}$$

Proof. With A_1, B_1, A_2, and B_2 as before, we have

$$A_1^m(1+B_1)^{n+j}A_2^n(1+B_2)^{m+i} = m!\, n!\binom{m+i}{n}\binom{n+j}{m},$$

so the left side of (5.4) is equal to

$$\begin{aligned}\sum_{m,n} A_1^m(1+B_1)^{n+j}A_2^n(1+B_2)^{m+i}\frac{x^m}{m!}\frac{y^n}{n!} &\\ &= e^{A_1(1+B_2)x+A_2(1+B_1)y}(1+B_2)^i(1+B_1)^j. \end{aligned}\tag{5.5}$$

Multiplying the right side of (5.5) by $u^i v^j/i!\, j!$, and summing on i and j, we obtain

$$e^{A_1(1+B_2x)+A_2(1+B_1)y+(1+B_2)u+(1+B_1)v} = e^{u+v}e^{A_1(1+B_2)x+B_1(v+A_2y)+A_2y+B_2u}.$$

Applying (5.3), with A_1 and B_1 for A and B, gives

$$e^{u+v}e^{(1+B_2)(v+A_2y)x+A_2y+B_2u} = e^{u+v+xv}e^{A_2(1+x)y+B_2(u+xv)+A_2B_2xy}.$$

Applying Lemma 5.1 (ii), we obtain

$$\frac{e^{u+v+xv}}{1-xy}\exp\left(\frac{(1+x)(u+xv)y}{1-xy}\right)=\frac{1}{1-xy}\exp\left(\frac{(1+x)v+(1+y)u}{1-xy}\right),$$

and extracting the coefficient of $u^i v^j/i!\,j!$ gives the desired result. □

We can also prove analogues of Doetsch's theorem (Theorem 4.3) for the straight Hermite polynomials. We need the following lemma, which enables us to evaluate the exponential of any quadratic polynomial in A and B.

Lemma 5.3.

$$e^{Av+Bw+A^2x+ABy+B^2z}=\frac{1}{\sqrt{(1-y)^2-4xz}}\exp\left(\frac{vw(1-y)+v^2z+w^2x}{(1-y)^2-4xz}\right).$$

Proof. Since the proof is similar to earlier proofs, we omit some of the details. The case $v=w=0$ is easy to prove directly. For the general case, we write $e^{Av+Bw+A^2x+ABy+B^2z}$ as $e^{Ar+Bs}\cdot e^{-Ar-Bs+Av+Bw+A^2x+ABy+B^2z}$ and choose r and s so that when Lemma 5.1 (i) is applied, the linear terms in A and B vanish. We find that the right values for r and s are

$$r=\frac{v(1-y)+2wx}{(1-y)^2-4xz}\quad\text{and}\quad s=\frac{w(1-y)+2vz}{(1-y)^2-4xz},$$

and the result of the substitution is

$$\exp\left(\frac{vw(1-y)+v^2z+w^2x}{(1-y)^2-4xz}\right)e^{A^2x+ABy+B^2z},$$

which may be evaluated by the case $v=w=0$. □

Theorem 5.4.

$$\sum_{m,n=0}^{\infty}H_{2m,n}(u)\frac{x^m}{m!}\frac{y^n}{n!}=e^{x+y+2uxy+u^2xy^2}$$

$$\sum_{m,n=0}^{\infty}H_{2m,2n}(u)\frac{x^m}{m!}\frac{y^n}{n!}=\frac{1}{\sqrt{1-4u^2xy}}\exp\left(\frac{x+y+4uxy}{1-4u^2xy}\right)$$

$$\sum_{m=0}^{\infty}H_{m,m}(u)\frac{x^m}{m!}=\frac{1}{1-ux}\exp\left(\frac{x}{1-ux}\right)$$

Proof. For the first formula, we have

$$\sum_{m,n=0}^{\infty}H_{2m,n}(u)\frac{x^m}{m!}\frac{y^n}{n!}=\sum_{m,n=0}^{\infty}(1+A)^{2m}(1+uB)^n\frac{x^m}{m!}\frac{y^n}{n!}=e^{(1+A)^2x+(1+uB)y}.$$

We simplify this with Lemma 5.3. The proofs of the other two formulas are similar. (The third formula is equivalent to a well-known generating function for Laguerre polynomials.) □

By the same reasoning, we can prove a more general formula that includes all three formulas of Theorem 5.4 as special cases.

Theorem 5.5.

$$\sum_{i,j,k,l,m=0}^{\infty} H_{i+2k+m,j+2l+m}(u)\frac{v^i}{i!}\frac{w^j}{j!}\frac{x^k}{k!}\frac{y^l}{l!}\frac{z^m}{m!} = \frac{1}{\sqrt{(1-uz)^2-4u^2xy}}$$
$$\times \exp\left(\frac{(1+uw)^2x+(1+uv)^2y+4uxy+(1-uz)(v+w+z+uvw)}{(1-uz)^2-4u^2xy}\right). \quad \square \quad (5.6)$$

6. Rogers-Szegő polynomials

Next we give a proof of a bilinear generating function for the Rogers-Szegő polynomials, which are closely related to q-Hermite polynomials. Our proof differs from the other proofs in this paper in that it uses a linear functional on a noncommutative polynomial algebra. A traditional proof of this result can be found in Andrews [1; p. 50, Example 9] which is also a good reference for basic facts about q-series.

In this section we let $(a)_m$ denote the q-factorial

$$(a)_m = (1-a)(1-aq)\cdots(1-aq^{m-1}),$$

with $(a)_\infty = \lim_{m\to\infty}(a)_m$ as a power series in q. In particular,

$$(q)_m = (1-q)(1-q^2)\cdots(1-q^m).$$

The q-binomial coefficient $\begin{bmatrix} n \\ k \end{bmatrix}$ is defined to be $(q)_n/(q)_k(q)_{n-k}$. The Rogers-Szegő polynomials $R_n(u)$ are defined by

$$R_n(u) = \sum_{k=0}^{n} \begin{bmatrix} n \\ k \end{bmatrix} u^k.$$

We will use a q-analogue of the exponential function,

$$e(x) = \sum_{n=0}^{\infty} \frac{x^n}{(q)_n}.$$

We will also need the q-binomial theorem

$$\sum_{n=0}^{\infty} \frac{(a)_n}{(q)_n} x^n = \frac{(ax)_\infty}{(x)_\infty};$$

the special case $a = 0$ gives

$$e(x) = \frac{1}{(x)_\infty},$$

from which it follows that $e(q^j x) = (x)_j e(x)$.

If A and B are noncommuting variables satisfying the commutation relation $BA = qAB$, then it is well known that

$$(A+B)^n = \sum_{k=0}^{n} \begin{bmatrix} n \\ k \end{bmatrix} A^k B^{n-k}, \quad (6.1)$$

and it follows easily from (6.1) that $e\big((A+B)x\big) = e(Ax)e(Bx)$, where x commutes with A and B. We shall also need the easily-proved fact that $B^jA^i = q^{ij}A^iB^j$.

Now let A, B, C, and D be noncommuting variables such that $BA = qAB$, $DC = qCD$, and all other pairs of variables commute. We shall work in the ring of formal power series in A, B, C, D, with our ring of scalars (which commute with everything) containing variables u, v, x and q. We define our evaluation functional by $\mathrm{eval}(A^iB^jC^kD^l) = u^iv^k$.

Since we need to do some of our computations in the ring of formal power series in A, B, C, and D, we write out the applications of eval explicitly in this proof.

Theorem 6.1.

$$\sum_{n=0}^{\infty} R_n(u)R_n(v)\frac{x^n}{(q)_n} = \frac{(uvx^2)_\infty}{(uvx)_\infty(ux)_\infty(vx)_\infty(x)_\infty}.$$

Proof. By (6.1),

$$\mathrm{eval}\left(\sum_{n=0}^{\infty}(A+B)^n(C+D)^n\frac{x^n}{(q)_n}\right) = \sum_{n=0}^{\infty} R_n(u)R_n(v)\frac{x^n}{(q)_n}. \tag{6.2}$$

Also, we have

$$\begin{aligned}\sum_{n=0}^{\infty}(A+B)^n(C+D)^n\frac{x^n}{(q)_n} &= e\big((A+B)(C+D)x\big)\\ &= e\big(A(C+D)x\big)e\big(B(C+D)x\big)\\ &= e(ACx)e(ADx)e(BCx)e(BDx).\end{aligned} \tag{6.3}$$

The only variables "out of order" in this product are the D's and C's in $e(ADx)e(BCx)$, so

$$\begin{aligned}&\mathrm{eval}\big(e(ACx)e(ADx)e(BCx)e(BDx)\big)\\ &\qquad= \mathrm{eval}\big(e(ACx)\big)\,\mathrm{eval}\big(e(ADx)e(BCx)\big)\,\mathrm{eval}\big(e(BDx)\big)\\ &\qquad= e(uvx)\,\mathrm{eval}\big(e(ADx)e(BCx)\big)e(x)\\ &\qquad= \frac{\mathrm{eval}\big(e(ADx)e(BCx)\big)}{(x)_\infty(uvx)_\infty}.\end{aligned} \tag{6.4}$$

We have

$$e(ADx)e(BCx) = \sum_{i,j=0}^{\infty}\frac{(ADx)^i}{(q)_i}\frac{(BCx)^j}{(q)_j} = \sum_{i,j=0}^{\infty}\frac{A^iB^jC^jD^iq^{ij}x^{i+j}}{(q)_i(q)_j},$$

so

$$\begin{aligned}\mathrm{eval}\big(e(ADx)e(BCx)\big) &= \sum_{i,j=0}^{\infty}\frac{u^iv^jq^{ij}x^{i+j}}{(q)_i(q)_j} = \sum_{i=0}^{\infty}\frac{(ux)^i}{(q)_i}\sum_{j=0}^{\infty}\frac{(vxq^i)^j}{(q)_j}\\ &= \sum_{i=0}^{\infty}\frac{(ux)^i}{(q)_i(vxq^i)_\infty} = \frac{1}{(vx)_\infty}\sum_{i=0}^{\infty}\frac{(vx)_i}{(q)_i}(ux)^i\\ &= \frac{1}{(vx)_\infty}\frac{(uvx^2)_\infty}{(ux)_\infty}.\end{aligned} \tag{6.5}$$

The theorem then follows from (6.2), (6.3), (6.4), and (6.5). ∎

It is worth pointing out that although our proof uses noncommuting variables, it does not yield a noncommutative generalization of the result, since the last application of eval is necessary for the final simplification.

7. Bernoulli numbers

The Bernoulli numbers B_n are defined by the exponential generating function

$$B(x) = \sum_{n=0}^{\infty} B_n \frac{x^n}{n!} = \frac{x}{e^x - 1}. \tag{7.1}$$

Since (7.1) implies that $e^x B(x) = x + B(x)$, the Bernoulli umbra B defined by $B^n = B_n$ satisfies

$$(B+1)^n = B^n + \delta_{n-1}, \tag{7.2}$$

where δ_m is 1 if $m = 0$ and is 0 otherwise. From (7.2) it follows by linearity that for any admissible formal power series f,

$$f(B+1) = f(B) + f'(0). \tag{7.3}$$

Formula (7.3) may be iterated to yield

$$f(B+k) = f(B) + f'(0) + f'(1) + \cdots + f'(k-1) \tag{7.4}$$

for any nonnegative integer k.

There are three other important basic identities for the Bernoulli umbra. Although the most straightforward proofs use exponential generating functions, the umbral proofs are interesting and are therefore included here. Very different umbral proofs of these identities have been given by Rota and Taylor [37, Theorem 4.2 and Proposition 8.3].

Theorem 7.1.

(i) $(B+1)^n = (-B)^n$.

(ii) $(-B)^n = B^n$ *for* $n \neq 1$, *with* $B_1 = -\frac{1}{2}$. *Thus* $B_n = 0$ *when* n *is odd and greater than 1.*

(iii) *For any positive integer* k,

$$kB^n = (kB)^n + (kB+1)^n + \cdots + (kB+k-1)^n.$$

Proof. We prove "linearized" versions of these formulas: for any polynomial f, we have

$$f(B+1) = f(-B) \tag{7.5}$$

$$f(-B) = f(B) + f'(0) \tag{7.6}$$

$$kf(B) = f(kB) + f(kB+1) + \cdots + f(kB+k-1) \tag{7.7}$$

First note that (7.6) follows immediately from (7.5) and (7.3). We prove (7.5) and (7.7) by choosing polynomials $f(x)$, one of each possible degree, for which the formula to be proved is an easy consequence of (7.3).

For (7.5), we take $f(x) = x^n - (x-1)^n$, where $n \geq 1$. Then

$$f(B+1) = (B+1)^n - B^n = \delta_{n-1} \quad \text{by (7.2)},$$

and since $f(-x) = (-1)^{n-1} f(x+1)$, we have

$$f(-B) = (-1)^{n-1} f(B+1) = (-1)^{n-1}\delta_{n-1} = \delta_{n-1} = f(B+1).$$

For (7.7), we take $f(x) = (x+1)^n - x^n$, where $n \geq 1$. Then $f(B) = \delta_{n-1}$ and

$$\begin{aligned}\sum_{i=0}^{k-1} f(kB+i) &= \sum_{i=0}^{k-1}(kB+i+1)^n - \sum_{i=0}^{k-1}(kB+1)^n \\ &= (kB+k)^n - (kB)^n = k^n\big((B+1)^n - B^n\big) \\ &= k^n\delta_{n-1} = k\delta_{n-1} = kf(B).\end{aligned}$$

□

For later use, we note two consequences of Theorem 7.1. First, combining (7.4) and (7.6) gives

$$f(B+k) - f(-B) = \sum_{i=1}^{k-1} f'(i). \tag{7.8}$$

Second, suppose that $f(u)$ is a polynomial satisfying $f(u+1) = f(-u)$. Then we have

$$\begin{aligned} f(B) &= \tfrac{1}{2}\big(f(2B) + f(2B+1)\big) \quad \text{by (7.7)} \\ &= \tfrac{1}{2}\big(f(2B) + f(-2B)\big) \\ &= f(2B) + f'(0) \quad \text{by (7.6)}. \end{aligned} \tag{7.9}$$

Next, we discuss an identity of Kaneko [29], who set $\tilde{B}_n = (n+1)B_n$ and gave the identity

$$\sum_{i=0}^{n+1} \binom{n+1}{i} \tilde{B}_{n+i} = 0, \tag{7.10}$$

noting that it (together with the fact that $B_{2j+1} = 0$ for $j > 0$) allows the computation of B_{2n} from only half of the preceding Bernoulli numbers. Kaneko's proof is complicated, though his paper also contains a short proof by D. Zagier. We shall show that Kaneko's identity is a consequence of the following nearly trivial result.

Lemma 7.2. *For any nonnegative integers m and n,*

$$\sum_{i=0}^{m} \binom{m}{i} B_{n+i} = (-1)^{m+n} \sum_{j=0}^{n} \binom{n}{j} B_{m+j}.$$

Proof. Take $f(x) = x^m(x-1)^n$ in (7.5). □

The key to Kaneko's identity is the observation that

$$\binom{n+1}{i}\tilde{B}_{n+i} = (n+1)\left[\binom{n+1}{i} + \binom{n}{i-1}\right] B_{n+i}, \tag{7.11}$$

which reveals that (7.10) is simply the case $m = n+1$ of Lemma 7.2.

We can generalize Kaneko's identity in the following way:

Theorem 7.3.

$$\frac{1}{n+1}\sum_{i=0}^{n+1} 2^{n+1-i}\binom{n+1}{i}\tilde{B}_{n+i} = (-1)^n,$$

$$\frac{1}{n+1}\sum_{i=0}^{n+1} 3^{n+1-i}\binom{n+1}{i}\tilde{B}_{n+i} = (-2)^{n-1}(n-4),$$

$$\frac{1}{n+1}\sum_{i=0}^{n+1} 4^{n+1-i}\binom{n+1}{i}\tilde{B}_{n+i} = (-1)^n\big(4^n + (2-\tfrac{4}{3}n)3^n\big),$$

and in general,

$$\frac{1}{n+1}\sum_{i=0}^{n+1} k^{n+1-i}\binom{n+1}{i}\tilde{B}_{n+i} = \sum_{i=1}^{k-1}\big((2n+1)i-(n+1)k\big)i^n(i-k)^{n-1}. \tag{7.12}$$

Proof. Using (7.11), we see that the left side of (7.12) is

$$(B+k)^{n+1}B^n + B^{n+1}(B+k)^n.$$

Setting $f(x) = x^m(x-k)^n$ in (7.8), we have

$$(B+k)^m B^n - (-1)^{m+n}B^m(B+k)^n = \sum_{i=0}^{k-1}\big((m+n)i-km\big)i^{m-1}(i-k)^{n-1}.$$

Setting $m = n+1$ gives (7.12).

□

There are several interesting identities for Bernoulli numbers that actually hold for any two sequences (c_n) and (d_n) related umbrally by $d^n = (c+1)^n$; i.e.,

$$d_n = \sum_{i=0}^{n}\binom{n}{i}c_i. \tag{7.13}$$

We note that (7.13) may inverted to give $c^n = (d-1)^n$; i.e.,

$$c_n = \sum_{i=0}^{n}(-1)^{n-i}\binom{n}{i}d_i.$$

By Theorem 7.1 (i), (7.13) holds with $c_n = B_n$, $d_n = (-1)^n B_n$. We shall next describe several pairs of sequences satisfying (7.13), and then give some identities for such sequences, which seem to be new.

Since (7.13) is equivalent to

$$\sum_{n=0}^{\infty} d_n\frac{x^n}{n!} = e^x\sum_{n=0}^{\infty} c_n\frac{x^n}{n!},$$

it is easy to find sequences satisfying (7.13) with simple exponential generating functions, though not all of our examples are of this form.

The derangement numbers D_n satisfy $n! = \sum_{i=0}^{n} \binom{n}{i} D_i$ so (7.13) holds with $c_n = D_n$, $d_n = n!$.

For any fixed nonnegative integer m, the Stirling numbers of the second kind $S(m,n)$ satisfy $n^m = \sum_{i=0}^{n} \binom{n}{i} i!\, S(m,i)$, so (7.13) holds with $c_n = n!\, S(m,n)$, $d_n = n^m$.

The Euler numbers E_n are defined by $\sum_{n=0}^{\infty} E_n x^n/n! = \operatorname{sech} x$. Let us define the "signed tangent numbers" T_n by $\tanh x = \sum_{n=0}^{\infty} T_n x^n/n!$. Then since $e^x \operatorname{sech} x = 1 + \tanh x$, we have that (7.13) holds with $c_n = E_n$, $d_n = \delta_n + T_n$.

The Genocchi numbers g_n are defined by $\sum_{n=0}^{\infty} g_n x^n/n! = 2x/(e^x+1)$. Then

$$\frac{2xe^x}{e^x+1} = 2x - \frac{2x}{e^x+1},$$

so (7.13) holds with $c_n = g_n$, $d_n = 2\delta_{n-1} - g_n$ (so that $d_1 = g_1 = 1$).

The Eulerian polynomials $A_n(t)$ satisfy

$$\sum_{n=0}^{\infty} A_n(t) \frac{x^n}{n!} = \frac{1-t}{1-te^{(1-t)x}}.$$

Then $A_0 = 1$, and $A_n(t)$ is divisible by t for $n > 1$. Let us set $\tilde{A}_n(t) = t^{-1} A_n(t)$ for $n > 0$, with $\tilde{A}_0(t) = 1$. It is easy to check that

$$e^{(1-t)x} \sum_{n=0}^{\infty} \tilde{A}_n(t) \frac{x^n}{n!} = \sum_{n=0}^{\infty} A_n(t) \frac{x^n}{n!},$$

so (7.13) holds with $c_n = A_n(t)/(1-t)^n$, $d_n = \tilde{A}_n(t)/(1-t)^n$.

The Fibonacci numbers F_n are defined by $F_0 = 1$, $F_1 = 1$, and $F_n = F_{n-1} + F_{n-2}$ for all integers n. It is easily verified that for every fixed integer m, (7.13) holds with $c_n = F_{m+n}$, $d_n = F_{m+2n}$, and also with $c_n = F_{m-n}$, $d_n = F_{m+n}$.

By the Chu-Vandermonde theorem, (7.13) holds with

$$c_n = (-1)^n \frac{(\alpha)_n}{(\beta)_n}, \quad d_n = \frac{(\beta-\alpha)_n}{(\beta)_n},$$

where $(\alpha)_n = \alpha(\alpha+1)\cdots(\alpha+n-1)$.

As Zagier observed [29], it is easy to characterize the pairs of sequences satisfying (7.13) with $d_n = (-1)^n c_n$, which, as we shall see, give analogues of Kaneko's identity. The condition, with $c(x) = e^{cx}$ and $d(x) = e^{dx}$, is $e^x c(x) = c(-x)$, which is equivalent to $e^{x/2} c(x) = e^{-x/2} c(-x)$; i.e., $e^{x/2} c(x)$ is even. Thus it is easy to construct such sequences, but not many seem natural. In addition to the Bernoulli numbers, we have an example with the Genocchi numbers g_n,

$$c(x) = \frac{2e^{-x/2}}{e^{x/2} + e^{-x/2}} = \frac{2}{e^x+1} = \sum_{n=0}^{\infty} \frac{g_{n+1}}{n+1} \frac{x^n}{n!},$$

and one with the Lucas numbers, $c_n = (-2)^{-n}(L_n + L_{2n})$, where $L_n = F_{n+1} + F_{n-1}$,

We now discuss the identities which are consequences of (7.13). Our first identity generalizes Lemma 7.2.

Theorem 7.4. *Suppose that the sequences c_n and d_n satisfy* (7.13)*. Then for all nonnegative integers m and n,*

$$\sum_{i=0}^{m}\binom{m}{i}c_{n+i}=\sum_{j=0}^{n}\binom{n}{j}(-1)^{n-j}d_{m+j}. \tag{7.14}$$

Proof. Let c and d be umbrae with $c^n = c_n$ and $d^n = d_n$. Then (7.13) implies that $(c+1)^n = d^n$, so for any polynomial $f(x)$, we have $f(c+1) = f(d)$. Taking $f(x) = x^m(x-1)^n$ yields the theorem. □

An application of Theorem 7.4 yields an interesting recurrence for Genocchi numbers. Let c_n be the Genocchi number g_n, so that, as noted above, $d_n = 2\delta_{n-1} - g_n$. Then taking $m = n$ in Theorem 7.4, we have for $n > 1$,

$$\sum_{i=0}^{n}\binom{n}{i}g_{n+i}=-\sum_{i=0}^{n}\binom{n}{i}(-1)^{n-i}g_{n+i},$$

so

$$\sum_{i=0}^{n}(1+(-1)^{n-i})\binom{n}{i}g_{n+i}=0.$$

The only nonzero terms in the sum are those with $n - i$ even, so we may set $2j = n - i$ and divide by 2 to get the recurrence

$$\sum_{j=0}^{\lfloor n/2\rfloor}\binom{n}{2j}g_{2n-2j}=0,\quad n>1. \tag{7.15}$$

Equation (7.15) is known as Seidel's recurrence (see, e.g., Viennot [42]). It implies that g_{2n} is an integer, which is not obvious from the generating function (it is easily shown that $g_{2i+1} = 0$ for $i > 0$), and it can also be used to derive a combinatorial interpretation for the Genocchi numbers. The reader can check that the Genocchi analogue of Kaneko's identity alluded to before Theorem 7.4 is also Seidel's recurrence in the form $\sum_{i=0}^{n}\binom{n}{i}g_{n+i} = 0$ (in this form true for all n).

We now derive some further identities for sequences satisfying (7.13), of which the first generalizes Theorem 7.4.

Theorem 7.5. *Suppose that the sequences (c_n) and (d_n) satisfy $\sum_{i=0}^{n}\binom{n}{i}c_i = d_n$. Then for all a and b,*

$$\sum_{i=0}^{n}\binom{a}{i}\binom{b}{n-i}d_i=\sum_{j=0}^{n}\binom{a}{j}\binom{a+b-j}{n-j}c_j \tag{7.16}$$

$$\sum_{i=0}^{n}\binom{a}{i}\binom{2a-2i}{n-i}(-2)^i d_i=\sum_{j=0}^{\lfloor n/2\rfloor}\binom{a}{n-j}\binom{n-j}{j}(-2)^{n-2j}c_{n-2j} \tag{7.17}$$

$$\sum_{i=0}^{n}\binom{a}{i}\binom{2a-2i}{n-i}(-4)^i d_i=(-1)^n\sum_{j=0}^{n}\binom{a}{j}\binom{2a-2j}{n-j}4^j c_j. \tag{7.18}$$

Proof. Let c be an umbra with $c^n = c_n$. Then (7.16)–(7.18) follow by substituting c for u in the following polynomial identities, where $v = 1 + u$:

$$\sum_{i=0}^{n} \binom{a}{i}\binom{b}{n-i} v^i = \sum_{j=0}^{n} \binom{a}{j}\binom{a+b-j}{n-j} u^j \tag{7.19}$$

$$\sum_{i=0}^{n} \binom{a}{i}\binom{2a-2i}{n-i} (-2v)^i = \sum_{j=0}^{\lfloor n/2 \rfloor} \binom{a}{n-j}\binom{n-j}{j} (-2u)^{n-2j} \tag{7.20}$$

$$\sum_{i=0}^{n} \binom{a}{i}\binom{2a-2i}{n-i} (-4v)^i = (-1)^n \sum_{j=0}^{n} \binom{a}{j}\binom{2a-2j}{n-j} (4u)^j. \tag{7.21}$$

We prove (7.19) by extracting the coefficient of x^n in $(1+x)^b(1+vx)^a$ in two ways. It is clear that this coefficient is given by the left side of (7.19). But we also have

$$(1+x)^b(1+vx)^a = (1+x)^b(1+x+ux)^a = (1+x)^{a+b}\left(1+\frac{ux}{1+x}\right)^a,$$

in which the coefficient of x^n is easily seen to be given by the right side of (7.19).

For (7.20), we extract the coefficient of x^n in

$$\big((1+x)^2 - 2xv\big)^a = \big((1+x)^2 - 2x - 2xu\big)^a = (1 + x^2 - 2xu)^a.$$

For the left side we have

$$\begin{aligned}
\big((1+x)^2 - 2xv\big)^a &= (1+x)^{2a}\left(1 - \frac{2xv}{(1+x)^2}\right)^a \\
&= (1+x)^{2a} \sum_i \binom{a}{i} \frac{(-2xv)^i}{(1+x)^{2i}} \\
&= \sum_i \binom{a}{i} x^i (1+x)^{2a-2i} (-2v)^i
\end{aligned}$$

and the coefficient of x^n is the left side of (7.20).

For the right side we have

$$\begin{aligned}
(1 + x^2 - 2xu)^a &= \sum_i \binom{a}{i} (x^2 - 2xu)^i \\
&= \sum_{i,j} \binom{a}{i}\binom{i}{j} x^{2j} (-2xu)^{i-j} \\
&= \sum_{i,j} \binom{a}{i}\binom{i}{j} x^{i+j} (-2u)^{i-j}.
\end{aligned}$$

Setting $i = n - j$ gives the right side of (7.20) as the coefficient of x^n.

For (7.21) we start with the identity

$$\big((1+x)^2 - 4xv\big)^a = \big((1+x)^2 - 4x - 4xu\big)^a = \big((1-x)^2 - 4xu\big)^a.$$

The coefficient of x^n may be extracted from both sides as on the left side of (7.20). □

We note that (7.19) is equivalent to a ${}_2F_1$ linear transformation and (7.20) to a ${}_2F_1$ quadratic transformation. Equation (7.21) is actually a special case of (7.19); it can be obtained from (7.19) by replacing a with $2a-n$ and b with $n-a-\frac{1}{2}$, and simplifying.

The special case $a=-1$ of (7.16) is worth noting. It may be written

$$\sum_{i=0}^{n}\binom{b}{n-i}(-1)^i d_i=(-1)^n\sum_{j=0}^{n}\binom{n-b}{n-j}c_j. \tag{7.22}$$

If we replace n by $m+n$ in (7.22) and then set $b=n$, it reduces to (7.14).

Next we prove a remarkable identity of Zagier [43] for Bernoulli numbers. Our proof is essentially an umbral version of Zagier's. The reader may find it instructive to compare the two presentations.

Theorem 7.6. *Let*

$$B_n^*=\sum_{r=0}^{n}\binom{n+r}{2r}\frac{B_r}{n+r}$$

for $n>0$. Then the value of B_n^* for n odd is periodic and is given by

$n \pmod{12}$	1	3	5	7	9	11
B_n^*	$\frac{3}{4}$	$-\frac{1}{4}$	$-\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$	$-\frac{3}{4}$

Proof. Since $\binom{n+r}{2r}=\binom{n+r-1}{2r-1}\frac{n+r}{2r}$ for $r>0$, we have

$$\begin{aligned}2\sum_{n=1}^{\infty}B_n^*x^n&=2\sum_{n=1}^{\infty}\left[\frac{1}{n}+\sum_{r=1}^{n}\binom{n+r-1}{2r-1}\frac{B^r}{2r}\right]x^n\\&=-\log(1-x)^2-\log\left(1-B\frac{x}{(1-x)^2}\right)\\&=-\log\left((1-x)^2-Bx\right).\end{aligned}$$

Now let $g(u)=-\log(1-ux+x^2)$, so that $2\sum_{n=1}^{\infty}B_n^*x^n=g(B+2)$. Note that

$$g'(u)=\frac{x}{1-ux+x^2}.$$

Taking $k=4$ and $f(u)=g(u-2)$ in (7.8), we have

$$\begin{aligned}g(B+2)-g(-B-2)&=g'(-1)+g'(0)+g'(1)\\&=\frac{x}{1+x+x^2}+\frac{x}{1+x^2}+\frac{x}{1-x+x^2}\\&=\frac{3x-x^3-x^5+x^7+x^9-3x^{11}}{1-x^{12}}.\end{aligned}$$

But $g(-B-2)=-\log\left((1+x)^2+Bx\right)=2\sum_{n=1}^{\infty}B_n^*(-x)^n$, so

$$g(B+2)-g(-B-2)=4\sum_{n\text{ odd}}B_n^*x^n,$$

and the result follows. □

8. Kummer Congruences

We say that a sequence (u_n) of integers satisfies *Kummer's congruence* for the prime p if for every integer n and every $j \geq n$,

$$\sum_{i=0}^{n}(-1)^{n-i}\binom{n}{i}u_{i(p-1)+j} \equiv 0 \pmod{p^n}. \tag{8.1}$$

There are many variations and generalizations of this congruence, and we refer the reader to [19], on which most of this section is based, for more information and further references.

If we set $j = n + k$, then (8.1) may be written umbrally as

$$(u^p - u)^n u^k \equiv 0 \pmod{p^n} \tag{8.2}$$

for all $n, k \geq 0$, where $u^m = u_m$.

The result that we prove here shows that if a sequence satisfies Kummer's congruence, then so does the coefficient sequence of the reciprocal of its exponential generating function. Similar results apply to products.

Theorem 8.1. *Let (u_n) and (v_n) be sequences of integers satisfying*

$$\left(\sum_{n=0}^{\infty}u_n\frac{x^n}{n!}\right)\left(\sum_{n=0}^{\infty}v_n\frac{x^n}{n!}\right) = 1. \tag{8.3}$$

Then if (u_n) satisfies Kummer's congruence for the prime p, so does (v_n).

Proof. The relation (8.3) may be written umbrally as $(u+v)^n = 0$, for $n > 0$, where u and v are independent umbrae satisfying $u^m = u_m$ and $v^n = v_n$, and this implies that if $f(x)$ is any polynomial with no constant term, then $f(u + v) = 0$. We shall prove by induction that if (8.2) holds for all $n, k \geq 0$ then

$$(v^p - v)^n v^k \equiv 0 \pmod{p^n} \tag{8.4}$$

for all $n, k \geq 0$.

The case $n = 0$ of (8.4) is trivial. Now let N be a positive integer and K a nonnegative integer, and suppose that (8.4) holds whenever $n < N$ and also when $n = N$ but $k < K$. Thus

$$\begin{aligned} 0 &= [(u+v)^p - (u+v)]^N (u+v)^K \\ &= [(u^p - u) + (v^p - v) + pR(u,v)]^N (u+v)^K \end{aligned}$$

for some polynomial $R(u, v)$ with integer coefficients,

$$= (v^p - v)^N v^K + \text{other terms}.$$

Here each other term is an integer times $(u^p-u)^a(v^p-v)^b\big(pR(u,v)\big)^c u^d v^e$, where $a+b+c = N$, $d + e = K$, and either $b < N$ or $b = N$, $c = 0$, and $e < K$. Thus by the inductive hypothesis and (8.2), each of the other terms is divisible by $p^{a+b+c} = p^N$, and therefore $(v^p - v)^N v^K$ is also. □

As an example, we apply Theorem 8.1 to generalized Euler numbers. Recall that the Euler numbers E_n are defined by $\operatorname{sech} x = \sum_{n=0}^{\infty} E_n x^n/n!$ (so $E_n = 0$ when n is odd). We define the generalized Euler numbers $e_n^{(m)}$ by

$$\sum_{n=0}^{\infty} e_n^{(m)} \frac{x^{mn}}{(mn)!} = \left(\sum_{n=0}^{\infty} \frac{x^{mn}}{(mn)!} \right)^{-1},$$

so that $e_n^{(2)} = E_{2n}$.

Theorem 8.2. *Let p be a prime and let m be a positive integer such that $d = (p-1)/m$ is an integer. Then for $j \geq n/m$,*

$$\sum_{i=0}^{n} (-1)^{n-i} \binom{n}{i} e_{id+j}^{(m)} \equiv 0 \pmod{p^n}.$$

Proof. Let us take $u_n = 1$ and $v_n = e_{n/m}^{(m)}$ if m divides n, with $u_n = v_n = 0$ otherwise. Then the sequences (u_n) and (v_n) satisfy (8.3), and (u_n) satisfy Kummer's congruence for p. Therefore (v_n) does also. □

For example, if we take $m = 4$ and $p = 5$ in Theorem 8.2, then $d = 1$ and we have the congruence

$$\sum_{i=0}^{n} (-1)^{n-i} \binom{n}{i} e_{i+j}^{(4)} \equiv 0 \pmod{5^n} \tag{8.5}$$

for $j \geq n/4$.

By the same kind of reasoning we can prove a variation of Theorem 8.1 [19]:

Theorem 8.3. *Let the sequences (u_n) and (v_n) be related by (8.3), and suppose that for some integer a,*

$$\sum_{i=0}^{n} a^{n-i} \binom{n}{i} u_{ip+j} \equiv 0 \pmod{p^n}$$

for all nonnegative integers j and n. Then

$$\sum_{i=0}^{n} (-a)^{n-i} \binom{n}{i} v_{ip+j} \equiv 0 \pmod{p^n}. \quad \square$$

Next we prove a Kummer congruence for Bernoulli numbers. A similar, but weaker, congruence was proved by Carlitz [7] using a different method.

We call a rational number 2-*integral* if its denominator is odd. If a and b are rational numbers, then by $a \equiv b \pmod{2^r}$ we mean that $(a-b)/2^r$ is 2-integral. For example, $\frac{1}{2} \equiv \frac{5}{2} \pmod 2$. We define $\rho_2(a)$ to be the largest integer for which $a/2^{\rho_2(a)}$ is 2-integral; so $\rho_2(\frac{1}{2}) = -1$ and $\rho_2(\frac{4}{3}) = 2$.

In the proof of the next theorem we will use the fact that $2B_n$ is 2-integral for all n, and that if n is even and positive then $B_n \equiv \frac{1}{2} \pmod 1$; this follows easily by induction from the case $k = 2$ of Theorem 7.1 (iii).

Theorem 8.4. *For nonnegative integers n and j,*

$$\sum_{i=0}^{n}(-1)^{n-i}\binom{n}{i}B_{2i+2j}\equiv 0 \pmod{2^{\tau_{j,n}}}, \tag{8.6}$$

where $\tau_{0,0}=0$, $\tau_{j,0}=\tau_{0,n}=-1$ for $j>0$ and $n>0$, $\tau_{j,1}=1$ for $j\geq 2$, and

$$\tau_{j,n}=\min\left(2j-2,2\left\lfloor\frac{3n-1}{2}\right\rfloor\right)$$

for $n\geq 2$ and $j\geq 1$. Moreover, the exponent in (8.6) is best possible if and only if $j\neq\lfloor(3n+1)/2\rfloor$.

Proof. For simplicity we prove only the most interesting case, in which $n\geq 2$ and $j\geq 1$. Let B be the Bernoulli umbra, $B^n=B_n$, so the sum in (8.6) is $(B^2-1)^nB^{2j}$.

Applying (7.7) with $k=2$ and $f(u)=(u^2-1)^nu^{2j}$, we obtain

$$(B^2-1)^nB^{2j}=2^{2j-1}(4B^2-1)^nB^{2j}+2^{2n-1}B^n(B+1)^n(2B+1)^{2j}. \tag{8.7}$$

The first term on the right side of (8.7) is $(-1)^n2^{2j-1}(B_{2j}-4nB_{2j+2}+\cdots)$. Since $j>0$, this is congruent to $(-1)^n2^{2j-2} \pmod{2^{2j}}$ and thus $\rho_2(2^{2j-1}(4B^2-1)^nB^{2j})=2j-2$.

Next, let $g(u)=u^n(u+1)^n(2u+1)^{2j}$. To determine $\rho_2\big(g(B)\big)$, we apply (7.3) in the form $g(B)=g(B-1)-g'(-1)$ and we find that (since $n>1$)

$$g(B)=B^n(B+1)^n(2B+1)^{2j}=B^n(B-1)^n(2B-1)^{2j}.$$

We now apply (7.9) to $f(u)=u^n(u-1)^n(2u-1)^{2i}$ and we obtain (since $n>1$)

$$g(B)=f(B)=f(2B)=2^nB^n(2B-1)^n(4B-1)^{2j}=(-2)^n\big(B_n-2nB_{n+1}+2K\big),$$

where K is 2-integral. Thus if n is even,

$$g(B)\equiv 2^nB_n\equiv 2^{n-1} \pmod{2^n},$$

and if n is odd

$$g(B)\equiv 2^{n+1}nB_{n+1}\equiv 2^n \pmod{2^{n+1}}.$$

Thus $\rho_2(g(B))$ is $n-1$ if n is even and n if n is odd; so in either case we have $\rho_2(g(B))=2\lfloor(n-1)/2\rfloor+1$. Thus the power of 2 dividing the second term on the right side of (8.7) is

$$\rho_2(g(B))=(2n-1)+2\lfloor(n-1)/2\rfloor+1=2\lfloor(3n-1)/2\rfloor,$$

and the congruence (8.6) follows. It is clear that the exponent in (8.6) is best possible if and only if $2j-2\neq 2\lfloor(3n-1)/2\rfloor$ and this is equivalent to the stated condition. □

We can use Theorem 8.4 to obtain congruences of a different kind for the Bernoulli numbers. As noted earlier, for sequences (c_n) and (d_n) we have $c_n=\sum_{i=0}^n(-1)^{n-i}\binom{n}{i}d_i$ if and only if $d_n=\sum_{i=0}^n\binom{n}{i}c_i$. Let us fix $j>0$ and take $d_n=B_{2n+2j}$, so that $c_n=(B^2-1)^nB^{2j}$. Then we have

$$B_{2n+2j}=\sum_{i=0}^{n}\binom{n}{i}c_i.$$

Moreover, it follows from Theorem 8.4 that if $i \geq (2j-1)/3$ and $i \geq 2$ then $c_i \equiv 0 \pmod{2^{2j-2}}$, so we obtain the congruence

$$B_{2n+2j} \equiv \sum_{i=0}^{M} \binom{n}{i} c_i \pmod{2^{2j-2}}, \tag{8.8}$$

where $M = \max(\lfloor 2(j-1)/3 \rfloor, 1)$. The cases $j = 2, 3, 4$ of (8.8), with simplifications obtained by reducing their coefficients, are

$$\begin{aligned}
B_{2n+4} &\equiv -\frac{1}{30} + \frac{2}{35}n \equiv \frac{1}{2} + 2n \pmod 4 \\
B_{2n+6} &\equiv \frac{1}{42} - \frac{2}{35}n \equiv \frac{13}{2} + 10n \pmod{16} \\
B_{2n+8} &\equiv -\frac{1}{30} + \frac{6}{55}n - \frac{2192}{5005}\binom{n}{2} \equiv \frac{17}{2} + 42n + 48\binom{n}{2} \pmod{64}.
\end{aligned}$$

We note for use in the next section simpler forms of the first two of these congruences:

Lemma 8.5. *Let n be an even integer.*

(i) *If $n \geq 4$ then $B_n \equiv \frac{1}{2} + n \pmod 4$.*

(ii) *If $n \geq 6$ then $B_n \equiv \frac{1}{2} + 5n \pmod{16}$.* □

Of course, more direct proofs of this lemma are possible. Similar congruences for Bernoulli numbers to other moduli have been given by Frame [16]. Many congruences for generalized Euler numbers, obtained in this way from Kummer congruences, can be found in [19].

9. Median Genocchi numbers and Kummer congruences for Euler numbers

It follows from Theorem 8.3 that the Euler numbers E_n satisfy the congruence

$$\sum_{i=0}^{n} \binom{n}{i} E_{2i+j} \equiv 0 \pmod{2^n}.$$

However, Frobenius [17] (see also Carlitz [7]) proved a much stronger congruence: the power of 2 dividing

$$\sum_{i=0}^{n} (-1)^{n-i} \binom{n}{i} E_{2i+j}$$

(for j even) is the same as the power of 2 dividing $2^n n!$. Using the same approach as Frobenius and Carlitz, we prove in this section a Kummer congruence for the numbers $F_n = nE_{n-1}$ in which the modulus is 2^{3n} or 2^{3n-1}, and derive from it Frobenius's congruence.

A special case of our result gives a divisibility property for the *median Genocchi numbers* (also called *Genocchi numbers of the second kind*). These numbers may be defined by

$$H_{2n+1} = \sum_{k=0}^{n} \binom{n}{k} g_{n+k+1},$$

where the g_i are the Genocchi numbers, defined by $\sum_{i=0}^{\infty} g_i x^i/i! = 2x/(e^x+1)$. (In combinatorial investigations, the notation H_{2n+1} is usually used for what in our notation is $|H_{2n+1}| = (-1)^n H_{2n+1}$.) The connection between median Genocchi numbers and the numbers $F_n = nE_{n-1}$ is given by the following result, due to Dumont and Zeng [12].

Lemma 9.1.

$$2^{2n} H_{2n+1} = \sum_{i=0}^{n} (-1)^{n-i} \binom{n}{i} F_{2i+1} = \sum_{i=0}^{n} (-1)^{n-i} \binom{n}{i} (2i+1) E_{2i}.$$

Proof. Let us define the umbrae g and F by $g^n = g_n$ and $F^n = F_n = nE_{n-1}$, so that $e^{Fx} = x \operatorname{sech} x$. Then

$$e^{gx} = \frac{2x}{e^x+1} = \frac{2xe^{-x/2}}{e^{x/2}+e^{-x/2}} = 2e^{-x/2} \cdot \frac{x}{2} \operatorname{sech} \frac{x}{2} = 2e^{-x/2} e^{\frac{F}{2}x} = 2e^{\frac{1}{2}(F-1)x}.$$

Thus $g^n = 2\left(\frac{F-1}{2}\right)^n$, and it follows by linearity that

$$\begin{aligned} 2^{2n} H_{2n+1} &= 2^{2n}(g+1)^n g^{n+1} = 2^{2n} \cdot 2 \left(\frac{F+1}{2}\right)^n \left(\frac{F-1}{2}\right)^{n+1} \\ &= (F-1)(F^2-1)^n = F(F^2-1)^n, \end{aligned}$$

since $F^m = 0$ for m even. □

Barsky [4] proved a conjecture of Dumont that H_{2n+1} is divisible by 2^{n-1}. More precisely, Barsky proved that for $n \geq 3$, $H_{2n+1}/2^{n-1}$ is congruent to 2 modulo 4 if n is odd and is congruent to 3 modulo 4 if n is even. Kreweras [30] gave a combinatorial proof of Dumont's conjecture, using a combinatorial interpretation of H_{2n+1} due to Dumont [11, Corollaire 2.4]. A q-analogue of Barsky's result was given by Han and Zeng [24].

It is interesting to note that (as pointed out in [38]), a combinatorial interpretation of the numbers $H_{2n+1}/2^{n-1}$ was given in 1900 by H. Dellac [9]. Dellac's interpretation may be described as follows: We start with a $2n$ by n array of cells and consider the set D of cells in rows i through $i+n$ of column i, for i from 1 to n. Then $H_{2n+3}/2^n$ is the number of subsets of D containing two cells in each column and one cell in each row. Dellac did not give any formula for these numbers, but he did compute them for n from 1 to 8. Dellac's interpretation can be derived without too much difficulty from Dumont's combinatorial interpretation, but it is not at all clear how Dellac computed these numbers.

Theorem 9.2. *Let $F_n = nE_{n-1}$, so that $\sum_{n=0}^{\infty} F_n x^n/n! = x \operatorname{sech} x$. Let $2^{\mu_{j,n}}$ be the highest power of 2 dividing*

$$\sum_{i=0}^{n} (-1)^{n-i} \binom{n}{i} F_{2i+j},$$

where j is odd. Then $\mu_{j,0} = 0$, $\mu_{j,1} = 2$, and for $n > 1$, $\mu_{j,n} = 3n$ if n is odd and $\mu_{j,n} = 3n-1$ if n is even.

Proof. We have

$$\operatorname{sech} x - 2e^{-x} = \frac{2}{e^x+e^{-x}} - \frac{2+2e^{-2x}}{e^x+e^{-x}} = -\frac{2e^{-2x}}{e^x+e^{-x}} = -\frac{2e^{-x}}{e^{2x}+1} = -2\frac{e^x-e^{-x}}{e^{4x}-1}.$$

Therefore

$$x \operatorname{sech} x = 2xe^{-x} - \sinh x \cdot B(4x) \tag{9.1}$$

where $B(x) = x/(e^x - 1)$ is the Bernoulli number generating function.

Now let us define the umbrae F, A, B, and C by

$$\begin{aligned} e^{Fx} &= x \operatorname{sech} x \\ e^{Ax} &= xe^{-x} = \sum_{n=1}^{\infty} (-1)^{n-1} n \frac{x^n}{n!} \\ e^{Bx} &= B(x) = \frac{x}{e^x - 1} \\ e^{Cx} &= \sinh x = \sum_{n \text{ odd}} \frac{x^n}{n!}. \end{aligned}$$

Then from (9.1) we have

$$F^n = 2A^n - (4B + C)^n. \tag{9.2}$$

We want to find the power of 2 dividing $F^j(F^2 - 1)^n$. It follows from (9.2) that

$$F^j(F^2 - 1)^n = 2A^j(A^2 - 1)^n - (4B + C)^j\big((4B + C)^2 - 1\big)^n. \tag{9.3}$$

First note that for any polynomial p, $p(A) = p'(-1)$. Therefore,

$$2A^j(A^2 - 1)^n = \begin{cases} 2(-1)^{j-1} j & \text{if } n = 0 \\ 4(-1)^{j-1} & \text{if } n = 1 \\ 0 & \text{if } n \geq 2 \end{cases} \tag{9.4}$$

We note also that $C^j(C^2 - 1)^n = 0$ for all integers $j \geq 0$ and $n \geq 1$. Then

$$\begin{aligned} (4B + C)^j\big((4B + C)^2 - 1\big)^n &= (4B + C)^j(16B^2 + 8BC + C^2 - 1)^n \\ &= 2^{3n}(4B + C)^j(2B^2 + BC)^n. \end{aligned} \tag{9.5}$$

We now need to determine the power of 2 dividing $(4B + C)^j(2B^2 + BC)^n$. Since $F^j(F^2 - 1)^n = 0$ if j is even, we may assume that j is odd. Since $2B_i$ is 2-integral, we have

$$(4B + C)^j(2B^2 + BC)^n \equiv C^j(B^nC^n + 2nB^{n+1}C^{n-1}) \pmod 2.$$

Using the facts that $B_i = 0$ when i is odd and greater than 1, and that

$$C^i = \begin{cases} 1 & \text{if } i \text{ is odd} \\ 0 & \text{if } i \text{ is even,} \end{cases}$$

we find that if $n = 0$ then

$$(4B + C)^j(2B^2 + BC)^n \equiv B_0 \equiv 1 \pmod 2,$$

if n is even and positive then

$$(4B + C)^j(2B^2 + BC)^n \equiv B_n \equiv \tfrac{1}{2} \pmod 1,$$

and if n is odd then

$$(4B+C)^j(2B^2+BC)^n \equiv 2nB_{n+1} \equiv 1 \pmod 2.$$

The theorem then follows from these congruences, together with (9.3), (9.4), and (9.5). □

By taking more terms in the expansion of $(4B+C)^j(2B^2+BC)^n$, we can get congruences modulo higher powers of 2. For example, if n is even then

$$(4B+C)^j(2B^2+BC)^n \equiv B_n + 4\binom{n}{2}B_{n+2} \pmod 8.$$

Applying Lemma 8.5 (ii), we find that if $n \geq 6$ then

$$B_n + 4\binom{n}{2}B_{n+2} \equiv \tfrac{1}{2} + n^2(n+3) \pmod 8.$$

Since n even implies $n^2 \equiv 2n \pmod 8$ and $4n \equiv 0 \pmod 8$, this simplifies to $\frac{1}{2} - 2n \pmod 8$.

Similarly, if n is odd then

$$(4B+C)^j(2B^2+BC)^n \equiv (2n+4j)B_{n+1} + 4\binom{n}{3} \pmod 8.$$

If $n \geq 3$ then Lemma 8.5 (i) gives $(2n+4j)B_{n+1} \equiv (n+2j)(3+2n) \pmod 8$, and we may easily verify that for n odd, $4\binom{n}{3} \equiv 2n-2 \pmod 8$. Using the fact that n odd implies $n^2 \equiv 1 \pmod 8$ and $4n \equiv 4 \pmod 8$, we obtain

$$(2n+4j)B_{n+1} + 4\binom{n}{3} \equiv 4 + 2j + n \pmod 8.$$

Therefore we may conclude that (for j odd) if n is even and $n \geq 6$ then

$$2^{-(3n-1)}\sum_{i=0}^{n}(-1)^{n-i}\binom{n}{i}F_{2i+j} \equiv 4n-1 \pmod{16},$$

and if n is odd and $n \geq 3$ then

$$2^{-3n}\sum_{i=0}^{n}(-1)^{n-i}\binom{n}{i}F_{2i+j} \equiv 4-2j-n \pmod 8.$$

In particular, we get a refinement of Barsky's theorem: If n is even and $n \geq 6$ then $H_{2n+1}/2^{n-1} \equiv 4n-1 \pmod{16}$, and if n is odd and $n \geq 3$ then $H_{2n+1}/2^n \equiv 2-n \pmod 8$. It is clear that by the same method we could extend these congruences to any power of 2.

Next we derive Frobenius's congruence from Theorem 9.2. (This derivation is similar to part of Frobenius's original proof.) Define the umbra E by $e^{Ex} = \operatorname{sech} x$, so $F^n = nE^{n-1}$. First note that if j is even then $E_j = F_{j+1}/(j+1)$ is odd, so Frobenius's congruence holds for $n = 0$. From $F^n = nE^{n-1}$, it follows that for any polynomial p, we have $p(F) = p'(E)$. Let us take $p(u) = u^{j+1}(u^2-1)^n$, where j is even and $n \geq 1$. Then

$p'(u) = (j+1)u^j(u^2-1)^n + 2nu^{j+2}(u^2-1)^{n-1}$. By Theorem 9.2, we have $p(F) \equiv 0 \pmod{2^{3n-1}}$, so

$$E^j(E^n-1)^n \equiv -\frac{2n}{j+1}E^{j+2}(E^2-1)^{n-1} \pmod{2^{3n-1}}.$$

By induction on n, the power of 2 dividing $E^{j+2}(E^2-1)^{n-1}$ is equal to the power of 2 dividing $2^{n-1}(n-1)!$, and Frobenius's result follows.

In view of Theorem 9.2, it is natural to ask whether there are analogous congruences for generalized Euler numbers. There seem to be many possibilities, but the most attractive is given by the following conjecture: Define numbers $f_n^{(m)}$ by

$$\sum_{n=0}^{\infty} f_n^{(m)} \frac{x^{(2n+1)m}}{\big((2n+1)m\big)!} = \frac{x^m}{m!} \Big/ \sum_{n=0}^{\infty} \frac{x^{2nm}}{(2nm)!}.$$

(Thus $f_n^{(1)}$ is F_{2n+1} as defined above.) Let $2^{\mu_{j,n,t}}$ be the highest power of 2 dividing

$$\sum_{i=0}^{n} (-1)^{n-i} \binom{n}{i} f_{i+j}^{(2^t)}.$$

Then for $t \geq 1$, we have $\mu_{j,0,t} = 0$, $\mu_{j,1,t} = 4$, and for $n > 1$, $\mu_{j,n,t} = \lfloor \frac{7n}{2} \rfloor - 1$, except when $t = 1$, $n \equiv 2 \pmod 4$, and $n \geq 6$.

In the exceptional case, $\mu_{j,n,1} = \frac{7n}{2} + 2 + \rho_2(j + \vartheta_n)$, where ϑ_n is some integer or 2-adic integer. The first few values of ϑ_n (or reasonably good 2-adic approximations to them) are $\vartheta_6 = 118$, $\vartheta_{10} = 7$, $\vartheta_{14} = 2$, $\vartheta_{18} = 13$, $\vartheta_{22} = 32$, and $\vartheta_{26} = 27$.

By way of illustration, $\mu_{0,1,t} = 4$ for $t \geq 1$ is equivalent to the (easily proved) assertion that $1 + \binom{3 \cdot 2^t}{2^t}$ is divisible by 16 but not by 32.

10. Bell numbers

The Bell numbers B_n are defined by the exponential generating function

$$B(x) = \sum_{n=0}^{\infty} B_n \frac{x^n}{n!} = e^{e^x - 1}. \tag{10.1}$$

Although we are using the same notation for the Bell numbers that we used for Bernoulli numbers, there should be no confusion. Rota [34] proved several interesting properties of the Bell numbers using umbral calculus in his fundamental paper. Here we prove a well-known congruence of Touchard for Bell numbers and a generalization due to Carlitz.

Differentiating (10.1) gives $B'(x) = e^x B(x)$, so

$$B_{n+1} = \sum_{k=0}^{n} \binom{n}{k} B_k.$$

With the Bell umbra B, given by $B^n = B_n$, this may be written $B^{n+1} = (B+1)^n$. Then by linearity, for any polynomial $f(x)$ we have

$$Bf(B) = f(B+1) \tag{10.2}$$

A consequence of (10.2), easily proved by induction, is that for any polynomial $f(x)$ and any nonnegative integer n,

$$B(B-1)\cdots(B-n+1)f(B) = f(B+n). \tag{10.3}$$

(A q-analogue of (10.3) has been given by Zeng [46, Lemma 8].) If we take $f(x) = 1$ in (10.3), we obtain (since $B_0 = 1$)

$$B(B-1)(B-2)\cdots(B-n+1) = 1. \tag{10.4}$$

We note that Rota took (10.4) as the *definition* of the Bell umbra and derived (10.2) and (10.1) from it.

As an application of these formulas, we shall prove Touchard's congruence for the Bell numbers [40, 41].

If $f(x)$ and $g(x)$ are two polynomials in $\mathbf{Z}[x]$, then by $f(x) \equiv g(x) \pmod{p}$, we mean that $f(x)-g(x) \in p\mathbf{Z}[x]$. We first recall two elementary facts about congruences for polynomials modulo a prime p. First we have Lagrange's congruence, $x(x-1)\cdots(x-p+1) \equiv x^p - x \pmod{p}$. Second, if $g(x) \in \mathbf{Z}[x]$ then $g(x+p) - g(x) \equiv 0 \pmod{p}$.

Theorem 10.1. *For any prime p and any nonnegative integer n,*

$$B_{n+p} - B_{n+1} - B_n \equiv 0 \pmod{p}.$$

Proof. By Lagrange's congruence,

$$(B^p - B - 1)B^n \equiv \big(B(B-1)\cdots(B-p+1) - 1\big)B^n \pmod{p}.$$

By (10.3),

$$\big(B(B-1)\cdots(B-p+1) - 1\big)B^n = (B+p)^n - B^n.$$

Since $(x+p)^n - x^n \equiv 0 \pmod{p}$, p divides $(B+p)^n - B^n$. □

Next we prove a generalization of Touchard's congruence analogous to a Kummer congruence, due to Carlitz [6].

Theorem 10.2. *For any prime p and any nonnegative integers n and k,*

$$(B^p - B - 1)^k B^n \equiv 0 \pmod{p^{\lceil k/2 \rceil}}.$$

Proof. Let $L(x)$ be the polynomial $x(x-1)\cdots(x-p+1)-1$. First we show that it suffices to prove that for any polynomial $f(x) \in \mathbf{Z}[x]$, $L(B)^k f(B) \equiv 0 \pmod{p^{\lceil k/2 \rceil}}$. To see this, note that we may write $L(x) = x^p - x - 1 - pR(x)$, where $R(x) \in \mathbf{Z}[x]$. Then $(B^p - B - 1)^k B^n = (L(B) + pR(B))^k B^n = \sum_{i=0}^{k} \binom{k}{i} p^i L(B)^{k-i} R(B)^i B^n$, and our hypothesis will show that $p^i L(B)^{k-i} R(B)^i B^n$ is divisible by p to the power $i + \lceil (k-i)/2 \rceil = \lceil (k+i)/2 \rceil \geq \lceil k/2 \rceil$.

We now prove by induction on k that for any polynomial $f(x) \in \mathbf{Z}[x]$,

$$L(B)^k f(B) \equiv 0 \pmod{p^{\lceil k/2 \rceil}}.$$

The assertion is trivially true for $k = 0$. For the induction step, note that we may write $L(x+p) = L(x) + pJ(x)$, where $J(x) \in \mathbf{Z}[x]$, and recall that by (10.3), $L(B)g(B) =$

$g(B+p)-g(B)$ for any polynomial g. Then for any $f(x)\in\mathbf{Z}[x]$ we have for $k>0$

$$\begin{aligned}L(B)^k f(B) &= L(B)\cdot L(B)^{k-1}f(B) = L(B+p)^{k-1}f(B+p) - L(B)^{k-1}f(B)\\ &= \big(L(B)+pJ(B)\big)^{k-1}f(B+p) - L(B)^{k-1}f(B)\\ &= L(B)^{k-1}\big(f(B+p)-f(B)\big) + \sum_{i=1}^{k-1} p^i \binom{k-1}{i} L(B)^{k-1-i}J(B)^i f(B+p).\end{aligned}$$

We show that each term of the last expression is divisible by $p^{\lceil k/2\rceil}$. Since $f(x+p)-f(x)=ph(x)$ for some $h(x)\in\mathbf{Z}[x]$, we have $L(B)^{k-1}\big(f(B+p)-f(B)\big)=pL(B)^{k-1}h(B)$, which by induction is divisible by p to the power $1+\lceil(k-1)/2\rceil\geq\lceil k/2\rceil$. By induction also, the ith term in the sum is divisible by p to the power $i+\lceil(k-1-i)/2\rceil=\lceil(k-1+i)/2\rceil\geq\lceil k/2\rceil$. This completes the proof. □

Theorem 10.2 can be extended in several ways (in particular, the modulus can be improved); see Lunnon, Pleasants, and Stephens [31] and Gessel [20], which both use umbral methods (though the latter is primarily combinatorial). Another congruence for Bell numbers, also proved umbrally, was given by Gertsch and Robert [18].

Acknowledgment: I would like to thank Jiang Zeng for his hospitality during my visit to the University of Lyon 1, where most of this paper was written. I would also like to thank Timothy Chow, Hyesung Min, and an anonymous referee for pointing out several errors in earlier versions of this paper.

Departmental secretary from before my arrival
until her retirement in December 1996

Acknowledgements

It would be impossible in this short space to individually thank everyone who has helped me to bring this thesis into existence; a few special 'thank you's must suffice.

On the academic side, Prof. Peter Cameron, my supervisor, has been wonderful. From explaining F_{20} to me when we first met, through to these final stages, his continual good cheer, encouragement and belief in me (not to mention his encyclopædic knowledge!) have kept me going throughout a very tough period of my life. Also, many of the ideas in Part I of this thesis had their origins in our weekly meetings.

Our departmental combinatorics study group, including in its number Prof. Rosemary Bailey and Dr. Leonard Soicher, gave me an opportunity to present various results and saved me from grave error at least once.

I met my co-author, Louis Kalikow, at his wedding shower. His unexpected email in response to some mathematics I wrote for him on a serviette (napkin) led to a fruitful and enjoyable collaboration, the results of which you can see in Part II of this thesis. Ben Tarlow had introduced me to the problem, and Louis's wife Aurora Mendelsohn was responsible for the colourful naming of the objects. Thanks, all!

The postgrads in rooms 203 and 201 have been fun and stimulating to be around—cheers, guys!

The secretarial staff—especially Ann Cook, whose caring for the postgrads even extended to hunting me down in Heathrow Airport to tell me that I had received a grant—have constantly helped me with all of those niggling little (and big) practical things.

A big collective thanks to all those who wrote and keep Linux, Debian and TEX and friends running; without them, this thesis would have had to be typed on a typewriter and the symbols written in by hand.

Finally, on the nonacademic side of life, thanks to my mum for supporting me through a long and tough stretch of graduate life. Thanks to Lis for being, and to Melissa for rescuing me. A special thank you goes to my 'surrogate mothers' Sue, Tamra and Leo for supporting and feeding me, along with their husbands Clive, Ian and Jonathan; their highly intelligent kids also provided much needed relief and other challenges. Also, thanks goes to my various housemates for keeping me in good spirits and livening the house with music at all hours.

There are many others who have kept me going in myriad ways; to all of them I am grateful.

London, December 2001

Abstract

Part I

Permutation Group Algebras

We consider the permutation group algebra defined by Cameron and show that if the permutation group has no finite orbits, then no homogeneous element of degree one is a zero-divisor of the algebra. We proceed to make a conjecture which would show that the algebra is an integral domain if, in addition, the group is oligomorphic. We go on to show that this conjecture is true in certain special cases, including those of the form H Wr S and H Wr A, and show that in the oligormorphic case, the algebras corresponding to these special groups are polynomial algebras. In the H Wr A case, the algebra is related to the shuffle algebra of free Lie algebra theory. We finish by considering some integer sequences which arise from certain of these groups.

Part II

Parking Functions, Valet Functions and Priority Queues

Parking functions on $[n] = \{1, \ldots, n\}$ are those functions $p : [n] \to [n]$ satisfying the condition $|\{\, i : p(i) \leqslant r \,\}| \geqslant r$ for each r, and are $(n+1)^{n-1}$ in number. These are equinumerate with allowable input-output pairs of permutations of $[n]$ in a priority queue. We present a new bijection between parking functions and allowable pairs which has many interesting invariance properties. We extend our bijection to allowable pairs of multisets and introduce valet functions as the corresponding extension of parking functions. Using our bijection, we interpret the inversion enumerator for trees in the case of allowable pairs. We end with a comparison of our bijection with other known bijections involving these combinatorial structures, including a new bijection between parking functions and labelled trees.

Part I

Permutation Group Algebras

In which we make some progress on a conjecture of Cameron, and discover some interesting connections with free Lie algebras

1 Introduction

Let G be a permutation group on an (infinite) set Ω. Cameron [2] defined a commutative, associative, graded algebra $A(G)$ which encodes information about the action of G on finite subsets of Ω. It is known that this algebra has zero divisors if G has any finite orbits. The question of what happens when G has no finite orbits is the subject of several conjectures due to Cameron [2], and we will be exploring two of them. The first is:

Conjecture 1.1. If G has no finite orbits, then ε is a prime element in $A(G)$.

Here ε is a certain element in the degree one component of the algebra, defined in section 2. The following weaker conjecture would follow from this, as we explain below.

Conjecture 1.2. If G has no finite orbits, then $A(G)$ is an integral domain.

The first conjecture would give us insight into the following question. If the number of orbits of G on unordered k-element subsets of Ω is n_k, then for which groups does $n_k = n_{k+1} < \infty$ hold? We will not study this question directly here; more information can be found in [2] and [3, sect. 3.5].

We first show that no homogeneous element of degree one in the algebra is a zero-divisor. Unfortunately, it is not obvious how to extend this argument to higher degrees. We then go on to give a conjecture which would, if proven, yield a proof of the weaker conjecture 1.2, and show that it holds in two interesting classes of permutation groups. It also turns out in these two cases that the algebra $A(G)$ is a polynomial algebra, and we determine an explicit set of polynomial generators. It will follow that the stronger conjecture also holds in these cases. Although these results do not help to answer the question raised in the previous paragraph (as in these cases, $n_k < n_{k+1}$ for all k), they do provide further evidence to support the conjectures.

Finally, using the inverse Euler transform, Cameron [5] determined the number of polynomial generators of each degree which would be needed for certain of these algebras if they were actually polynomial algebras. Some of these sequences appear in The On-Line Encyclopedia of Integer Sequences [12] in the context of free Lie algebras. Our work gives an explanation for the sequences observed and the connection with free Lie algebras.

2 The graded algebra of a permutation group

We now give the definition of the algebra under consideration. Let G be a permutation group acting on Ω. Let K be a field of characteristic 0 (either $\mathbb{Q}$ or $\mathbb{C}$ will do). Define $V_n(G)$ to be the K-vector space of all functions from n-subsets of Ω to K which are invariant under the natural action of G on n-subsets of Ω. Define the graded algebra

$$A(G) = \bigoplus_{n=0}^{\infty} V_n(G)$$

with multiplication defined by the rule that for any $f \in V_m(G)$ and $g \in V_n(G)$, the product $fg \in V_{m+n}(G)$ is such that for any $(m+n)$-subset $X \subseteq \Omega$,

$$(fg)(X) = \sum_{\substack{Y \subseteq X \\ |Y|=m}} f(Y)g(X \setminus Y).$$

It is easy to check that, with this multiplication, $A(G)$ is a commutative, associative, graded algebra.

If G has any finite orbits, then this algebra contains zero-divisors. For let $X \subseteq \Omega$ be a finite orbit, $|X| = n$, and let $f \in V_n(G)$ be the characteristic function of this set (so $f(X) = 1$ and $f(Y) = 0$ for $Y \neq X$); then clearly $f^2 = 0$.

Considering Conjecture 1.2, it is clear that there are no zero-divisors in $V_0(G)$, as multiplying by an element of $V_0(G)$ is equivalent to multiplying by an element of K.

We also note that if there is a zero-divisor in $A(G)$, so we have $fg = 0$ with $0 \neq f, g \in A(G)$, then we can consider the non-zero homogeneous components of f and g with lowest degree; say these are f_m of degree m and g_n of degree n respectively. Then the term of degree $m+n$ in fg will be precisely $f_m g_n$, and as $fg = 0$, we must have $f_m g_n = 0$. So we may restrict our attention to considering homogeneous elements, and showing that for any positive integers m and n, we cannot find non-zero $f \in V_m(G)$ and $g \in V_n(G)$ with $fg = 0$.

Furthermore, we will show in the next section that $V_1(G)$ contains no zero-divisors as long as G has no finite orbits, so in particular, the element $\varepsilon \in V_1(G)$ defined by $\varepsilon(x) = 1$ for all $x \in \Omega$ is a non-zero-divisor. So if f is a homogeneous zero-divisor of degree m, with $fg = 0$, and g is homogeneous of degree $n > m$, we also have $(\varepsilon^{n-m} f)g = 0$, so $\varepsilon^{n-m} f \neq 0$ is a zero-divisor of degree n. Thus, if we wish, we can restrict our attention to showing that, for each positive integer n, we cannot find non-zero $f, g \in V_n(G)$ with $fg = 0$.

Turning now to the stronger Conjecture 1.1, we see that the second conjecture

follows from this (as in [2]). For if $fg = 0$, with f and g homogeneous and non-zero, and $\deg f + \deg g$ is minimal subject to this, then $\varepsilon \mid fg$, so we can assume $\varepsilon \mid f$ by primality. Thus $f = \varepsilon f'$, and $\deg f' = \deg f - 1$. Thus $\varepsilon f' g = 0$, which implies $f'g = 0$ by the above, contrary to the minimality of $\deg f + \deg g$.

3 The degree one case

We intend to prove the following theorem.

Theorem 3.1. *If G has no finite orbits, then $V_1(G)$ contains no zero-divisors.*

In order to prove this theorem, we will make use of a technical proposition, which is based on a theorem of Kantor [8]. We first quote a version of Kantor's theorem, as we will have use for it later.

Proposition 3.2. *Let $0 \leqslant e < f \leqslant d - e$. Let X be a set with $|X| = d$. We define (E, F) for subsets $E, F \subset X$ with $|E| = e$ and $|F| = f$ by*

$$(E, F) = \begin{cases} 1 & \text{if } E \subset F \\ 0 & \text{otherwise,} \end{cases}$$

and the matrix $M = ((E, F))$, where the rows of M are indexed by the e-subsets of X and the columns by the f-subsets.

Then $\operatorname{rank} M = \binom{d}{e}$.

The extension of this result is as follows.

Proposition 3.3. *Let $0 \leqslant e < f \leqslant d - 2e$. Let X be a set with $|X| = d$, and let $E_0 \subset X$ with $|E_0| = e$ be a distinguished subset of X. Let w be a weight function on the $(f - e)$-subsets of X with values in the field K, satisfying the condition that $w(X') = 1$ whenever X' is an $(f - e)$-subset of X such that $X' \nsubseteq E_0$. We define (E, F) for subsets $E, F \subset X$ with $|E| = e$ and $|F| = f$ by*

$$(E, F) = \begin{cases} w(F \setminus E) & \text{if } E \subset F \\ 0 & \text{otherwise,} \end{cases}$$

and the matrix $M = ((E, F))$, where the rows of M are indexed by the e-subsets of X and the columns by the f-subsets.

Then $\operatorname{rank} M = \binom{d}{e}$.

Proof of theorem 3.1. Let $g \in V_1(G)$ with $g \neq 0$, and assume $h \in V_n(G)$ with $n \geqslant 1$ and $gh = 0$ (the $n = 0$ case has been dealt with in section 2). We must show that $h = 0$, so that for any $Y \subset \Omega$ with $|Y| = n$, we have $h(Y) = 0$. We assume that a set Y has been fixed for the remainder of this proof.

Since $g \neq 0$, there exists some (infinite) orbit $\Delta \subseteq \Omega$ on which g is non-zero; multiplying by a scalar if necessary, we may assume that $g(\delta) = 1$ for all $\delta \in \Delta$. Pick $X \subset \Omega$ with $|X| = 3n + 1$, $Y \subset X$ and $X \setminus Y \subset \Delta$.

Now for any $(n+1)$-subset $F \subset X$, we have $(hg)(F) = 0$ as $gh = hg = 0$, so that

$$(hg)(F) = \sum_{\substack{E \subset F \\ |E|=n}} h(E)g(F \setminus E) = 0.$$

This can be thought of as a system of linear equations in the unknowns $h(E)$ for $E \subset X$, $|E| = n$, with the matrix $M = (m_{EF})$ given by $m_{EF} = g(F \setminus E)$ if $E \subset F$, and $m_{EF} = 0$ otherwise.

This is precisely the situation of the proposition if we let $e = n$, $f = n+1$ (so that $f - e = 1$), $d = 3n + 1$, $E_0 = Y$ and $w(\alpha) = g(\alpha)$; note that $w(\alpha) = 1$ whenever $\alpha \notin E_0$. (We write $g(\alpha)$ instead of the more correct $g(\{\alpha\})$; no confusion should arise because of this.) Thus $\operatorname{rank} M = \binom{d}{e}$ and the system of equations has a unique solution, which must be $h(E) = 0$ for all $E \subset X$ with $|E| = n$, as this is a possible solution. In particular, this means that $h(Y) = 0$, and since Y was chosen arbitrarily, it follows that $h = 0$.

Hence g is not a zero-divisor. □

Proof of proposition 3.3. Let $R(E)$ be the row of M corresponding to E. M has $\binom{d}{e}$ rows, so we must show that the rows are linearly independent. We thus assume that there is a linear dependence among the rows of M, so

$$R(E^*) = \sum_{E \neq E^*} a(E)R(E) \tag{1}$$

for some e-set E^* and some $a(E) \in K$. We first note that $R(E^*)$ itself is non-zero: this follows as we can pick some $F \supset E^*$ with $F \setminus E^* \not\subseteq E_0$; for this F, we have $(E^*, F) = 1$.

Let Γ be the subgroup of $\mathrm{Sym}(X)$ which stabilises E_0 pointwise and E^* setwise. If $\sigma \in \Gamma$, then

$$(E^\sigma, F^\sigma) = \begin{cases} w((F \setminus E)^\sigma) = w(F \setminus E) & \text{if } E \subset F \\ 0 & \text{otherwise;} \end{cases}$$

either way, $(E^\sigma, F^\sigma) = (E, F)$. (For the result $w((F \setminus E)^\sigma) = w(F \setminus E)$, note that both sides are equal to 1 unless $F \setminus E \subseteq E_0$, in which case σ fixes this set pointwise.) Thus (1) implies that, for all F,

$$\begin{aligned}(E^*, F) = (E^*, F^\sigma) &= \sum_{E \neq E^*} a(E^\sigma)(E^\sigma, F^\sigma) \\ &= \sum_{E \neq E^*} a(E^\sigma)(E, F).\end{aligned}$$

Thus

$$R(E^*) = \sum_{E \neq E^*} a(E^\sigma) R(E).$$

It follows that

$$\begin{aligned} |\Gamma|\, R(E^*) &= \sum_{\sigma \in \Gamma} \sum_{E \neq E^*} a(E^\sigma) R(E) \\ &= \sum_{E \neq E^*} R(E) \sum_{\sigma \in \Gamma} a(E^\sigma). \end{aligned} \tag{2}$$

We now consider the orbits of Γ on the e-subsets of X, excluding E^*. The e-sets E_1 and E_2 will lie in the same orbit if and only if $E_1 \cap E_0 = E_2 \cap E_0$ and $|E_1 \cap E^*| = |E_2 \cap E^*|$. Thus every orbit is described by a subset $E' \subseteq E_0$ and an integer $0 \leqslant i \leqslant e-1$. (We cannot have $i = e$, as we are excluding E^* from consideration.) Clearly not all possible pairs (E', i) will actually correspond to an orbit (it is not hard to see that necessary and sufficient conditions for this are $|E' \cap E^*| \leqslant i \leqslant \min\{e-1, e-|E' \setminus E^*|\}$), so that whenever we consider or sum over such pairs below, we implicitly restrict attention to those which correspond to an orbit. In such cases, we write $\mathcal{E}(E', i)$ for the orbit. Also, for each such pair, pick some $E(E', i) \in \mathcal{E}(E', i)$. Then (2) implies

$$\begin{aligned} |\Gamma|\, R(E^*) &= \sum_{(E',i)} \sum_{E \in \mathcal{E}(E',i)} R(E) \sum_{\sigma \in \Gamma} a(E^\sigma) \\ &= \sum_{(E',i)} \sum_{E \in \mathcal{E}(E',i)} R(E) \sum_{\sigma \in \Gamma} a(E(E',i)^\sigma) \\ &= \sum_{(E',i)} \sum_{\sigma \in \Gamma} a(E(E',i)^\sigma) \sum_{E \in \mathcal{E}(E',i)} R(E) \end{aligned}$$

so that

$$R(E^*) = \sum_{(E',i)} b(E',i) \sum_{E \in \mathcal{E}(E',i)} R(E) \tag{3}$$

with $b(E', i) \in K$, and clearly not all of the $b(E', i)$ can be zero as $R(E^*)$ is not zero.

We define a total order on the pairs (E', i) as follows. Extend the partial order given by $\subseteq$ on the subsets of E_0 to a total order $\leqslant$, and then define $(E', i) \leqslant (E'', j)$ if $E' < E''$ or $E' = E''$ and $i \leqslant j$. We now proceed to derive a contradiction by showing that (3) leads to a system of linear equations for the $b(E', i)$ which is triangular under this total order, with non-zero diagonal entries, and deduce that all of the $b(E', i)$ must be zero.

Let $(\bar{E}, n)$ be a pair corresponding to an orbit. Since $2e + f \leqslant d$, there exists

an f-set $F(\bar{E}, n)$ satisfying $F(\bar{E}, n) \cap E_0 = \bar{E}$ and $|F(\bar{E}, n) \cap E^*| = n$. (Simply take $E(\bar{E}, n)$ and adjoin $f - e$ points lying in $X \setminus (E_0 \cup E^*)$.) As $n \leqslant e - 1$, it follows that $F(\bar{E}, n) \not\supseteq E^*$, so $(E^*, F(\bar{E}, n)) = 0$. Hence by (3), we have

$$0 = \sum_{(E',i)} b(E', i) \sum_{E \in \mathcal{E}(E',i)} (E, F(\bar{E}, n)) \tag{4}$$

for all such pairs $(\bar{E}, n)$.

We note that $F(\bar{E}, n) \cap E_0 = \bar{E}$, and further that $E \in \mathcal{E}(E', i)$ implies that $E \cap E_0 = E'$; thus for the term $(E, F(\bar{E}, n))$ in equation (4) to be non-zero, where $E \in \mathcal{E}(E', i)$, we require $E' \subseteq \bar{E}$, hence also $E' \leqslant \bar{E}$. Furthermore, if $(E, F(\bar{E}, n)) \neq 0$, we must have $i \leqslant n$ as $E \subset F(\bar{E}, n)$. Thus if $(\bar{E}, n) < (E', i)$, we have

$$\sum_{E \in \mathcal{E}(E',i)} (E, F(\bar{E}, n)) = 0. \tag{5}$$

Also, there is an e-set $E \subset F(\bar{E}, n)$ satisfying $E \cap E^* = F(\bar{E}, n) \cap E^*$ and $E \cap E_0 = F(\bar{E}, n) \cap E_0 = \bar{E}$; just take the union of $\bar{E}$ with $F(\bar{E}, n) \cap E^*$ and sufficiently many remaining points of $F(\bar{E}, n)$. For each such E, we have $F(\bar{E}, n) \setminus E \not\subseteq E_0$, so $(E, F(\bar{E}, n)) = 1$. Since K has characteristic zero, we deduce that

$$\sum_{E \in \mathcal{E}(\bar{E},n)} (E, F(\bar{E}, n)) \neq 0, \tag{6}$$

as the sum is over all sets of precisely this form.

It then follows from (4) and (5) that for each pair $(\bar{E}, n)$:

$$0 = \sum_{(E',i) \leqslant (\bar{E},n)} b(E', i) \sum_{E \in \mathcal{E}(E',i)} (E, F(\bar{E}, n)).$$

Now this is a system of linear equations in the unknowns $b(E', i)$ which is lower triangular. Also, by (6), the diagonal entries are non-zero. It follows that the unique solution to this system is that all of the $b(E', i)$ are zero, which provides the required contradiction to equation (3) above. □

4 Oligomorphic-type cases: our conjecture

4.1 Ramsey orderings on orbits of n-sets

Cameron proved the following Ramsey-type result in [3, Prop. 1.10].

Lemma 4.1. *Suppose that the n-sets of an infinite set X are coloured with r colours, all of which are used. Then there is an ordering $c_1, \ldots, c_r$ of the colours and infinite subsets $X_1, \ldots, X_r$, such that X_i contains an n-set of colour c_i but no set of colour c_j for $j > i$.*

We use this as the inspiration for the following definition. If G is a permutation group on Ω, we say that the orbits of G on n-sets of Ω can be *Ramsey ordered* if, given any finite $N > n$, there is an ordering of the orbits c_α, $\alpha \in \mathcal{A}$, where $\mathcal{A}$ is a well-ordered set, and a corresponding sequence of (possibly infinite) subsets $X_\alpha \subseteq \Omega$ with $|X_\alpha| \geqslant N$, and such that X_α contains an n-set in the orbit c_α but no n-set in an orbit c_β for $\beta > \alpha$. (We can take $\mathcal{A}$ to be a set of ordinals with the $\in$-ordering if we wish; this is the reason for using Greek letters.) This pair of sequences forms a *Ramsey ordering*. While the particular Ramsey ordering may depend on N, we do not usually mention N unless we have to. The reader may think throughout of N having a very large finite value. It turns out that this makes certain constructions below simpler than if we required the X_α to be infinite sets.

Not every permutation group has such an ordering. For example, in the regular action of $\mathbb{Z}$ on $\mathbb{Z}$, there is no set with more than two elements, all of whose 2-subsets are in the same orbit, so there cannot be a Ramsey ordering on 2-subsets. However, Cameron's result implies that if G is *oligomorphic* (that is, there are only finitely many orbits on n-sets for each n), then the orbits of G on n-sets can be Ramsey ordered for each n.

It turns out that Ramsey orderings on n-sets naturally yield Ramsey orderings on m-sets whenever $m < n$.

Proposition 4.2. *Let G be a permutation group acting on an infinite set Ω. Let $m < n$ be positive integers, and assume that the n-set orbits of G can be Ramsey ordered, say c_α and X_α with $\alpha \in \mathcal{A}$ are a Ramsey-ordering with $N \geqslant m + n$. Then this ordering induces a Ramsey ordering on the m-set orbits as follows. There is a subset $\mathcal{B} \subseteq \mathcal{A}$ and a labelling of the m-set orbits as d_β, $\beta \in \mathcal{B}$, such that for each $\beta \in \mathcal{B}$, an m-set in the orbit d_β appears in X_β, and that for each $\alpha \in \mathcal{A}$, X_α contains no m-sets in the orbit d_β for $\beta > \alpha$.*

We call the ordering of orbits d_β, $\beta \in \mathcal{B}$ together with the corresponding sets X_β given by this proposition the *induced Ramsey ordering*. Note that we use the same parameter N in both orderings.

The proof uses the following application of Kantor's theorem (Proposition 3.2 above), shown to me by Peter Cameron.

Lemma 4.3. *Let $m < n$ be positive integers, and let X be a finite set with $|X| \geqslant m+n$. Let the m-sets of X be coloured with colours from the set $\mathbb{N}$. Given an n-subset of X, we define its* colour-type *to be the multiset of colours of its $\binom{n}{m}$ m-subsets. Then the number of distinct m-set colours used in X is less than or equal to the number of distinct colour-types among the n-subsets of X.*

Proof. We note that only a finite number of colours appear among the m-subsets of X, as they are finite in number. Without loss of generality, we may assume that the colours used are precisely 1, 2, ..., s.

As in Kantor's theorem (Proposition 3.2), we let M be the incidence matrix of the m-subsets versus n-subsets of X. By that theorem, as $m < n$ and $|X| \geqslant m+n$, this matrix has rank $\binom{|X|}{m}$, which equals the number of rows in the matrix. Thus, by the rank-nullity theorem, M represents an injective linear transformation.

Now for each $i = 1, \ldots, s$, let v_i be the row vector, with entries indexed by the m-subsets of X, whose j-th entry is 1 if the j-th m-subset has colour i, and 0 if it does not. Then v_iM is a row vector, indexed by the n-subsets of X, whose k-th entry is the number of m-subsets of the k-th n-subset which have colour i.

Consider now the matrix M' whose rows are $v_1M, \ldots, v_sM$. Note that the k-th column of this matrix gives the colour-type of the k-th n-subset of X. Its rank is given by

$$\operatorname{rank} M' = \dim \langle v_1M, \ldots, v_sM \rangle = \dim \langle v_1, \ldots, v_s \rangle = s,$$

as M represents an injective linear transformation, and the s vectors $v_1, \ldots, v_s$ are clearly linearly independent. Now since the row rank and column rank of a matrix are equal, we have $s = \operatorname{rank} M' \leqslant$ number of distinct columns in M', which is the number of n-set colour-types in X. Thus the number of m-set colours appearing in X is less than or equal to the number of n-set colour-types in X, as we wanted. □

Proof of Proposition 4.2. Let c_α be any n-set orbit, and let X be a representative of this orbit. We observe that the multiset of m-set orbits represented by the $\binom{m}{n}$ m-subsets of X is independent of the choice of X in this orbit. (For let $\bar{X}$ be another representative of the orbit c_α, with $\bar{X} = g(X)$, where $g \in G$. Then the set of m-subsets of X is mapped to the set of m-subsets of $\bar{X}$ by g, and so the multisets of m-set orbits represented by these two sets are identical.) In particular, we may say that an n-set orbit contains an m-set orbit, meaning that any representative of the n-set orbit contains a representative of the m-set orbit.

We first claim that every m-set orbit appears in some X_α: take a representative of an m-set orbit, say $Y \subset \Omega$. Adjoin a further $n-m$ elements to get an n-set $\bar{X}$. This n-set lies in some orbit, so there is a representative of this orbit in one of the X_α, say $X \subset X_\alpha$. Then this X_α contains a representative of our m-set orbit by the above argument, as we wished to show.

Now if $Y \subset \Omega$ is a representative of an m-set orbit, we set

$$\beta_Y = \min\{\, \alpha : g(Y) \subset X_\alpha \text{ for some } g \in G \,\}.$$

Note that this implies that the m-set orbit containing Y is contained in c_{β_Y} but not in c_α for any $\alpha < \beta_Y$. We set $\mathcal{B} = \{\, \beta_Y : Y \subset \Omega \text{ and } |Y| = m \,\}$, and if Y is an m-set, then we set d_{β_Y} to be the orbit of Y. We claim that $\mathcal{B}$ satisfies the conditions of the proposition with this orbit labelling. Certainly an m-set in the orbit d_{β_Y} appears in X_{β_Y} for each Y, by construction, and for each $\alpha \in \mathcal{A}$, X_α contains no m-sets in the orbit d_β for $\beta > \alpha$, again by construction. However, for d_{β_Y} to be well-defined, we require that $\beta_{Y_1} \neq \beta_{Y_2}$ if Y_1 and Y_2 lie in distinct orbits. We now show this to be the case by demonstrating that given any $\alpha_0 \in \mathcal{A}$, there can only be one m-set orbit appearing in c_{α_0} which has not appeared in any c_α with $\alpha < \alpha_0$.

So let $\alpha_0 \in \mathcal{A}$, and let $X \subseteq X_{\alpha_0}$ have size $m+n$ and contain an n-set in the orbit c_{α_0}. By the observation we made above, namely that the m-set orbits appearing in an n-set are independent of the choice of the n-set in its n-set orbit, it suffices to show that our set X contains at most one new m-set orbit. To use the lemma, we colour the m-subsets of X as follows. If Y is an m-set with $\beta_Y < \alpha_0$, then Y is given colour 1. Those $Y \subset X$ with $\beta_Y = \alpha_0$ are given the colours 2, 3, ..., with a distinct colour per m-set orbit. (Note that any $Y \subset X$ has $\beta_Y \leqslant \alpha_0$, as all n-subsets of X_{α_0} lie in orbits c_α with $\alpha \leqslant \alpha_0$.)

We now consider the possible colour-types of the n-sets of X. Note first that since the m-sets in a given m-set orbit all have the same colour, the colour-type of an n-set depends only upon the n-set orbit in which it lies. There is some n-subset of X in the orbit c_{α_0} by construction, and this has a certain colour-type. Any other n-subset $\tilde{X} \subset X$ is either in the same orbit c_{α_0}, and so has the same colour-type, or it is in some other orbit c_α with $\alpha < \alpha_0$. In the latter case, every m-subset $Y \subset \tilde{X}$ must have $\beta_Y \leqslant \alpha < \alpha_0$, and so it has colour 1. Thus the colour-type of such an n-set must be the multiset $[1, 1, \ldots, 1]$.

If every n-subset of X is in the orbit c_{α_0}, then there is only one colour-type, and so there can only be one m-set colour in X by the lemma, that is, only one m-set orbit with $\beta_Y = \alpha_0$. On the other hand, if X contains an n-set in an orbit c_α with $\alpha < \alpha_0$, then there are at most two colour-types in X: the all-1 colour-type and the colour-type of c_{α_0}. Thus, by the lemma, X contains at most

two m-set colours. Colour 1 appears in c_α, and so there is at most one other colour present, that is, there is at most one m-set orbit with $\beta_Y = \alpha_0$. Thus d_{β_Y} is well-defined on m-set orbits, and we are done. □

4.2 The Ramsey-ordering conjecture

Let G be a permutation group on Ω and let m and n be positive integers. Let d be an m-set orbit and e an n-set orbit. If c is an $(m+n)$-set orbit, then we say that c *contains a* $d \cup e$ *decomposition* if an $(m+n)$-set X in the orbit c can be written as $X = X_m \cup X_n$ with X_m in d and X_n in e. We can easily show using a theorem of P. M. Neumann that if G has no finite orbits, then for every pair (d, e), there exists an $(m+n)$-set orbit c containing a $d \cup e$ decomposition, as follows.

Neumann [9] proved the following: Let G be a permutation group on Ω with no finite orbits, and let Δ be a finite subset of Ω. Then there exists $g \in G$ with $g\Delta \cap \Delta = \varnothing$. It follows trivially that if Y and Z are finite subsets of Ω, then there exists $g \in G$ with $gY \cap Z = \varnothing$ (just take $\Delta = Y \cup Z$). In our case, let X_m and X_n be representatives of d and e respectively. Then there exists $g \in G$ with $gX_m \cap X_n = \varnothing$, and $gX_m \cup X_n$ is an $(m+n)$-set with the required decomposition, hence we can take c to be its orbit.

We will be considering groups G which have a Ramsey ordering on their $(m+n)$-set orbits. Let c_α, $\alpha \in \mathcal{A}$ be the ordering on $(m+n)$-sets, and let d_β, $\beta \in \mathcal{B}$ and e_γ, $\gamma \in \mathcal{C}$ be the induced Ramsey orderings on m- and n-sets respectively (where we assume N is sufficiently large). We then define

$$\beta \vee \gamma = \min\{\, \alpha : c_\alpha \text{ contains a } d_\beta \cup e_\gamma \text{ decomposition} \,\}.$$

Here is our main conjecture.

Conjecture 4.4. Let G be a permutation group on Ω with no finite orbits and for which the orbits on n-sets can be Ramsey ordered for every n. Then given positive integers m and n, there exists some Ramsey ordering of the orbits on $(m+n)$-sets with $N \geqslant 2(m+n)$, say c_α, $\alpha \in \mathcal{A}$ with corresponding sets $X_\alpha \subseteq \Omega$, which induces Ramsey orderings d_β, $\beta \in \mathcal{B}$ and e_γ, $\gamma \in \mathcal{C}$ on the m-set orbits and n-set orbits respectively, and which satisfies the following conditions for all $\beta, \beta' \in \mathcal{B}$ and $\gamma, \gamma' \in \mathcal{C}$:

$$\beta \vee \gamma < \beta' \vee \gamma \text{ if } \beta < \beta' \quad \text{and} \quad \beta \vee \gamma < \beta \vee \gamma' \text{ if } \gamma < \gamma'.$$

Note that the conditions of this conjecture also imply that if $\beta < \beta'$ and $\gamma < \gamma'$, then $\beta \vee \gamma < \beta \vee \gamma' < \beta' \vee \gamma'$, so that $\beta \vee \gamma \leqslant \beta' \vee \gamma'$ implies that either

$\beta < \beta'$ or $\gamma < \gamma'$ or $(\beta, \gamma) = (\beta', \gamma')$.

Given this conjecture, it is easy to show that $A(G)$ is an integral domain for such groups. For if $fg = 0$ with $0 \neq f \in V_m(G)$ and $0 \neq g \in V_n(G)$, let β_0 be such that $f(d_\beta) = 0$ for $\beta < \beta_0$ but $f(d_{\beta_0}) \neq 0$, and let γ_0 be such that $g(e_\gamma) = 0$ for $\gamma < \gamma_0$ but $g(e_{\gamma_0}) \neq 0$. (We write $f(d_\beta)$ to mean the value of $f(Y)$ where Y is any representative of the orbit d_β, and so on.) Letting $\alpha_0 = \beta_0 \vee \gamma_0$, we can consider $fg(c_{\alpha_0})$. Now since $fg = 0$, this must be zero, but we can also determine this explicitly. Letting X be a representative of c_{α_0}, we have

$$fg(c_{\alpha_0}) = fg(X) = \sum_{\substack{Y \subset X \\ |Y| = m}} f(Y) g(X \setminus Y).$$

Every term in the sum is of the form $f(d_\beta)g(e_\gamma)$ where $d_\beta \cup e_\gamma$ is a decomposition of c_{α_0}, so that $\beta \vee \gamma \leqslant \alpha_0 = \beta_0 \vee \gamma_0$. But by the conjecture, this implies that except for terms of the form $f(d_{\beta_0})g(e_{\gamma_0}) \neq 0$, every term either has $\beta < \beta_0$ so that $f(d_\beta) = 0$, or $\gamma < \gamma_0$ so that $g(e_\gamma) = 0$, and hence every one of these terms is zero. Since there exist terms of the form $f(d_{\beta_0})g(e_{\gamma_0})$ by the choice of α_0, we must have $fg(c_{\alpha_0}) \neq 0$. But this contradicts $fg = 0$, and so $A(G)$ is an integral domain.

Recall from section 2 that we can assume $m = n$ when showing that $A(G)$ is an integral domain (that is, $fg = 0$ where $f, g \in V_n(G)$ implies $f = 0$ or $g = 0$); hence we can restrict ourselves to proving the conjecture in the case $m = n$ if this is easier.

5 Special cases (I): Wreath-S-like groups

5.1 Notational conventions

We gather here some notation that we will be using for the rest of this part of the thesis.

We will make use of the lexicographical order on finite sequences and multisets, which we define as follows. Let $(X, <)$ be a totally ordered set. If $x = (x_1, \dots, x_r)$ and $y = (y_1, \dots, y_s)$ are two ordered sequences of elements of X, then we say that x is lexicographically smaller than y, written $x <_{\text{lex}} y$, if there is some t with $x_i = y_i$ for all $i < t$, but either $x_t < y_t$ or $r + 1 = t \leqslant s$. If we now take a finite multiset of elements of X, say M, we write $\text{seq}(M)$ to mean the sequence obtained by writing the elements of M (as many times as they appear in M) in decreasing order. Then if M_1 and M_2 are finite multisets, we define $M_1 <_{\text{lex}} M_2$ to mean $\text{seq}(M_1) <_{\text{lex}} \text{seq}(M_2)$. Note that $<_{\text{lex}}$ is a total order on the set of finite multisets, for $\text{seq}(M_1) = \text{seq}(M_2)$ if and only if $M_1 = M_2$. If we need to explicitly list the elements of a multiset, we will write $[x_1, x_2, \dots]$. We write $M_1 + M_2$ for the multiset sum of the multisets M_1 and M_2, so if $M_1 = [x_1, \dots, x_r]$ and $M_2 = [y_1, \dots, y_s]$, then $M_1 + M_2 = [x_1, \dots, x_r, y_1, \dots, y_s]$.

In the following sections, we will talk about a set of *connected blocks* for a permutation group, the idea being that every orbit will correspond to a multiset or sequence of connected blocks. The choice of terminology will be explained below, and is not related to blocks of imprimitivity. Also, the individual words "connected" and "block" have no intrinsic meaning in the context of the definitions in this thesis. Every connected block has a positive integral weight (for which we write $\text{wt}(\Delta)$), and the weight of a sequence or multiset of connected blocks is just the sum of weights of the individual connected blocks. We well-order the connected blocks of each weight, and denote the connected blocks of weight i by $\Delta_i^{(j)}$, where j runs through some well-ordered indexing set. Without loss of generality, we assume that $\Delta_1^{(1)}$ is the least connected block of weight 1. We then define a well-ordering on all connected blocks by $\Delta_i^{(j)} < \Delta_{i'}^{(j')}$ if $i < i'$ or $i = i'$ and $j < j'$. Using this ordering, we can then talk about the lexicographic ordering on sequences or multisets of connected blocks.

5.2 Wreath-S-like groups

Our prototypical family of groups for this class of groups are those of the form $G = H \text{ Wr } S$, where H is a permutation group on Δ and $S = \text{Sym}(\mathbb{Z})$, the symmetric group acting on a countably infinite set (we take the integers for convenience). The action is the imprimitive one, so G acts on $\Omega = \Delta \times \mathbb{Z}$. We

extract those features of this group which are necessary for the proof below to work.

Definition 5.1. We say that a permutation group G on Ω is *wreath-S-like* if there is a set of connected blocks $\{\Delta_i^{(j)}\}$ and a bijection ϕ from the set of orbits of G on finite subsets of Ω to the set of all finite multisets of connected blocks, with the bijection satisfying the following conditions (where we again blur the distinction between orbits and orbit representatives):

(i) If $Y \subset \Omega$ is finite, then $\mathrm{wt}(\phi(Y)) = |Y|$.

(ii) If $Y \subset \Omega$ is finite and $\phi(Y) = [\Delta_{i_1}^{(j_1)}, \ldots, \Delta_{i_k}^{(j_k)}]$, we can partition Y as $Y = Y_1 \cup \cdots \cup Y_k$ with $|Y_l| = i_l$ for each l. Furthermore, if $Z \subseteq Y$ and $Z = Z_1 \cup \cdots \cup Z_k$, where $Z_l \subseteq Y_l$ for each l, then we can write $\phi(Z)$ as a sum of multisets $\phi(Z) = M_1 + \cdots + M_k$, where $\mathrm{wt}(M_l) = |Z_l|$ for each l and $M_l = [\Delta_{i_l}^{(j_l)}]$ if $Z_l = Y_l$.

Note that condition (ii) implies that $\phi(Y_l) = [\Delta_{i_l}^{(j_l)}]$ for $j = 1, 2, \ldots, k$. Essentially, this condition means that subsets of Y correspond to "submultisets" of $\phi(Y)$ in a suitable sense.

In the case of $G = H$ Wr S mentioned above, we take the connected blocks of weight n to be the orbits of the action of H on n-subsets of Δ. Then every orbit of G can be put into correspondence with a multiset of H-orbits as follows. If $Y \subset \Omega$ is an orbit representative, then $\phi(Y) = [\,\pi_i(Y) : \pi_i(Y) \neq \varnothing\,]$, where the π_i are projections: $\pi_i(Y) = \{\,\delta : (\delta, i) \in Y\,\}$, and we identify orbits of H with orbit representatives. Note that $\mathrm{wt}(\phi(Y)) = |Y|$ as required, and that condition (ii) is also satisfied; in fact, in the notation of the condition, we have $M_l = [\Delta_{i'_l}^{(j'_l)}]$ for each l, for some appropriate i'_l and j'_l.

Another example is the automorphism group of the random graph. The random graph is the unique countable homogeneous structure whose age consists of all finite graphs. It is also known as the Fraïssé limit of the set of finite graphs; see Cameron [3] for more information on homogeneous structures and Fraïssé's theorem. We take the set of connected blocks to be the isomorphism classes of finite connected graphs, where the weight of a connected block is the number of vertices in it. Any orbit can be uniquely described by the multiset of connected graph components in an orbit representative. Condition (i) is immediate, as is condition (ii). Note, however, that there are examples in this scenario where M_l may not be a singleton. For example, if $Y = P_2$ is the path of length 2 (with three vertices), so that $\phi(Y) = [P_2]$, and $Z \subset Y$ consists of the two end vertices of the path, then $\phi(Z) = [K_1, K_1]$.

This prototypical example explains the choice of terminology: the basic units in this example are the connected graphs, so we have called our basic units

connected blocks, both to suggest this example and that of strongly connected components in tournaments as considered in section 6 below.

Cameron [4, Sec. 2] has shown that $A(G)$ is a polynomial algebra if G is an oligomorphic wreath-S-like group, from which it follows that $A(G)$ is an integral domain in this case. It also follows that ε is a prime element, so both Conjectures 1.1 and 1.2 hold in this case. The argument that $A(G)$ is a polynomial algebra in the oligomorphic case is similar to that presented below for wreath-A-like groups, only significantly simpler.

We now show, using a new argument based on Ramsey-orderings, that $A(G)$ is an integral domain in the wreath-S-like case, even without the assumption that G is oligomorphic. This will also provide a basis for the arguments presented in the next section for wreath-A-like groups.

Theorem 5.2. *If G is wreath-S-like, then $A(G)$ is an integral domain.*

Proof. We claim that in such a situation, the conditions of Conjecture 4.4 are satisfied, and hence $A(G)$ is an integral domain.

Following the requirements of the conjecture, let m and n be positive integers and pick any integer $N \geqslant 2(m+n)$. Denote the inverse of ϕ by ψ and let α run through all multisets of connected blocks of total weight $m+n$, then we set $c_\alpha = \psi(\alpha)$ and let X_α be an N-set in the orbit $\psi(\alpha + [\Delta_1^{(1)}, \ldots, \Delta_1^{(1)}])$, where the second multiset has $N-(m+n)$ copies of $\Delta_1^{(1)}$. We claim that this gives a Ramsey ordering of the orbits on $(m+n)$-sets, where the multisets are ordered lexicographically (which gives a well-ordering on the multisets). Firstly, every $(m+n)$-set orbit appears among the list by hypothesis, as ψ is a bijection. Secondly, by construction, there is an $(m+n)$-subset of X_α in the orbit $\psi(\alpha)$, namely partition X_α as in condition (ii) of the definition, and remove all of the elements corresponding to the copies of $\Delta_1^{(1)}$ added. This subset will then map to α under ϕ, by condition (ii). Finally, any $(m+n)$-subset of X_α can be seen to correspond to a multiset lexigraphically less than or equal to α, again using condition (ii) and the fact that $\Delta_1^{(1)}$ is the least connected block, so the subset will be in an orbit c_β with $\beta \leqslant_{\text{lex}} \alpha$, as required.

We note that the induced Ramsey orderings on m-set orbits and n-set orbits are given by precisely the same construction. Specifically, let β be a multiset with $\text{wt}(\beta) = n$. Then the orbit corresponding to the multiset β first appears in X_{α_0} where $\alpha_0 = \beta + [\Delta_1^{(1)}, \ldots, \Delta_1^{(1)}]$. For assume that an n-set Z in the orbit $\psi(\beta)$ appears in X_α. As we have $\phi(Z) = \beta$, β must be a "submultiset" of α in the sense of condition (ii), and it is clear that the lexicographically smallest such α is the one given by adjoining an appropriate number of copies of $\Delta_1^{(1)}$ to β. It is not difficult to show that $\beta \vee \gamma$ is precisely the multiset $\beta + \gamma$, and that $\beta <_{\text{lex}} \beta'$ implies $\beta + \gamma <_{\text{lex}} \beta' + \gamma$, and therefore $\beta \vee \gamma <_{\text{lex}} \beta' \vee \gamma$;

similarly, $\gamma <_{\text{lex}} \gamma'$ implies $\beta \vee \gamma <_{\text{lex}} \beta \vee \gamma'$. (The argument is similar to that of Theorem 6.2 below.) Thus the conditions of the conjecture are satisfied by this Ramsey ordering, and hence $A(G)$ is an integral domain. □

6 Special cases (II): Wreath-A-like groups

We can now apply the same ideas used for the wreath-S-like case to the next class of groups, although the details are more intricate. The only essential difference between these two classes is that here we deal with ordered sequences of connected blocks instead of unordered multisets of connected blocks. We first define this class of groups and show that their algebras are integral domains. We then show that in the oligomorphic case, they have a structure similar to that of shuffle algebras, and deduce that they are polynomial rings. With this information, we then look at some integer sequences which arise from this family of groups.

6.1 Wreath-A-like groups

If we have two finite sequences $S_1 = (x_1, \ldots, x_r)$ and $S_2 = (y_1, \ldots, y_s)$, then we write $S_1 \oplus S_2 = (x_1, \ldots, x_r, y_1, \ldots, y_s)$ for their concatenation.

Definition 6.1. We say that a permutation group G on Ω is *wreath-A-like* if there is a set of connected blocks $\{\Delta_i^{(j)}\}$ and a bijection ϕ from the set of orbits of G on finite subsets of Ω to the set of all finite sequences of connected blocks, with the bijection satisfying the following conditions:

(i) If $Y \subset \Omega$ is finite, then $\mathrm{wt}(\phi(Y)) = |Y|$.

(ii) If $Y \subset \Omega$ is finite and $\phi(Y) = (\Delta_{i_1}^{(j_1)}, \ldots, \Delta_{i_k}^{(j_k)})$, we can partition Y as an ordered union $Y = Y_1 \cup \cdots \cup Y_k$ with $|Y_l| = i_l$ for each l. Furthermore, if $Z \subseteq Y$ and $Z = Z_1 \cup \cdots \cup Z_k$, where $Z_l \subseteq Y_l$ for each l, then we can write $\phi(Z)$ as a concatenation of sequences $\phi(Z) = S_1 \oplus \cdots \oplus S_k$ where $\mathrm{wt}(S_l) = |Z_l|$ for each l, and $S_l = (\Delta_{i_l}^{(j_l)})$ if $Z_l = Y_l$.

As in the wreath-S-like case, condition (ii) implies that $\phi(Y_l) = (\Delta_{i_l}^{(j_l)})$ for $l = 1, 2, \ldots, k$.

Our prototypical family of groups for this class of groups are those of the form $G = H \mathrm{\ Wr\ } A$, where H is a permutation group on Δ, and A is the group of all order-preserving permutations of the rationals. Again, the wreath product action is the imprimitive one, so G acts on $\Omega = \Delta \times \mathbb{Q}$. As before, we take the connected blocks of weight n to be the orbits of the action of H on n-subsets of Δ. Then every orbit of G can be put into correspondence with a unique sequence of H-orbits as follows. If $Y \subset \Omega$ is an orbit representative, we can apply an element of the top group A to permute Y to a set of the form $(\Delta_1 \times \{1\}) \cup (\Delta_2 \times \{2\}) \cup \cdots \cup (\Delta_t \times \{t\})$, where each Δ_i is non-empty. Each of the Δ_i is a representative of some H-orbit, so we set $\phi(Y) = (\Delta_1, \Delta_2, \ldots, \Delta_t)$,

again blurring the distinction between orbits and orbit representatives. It is again easy to see that conditions (i) and (ii) of the definition hold in this case.

Another example is the automorphism group of the random tournament. In this context, a tournament is a complete graph, every one of whose edges is directed, and the random tournament is the Fraïssé limit of the set of finite tournaments. A tournament is called strongly connected if there is a path between every ordered pair of vertices. It can be shown quite easily that every tournament can be decomposed uniquely as a sequence of strongly connected components, where the edges between components are all from earlier components to later ones. So here we take our set of connected blocks to be the isomorphism classes of finite strongly connected tournaments (and again, the weight of a connected block is the number of vertices in it), and if T is a finite subset of the random tournament, we set $\phi(T)$ to be the sequence of strongly connected components of T. Again, it is not difficult to see that conditions (i) and (ii) hold. Also, as in the case of the random graph, it may be that a sub-tournament has more components that the original tournament; for example, the cyclically-oriented 3-cycle is strongly connected, but any 2-element subset of it consists of two strongly connected 1-sets.

A third example is the automorphism group of the "generic pair of total orders". This is the Fraïssé limit of the class of finite sets, where each finite set carries two (unrelated) total orders, which can be taken as $a_1 < a_2 < \cdots < a_n$ and $a_{\pi(1)} \prec a_{\pi(2)} \prec \cdots \prec a_{\pi(n)}$ for some permutation $\pi \in S_n$. Thus orbits of the Fraïssé limit are described by permutations. We can take the connected blocks for this group to be the permutations $\pi \in S_n$ for which there exists no k with $0 < k < n$ such that π maps $\{1, \ldots, k\}$ to itself. The details of this example are not hard to check.

Theorem 6.2. *If G is wreath-A-like, then $A(G)$ is an integral domain.*

Proof. The proof runs along very similar lines to that of Theorem 5.2. If α is a sequence of connected blocks, we write $[\alpha]$ to denote the multiset whose elements are the terms of the sequence with their multiplicities. We define an ordering on sequences by $\alpha < \beta$ if $[\alpha] <_{\text{lex}} [\beta]$ or $[\alpha] = [\beta]$ and $\alpha >_{\text{lex}} \beta$.

Again, we show that the conditions of Conjecture 4.4 are satisfied in this case. Let m and n be positive integers and let N be a positive integer with $N \geqslant 2(m+n)$. Denoting the inverse of ϕ by ψ and letting α run through all sequences of connected blocks of total weight $m+n$, we set $c_\alpha = \psi(\alpha)$ and let X_α be a N-set in the orbit $\psi(\alpha \oplus (\Delta_1^{(1)}, \ldots, \Delta_1^{(1)}))$, where the second sequence has $N-(m+n)$ copies of $\Delta_1^{(1)}$. We claim that this gives a Ramsey ordering of the orbits on $(m+n)$-sets, where the sequences are ordered as described in the previous paragraph. Firstly, every $(m+n)$-set orbit appears in the list by

hypothesis, as ψ is a bijection. Secondly, by construction, there is an $(m+n)$-subset of X_α in the orbit $\psi(\alpha)$, namely partition X_α as in condition (ii) of the definition, and remove all of the elements corresponding to the copies of $\Delta_1^{(1)}$ appended. This subset will then map to α under ϕ, by condition (ii).

To show the final condition of Ramsey orderings, we must show that any $(m+n)$-subset of X_α is in an orbit corresponding to a sequence less than or equal to α. Using the notation of condition (ii), we let $\alpha = (\Delta_{i_1}^{(j_1)}, \ldots, \Delta_{i_k}^{(j_k)})$ and $X_\alpha = X_1 \cup \cdots \cup X_k \cup X_{k+1} \cup \cdots \cup X_r$, where X_{k+1}, ..., X_r correspond to the appended copies of $\Delta_1^{(1)}$. Consider a subset $Y = Y_1 \cup \cdots \cup Y_r \subset X_\alpha$ with $|Y| = m+n$. If $Y_l \neq X_l$ for some l with $X_l \neq \Delta_1^{(1)}$, then clearly $[\phi(Y)] <_{\text{lex}} [\alpha]$, as $\text{wt}(S_l) < i_l$, and the only new connected blocks which can be used are copies of $\Delta_1^{(1)}$, which is the least connected block. So the remaining case to consider is where some of the $\Delta_{i_l}^{(j_l)}$ are equal to $\Delta_1^{(1)}$, and for some or all of those, $Y_l = \varnothing$, whereas $Y_s = X_s$ for some $s > k$. But in such a case, while we have $[\phi(Y)] = [\alpha]$, it is clear that $\phi(Y) \geqslant_{\text{lex}} \alpha$. So in either case, we have $\phi(Y) \leqslant \alpha$, or equivalently $Y \leqslant c_\alpha$, as required.

We note that the induced Ramsey orderings on m-set orbits and n-set orbits are given by precisely the same construction; in particular, the orbit given by the sequence β first appears in X_α, where $\alpha = \beta \oplus (\Delta_1^{(1)}, \ldots, \Delta_1^{(1)})$.

Finally, we must show that the remaining conditions of the conjecture are satisfied by this Ramsey ordering. We will only show that $\beta < \beta'$ implies $\beta \vee \gamma < \beta' \vee \gamma$; the other condition follows identically. We first deduce an explicit description of $\beta \vee \gamma$.

A *shuffle* of two sequences, say $(x_1, \ldots, x_r)$ and $(y_1, \ldots, y_s)$, is a sequence $(z_1, \ldots, z_{r+s})$ for which there is a partition of $\{1, 2, \ldots, r+s\}$ into two disjoint sequences $1 \leqslant i_1 < i_2 < \cdots < i_r \leqslant r+s$ and $1 \leqslant j_1 < j_2 < \cdots < j_s \leqslant r+s$ with $z_{i_k} = x_k$ for $1 \leqslant k \leqslant r$ and $z_{j_k} = y_k$ for $1 \leqslant k \leqslant s$.

We first show that $\beta \vee \gamma$ is the lexicographically greatest shuffle of β with γ; this is not difficult although the argument is a little intricate. We let α_0 be this greatest shuffle and note that $[\alpha_0] = [\beta] + [\gamma]$. Now let α be any sequence of connected blocks for which c_α contains a $d_\beta \cup e_\gamma$ decomposition; we must show that $\alpha_0 \leqslant \alpha$. (Here d_β and e_γ are the orbits on m-sets and n-sets corresponding to β and γ respectively.)

We let $\alpha = (A_1, \ldots, A_k)$ be this sequence of connected blocks, and let Y be a representative of the orbit c_α. Write Y as an ordered union $Y = Y_1 \cup \cdots \cup Y_k$ as in condition (ii) of the definition of wreath-A-like groups. Then any decomposition of c_α into two subsets can be written as

$$c_\alpha = Z \cup Z' = (Z_1 \cup \cdots \cup Z_k) \cup (Z_1' \cup \cdots \cup Z_k'),$$

where $Y_l = Z_l \cup Z'_l$ as a disjoint union for each l. Now if we require $\phi(Z) = \beta$ and $\phi(Z') = \gamma$, this means that the sequences $S_1 \oplus \cdots \oplus S_k$ and $S'_1 \oplus \cdots \oplus S'_k$ corresponding to Z and Z' respectively, as given by condition (ii), must equal β and γ respectively. If $\{Z_l, Z'_l\} = \{Y_l, \varnothing\}$, then $[S_l] + [S'_l] = [A_l]$ by condition (ii), but if not, then $[S_l] + [S'_l] <_{\text{lex}} [A_l]$ by comparing weights. As $M_1 <_{\text{lex}} M_2$ implies $M_1 + M <_{\text{lex}} M_2 + M$ for any multisets M_1, M_2 and M, it follows that $[\beta] + [\gamma] \leqslant_{\text{lex}} [\alpha]$ with equality if and only if $\{Z_l, Z'_l\} = \{Y'_l, \varnothing\}$ for each l, that is, $[\alpha_0] \leqslant_{\text{lex}} [\alpha]$ with equality if and only if α is a shuffle of β and γ. And if α is such a shuffle, then $\alpha \leqslant_{\text{lex}} \alpha_0$ by construction, so $\alpha_0 \leqslant \alpha$, as required.

Given this, we can now show that if $\beta < \beta'$, then $\beta \vee \gamma < \beta' \vee \gamma$. We first consider the case that $[\beta] <_{\text{lex}} [\beta']$, from which it follows that $[\beta] + [\gamma] <_{\text{lex}} [\beta'] + [\gamma]$. Since $[\beta \vee \gamma] = [\beta] + [\gamma]$ and $[\beta' \vee \gamma] = [\beta'] + [\gamma]$, we deduce that $[\beta \vee \gamma] <_{\text{lex}} [\beta' \vee \gamma]$, so $\beta \vee \gamma < \beta' \vee \gamma$.

Now consider the other possible case, namely $[\beta] = [\beta']$ but $\beta >_{\text{lex}} \beta'$. Note that $[\beta \vee \gamma] = [\beta' \vee \gamma]$ in this case, so we must show that $\beta \vee \gamma >_{\text{lex}} \beta' \vee \gamma$. We let $\beta = (\Delta_1, \ldots, \Delta_r)$, $\beta' = (\Delta'_1, \ldots, \Delta'_r)$ and $\gamma = (E_1, \ldots, E_s)$ in the following. We also let $\alpha = \beta \vee \gamma = (A_1, \ldots, A_{r+s})$ and $\alpha' = \beta' \vee \gamma = (A'_1, \ldots, A'_{r+s})$. Recalling that $\beta \vee \gamma$ is the lexicographically greatest shuffle of β and γ, we can construct $\beta \vee \gamma$ by using the following merge-sort algorithm (written in pseudo-code).

function *MergeSort*(β, γ)
  { *We have* $\beta = (\Delta_1, \ldots, \Delta_r)$ *and* $\gamma = (E_1, \ldots, E_s)$ }
  $i \leftarrow 1$
  $j \leftarrow 1$
  while $i \leqslant r$ **or** $j \leqslant s$ **do**
    if $(i > r)$ **then** { $A_{i+j-1} \leftarrow E_j$; $j \leftarrow j + 1$ }
    else if $(j > s)$ **then** { $A_{i+j-1} \leftarrow \Delta_i$; $i \leftarrow i + 1$ }
    else if $(E_j \geqslant \Delta_i)$ **then** { $A_{i+j-1} \leftarrow E_j$; $j \leftarrow j + 1$ }
    else { $A_{i+j-1} \leftarrow \Delta_i$; $i \leftarrow i + 1$ }
  od
  return $\alpha = (A_1, \ldots, A_{r+s})$

Observe what happens if we run the algorithm on the pairs (β, γ) and (β', γ). Assume that $\Delta_i = \Delta'_i$ for $i < i_0$, but that $\Delta_{i_0} > \Delta'_{i_0}$. Then they will run identically as long as $i < i_0$. When $i = i_0$, they will both continue taking terms from γ until $E_j < \Delta_{i_0}$ or γ is exhausted. Once this happens, the (β, γ) algorithm will take Δ_{i_0} next, so $A_{i_0+j-1} = \Delta_{i_0}$, but the (β', γ) algorithm will take $\max\{\Delta'_{i_0}, E_j\}$, so $A'_{i_0+j-1} = \max\{\Delta'_{i_0}, E_j\} < \Delta_{i_0} = A_{i_0+j-1}$. Thus we have $\beta \vee \gamma >_{\text{lex}} \beta' \vee \gamma$, so $\beta \vee \gamma < \beta' \vee \gamma$ as required.

It follows that $A(G)$ is an integral domain, as we wanted. □

6.2 Shuffle algebras

In the oligomorphic case, we can do better: the algebra $A(G)$ is actually a polynomial algebra if G is an oligomorphic wreath-A-like group. We show this by noting strong similarities between our algebra and standard shuffle algebras, and using well-known properties of shuffle algebras, in particular that the Lyndon words form a polynomial basis for the shuffle algebra.

We start by briefly recalling the key facts we will need. We take these results from Reutenauer's book on free Lie algebras [11]. The references to definitions, theorems and so forth are to his book.

Let T be an alphabet. Although Reutenauer sometimes assumes the alphabet to be finite, it will be clear that all of the results we use below work equally well in the infinite case: since words are always of finite length and we only ever work with finitely many words at once, we can always restrict attention to the finite subset of T containing the letters in use.

We write T^* for the set of words in the alphabet T. We write $K\langle T\rangle$ for the K-vector space with basis T^*. If we use the concatenation product (where the product of two words is just their concatenation), then this is the ring of non-commuting polynomials over T. But there is another product that we can define on words, and by extension on $K\langle T\rangle$, called the *shuffle product*. This is explained in section 1.4 of Reutenauer, and we now essentially quote parts of it.

Let $w = a_1 \cdots a_n$ be a word of length n in T^*, and let $I \subseteq \{1, \ldots, n\}$. We denote by $w|I$ the word $a_{i_1} \cdots a_{i_k}$ if $I = \{i_1 < i_2 < \cdots < i_k\}$; in particular, $w|I$ is the empty word if $I = \varnothing$. (Such a word $w|I$ called a *subword* of w.) Note that when

$$\{1, \ldots, n\} = \bigcup_{j=1}^{p} I_j,$$

then w is determined by the p words $w|I_j$ and the p subsets I_j.

Given two words u_1 and u_2 of respective lengths n_1 and n_2, their *shuffle product*, denoted by $u_1 \sqcup\!\sqcup u_2$, is the polynomial

$$u_1 \sqcup\!\sqcup u_2 = \sum w(I_1, I_2),$$

where the sum is taken over all pairs (I_1, I_2) of disjoint subsets of $\{1, \ldots, n\}$ with $I_1 \cup I_2 = \{1, \ldots, n\}$ and $|I_j| = n_j$ for $j = 1, 2$, and where the word $w = w(I_1, I_2)$ is defined by $w|I_j = u_j$ for $j = 1, 2$. Note that $u_1 \sqcup\!\sqcup u_2$ is a sum of words of length n, each with the same multiset of letters, and so is a homogeneous polynomial of degree n. Note also that the empty word, denoted by 1, is the identity for the shuffle product, that the shuffle product is commutative and associative, and that it is distributive with respect to addition. Thus $K\langle T\rangle$ with

the shuffle product is a commutative, associative algebra, called the *shuffle algebra*.

Using the associative and distributive properties of the shuffle product, we can also give an expression for the shuffle product of the words $u_1, \ldots, u_p$, of respective lengths $n_1, \ldots, n_p$; their shuffle product is the polynomial

$$u_1 \sqcup\!\sqcup \cdots \sqcup\!\sqcup u_p = \sum w(I_1, \ldots, I_p),$$

where now the sum is taken over all p-tuples $(I_1, \ldots, I_p)$ of pairwise disjoint subsets of $\{1, \ldots, n\}$ with $\bigcup_{i=1}^{p} I_j = \{1, \ldots, n\}$ and $|I_j| = n_j$ for each $j = 1, \ldots, p$, and where the word $w = w(I_1, \ldots, I_p)$ is defined by $w|I_j = u_j$ for each $j = 1, \ldots, p$.

A word appearing in the shuffle product $u_1 \sqcup\!\sqcup \cdots \sqcup\!\sqcup u_p$ is called a *shuffle* of $u_1, \ldots, u_p$. Note that this is consistent with the definition of shuffle we used in the proof of Theorem 6.2 above. As an example, if $a, b, c \in T$, then $ab \sqcup\!\sqcup ac = abac + 2aabc + 2aacb + acab$, and $aabc$ and $acab$ are both shuffles of ab and ac.

The next definition we need is that of a Lyndon word. Assume that our alphabet T is totally ordered. Then a *Lyndon word* in T^* is a non-empty word which is lexicographically smaller than all of its nontrivial proper right factors; in other words, w is a Lyndon word if $w \neq 1$ and if for each factorisation $w = uv$ (concatenation product) with $u, v \neq 1$, one has $w <_{\text{lex}} v$.

An alternative categorisation of Lyndon words is as follows (Corollary 7.7 in Reutenauer). Given a word $w = a_1 \cdots a_n$ of length n, we can define the rotation operator ρ by $\rho(w) = a_2 \cdots a_n a_1$. Then a word w of length $n \geqslant 1$ is Lyndon if and only if $w <_{\text{lex}} \rho^k(w)$ for $k = 1, \ldots, n-1$, which is to say that w is primitive (it does not have the form $w = u^r$ for some $r > 1$) and that it is lexicographically smaller than any rotation (cyclic permutation) of itself. It follows that Lyndon words are in bijective correspondence with primitive necklaces; see [11, Chap. 7] for more information.

A key property of Lyndon words is that every word $w \in T^*$ can be written *uniquely* as a decreasing product of Lyndon words, so $w = l_1^{r_1} \cdots l_k^{r_k}$, where $l_1 >_{\text{lex}} \cdots >_{\text{lex}} l_k$ and $r_1, \ldots, r_k \geqslant 1$. (This follows from Theorem 5.1 and Corollary 4.4, and can also easily be proved directly—see section 7.3.)

Finally, Theorem 6.1 states that the shuffle algebra $K\langle T\rangle$ is a polynomial algebra generated by the Lyndon words, and that for each word w, written as a decreasing product of Lyndon words $w = l_1^{r_1} \cdots l_k^{r_k}$ as in the previous paragraph,

one has

$$S(w) \stackrel{\text{def}}{=} \frac{1}{r_1! \cdots r_k!}\, l_1^{\sqcup\!\sqcup r_1} \sqcup\!\sqcup \cdots \sqcup\!\sqcup l_k^{\sqcup\!\sqcup r_k} = w + \sum_{\substack{[u]=[w] \\ u <_{\text{lex}} w}} \alpha_u u, \tag{7}$$

for some non-negative integers α_u, where $l^{\sqcup\!\sqcup r}$ means $l \sqcup\!\sqcup \cdots \sqcup\!\sqcup l$ with r terms in the product, and, in this context, $[u]$ means the multiset of letters in the word u.

Note that it is equation (7) which proves that $K\langle T\rangle$ is a polynomial algebra: the set T^* is a K-vector space basis for $K\langle T\rangle$, and given any finite multiset M of elements of T, the matrix relating the basis elements $\{\, w : w \in T^* \text{ and } [w] = M \,\}$ to $\{\, S(w) : w \in T^* \text{ and } [w] = M \,\}$ is unitriangular when the words are listed in lexicographic order, so that $\{\, S(w) : w \in T^* \,\}$ also forms a basis for $K\langle T\rangle$. This argument is true whether T is finite or infinite.

We can now apply this to our case of oligomorphic wreath-A-like permutation groups. Let G acting on Ω be such a group, as in Definition 6.1 above. We obviously take our alphabet T to be the set of connected blocks of the action (as given by the definition of wreath-A-like groups), so that T^* corresponds bijectively to the set of orbits of G on finite subsets of Ω. The alphabet T has the standard ordering defined on connected blocks, and the set T^* can then be ordered either by the lexicographic order (denoted $<_{\text{lex}}$) or by the order we defined at the start of Theorem 6.2 (denoted $<$).

Clearly $A(G)$ can be regarded as a K-vector space, with the set of characteristic functions of finite orbits as basis. We will identify the connected block sequence $w = (\Delta_{i_1}^{(j_1)}, \ldots, \Delta_{i_k}^{(j_k)})$ with the characteristic function of the corresponding orbit, writing w for both. Via this correspondence, we can identify $A(G)$ with $K\langle T\rangle$ as vector spaces. The grading on $A(G)$ induces a grading on $K\langle T\rangle$: the homogeneous component $V_n(G)$ is identified with the subspace of $K\langle T\rangle$ spanned by $\{\, w \in T^* : \mathrm{wt}(w) = n \,\}$. We then consider the product that the vector space $K\langle T\rangle$ inherits via this identification. Let $v \in T^*$ be another connected block sequence. We write $v \mathbin{\overline{\sqcup\!\sqcup}} w$ for the product in $A(G)$ and the induced product in $K\langle T\rangle$. The notation is designed to indicate that this product is related to the shuffle product, as we will see, and we call it the *complete shuffle product*. (It is also somewhat related to the infiltration product on $K\langle T\rangle$; see [11, sect. 6.3].) Recalling the definition of multiplication in $A(G)$, we see that for any finite subset $X \subset \Omega$ with $|X| = \mathrm{wt}(v) + \mathrm{wt}(w)$,

$$(v \mathbin{\overline{\sqcup\!\sqcup}} w)(X) = \sum_{\substack{Y \subseteq X \\ |Y| = \mathrm{wt}(v)}} v(Y) w(X \setminus Y).$$

But $v(Y)$ is none other than the characteristic function which has value 1 if

$\phi(Y) = v$ and 0 otherwise, and similarly for $w(Y \setminus X)$. So we have

$$(v \mathbin{\overline{\sqcup\!\sqcup}} w)(X) = |\{\, Y \subseteq X : \phi(Y) = v,\ \phi(X \setminus Y) = w \,\}|.$$

Thus, setting $u = \phi(X)$ and writing $u \to v \cup w$ if there is a $Y \subseteq X$ with $\phi(Y) = v$ and $\phi(X \setminus Y) = w$, we have

$$v \mathbin{\overline{\sqcup\!\sqcup}} w = \sum_{u \in T^*} \beta_u u,$$

where $\beta_u > 0$ if $u \to v \cup w$ and $\beta_u = 0$ otherwise.

Now we can characterise those u for which $u \to w \cup v$ quite easily. Firstly, consider the case that $[u] = [w] + [v]$, that is, the set of connected blocks of u is the same as those of w and v combined. Then $u \to w \cup v$ if and only if u is a shuffle of w and v, by condition (ii) of Definition 6.1, as in the proof of Theorem 6.2. In fact, the terms in $w \mathbin{\overline{\sqcup\!\sqcup}} v$ with $[u] = [w] + [v]$ will be precisely $w \sqcup\!\sqcup v$, which is easy to see. Now consider those terms with $[u] \neq [w] + [v]$. If $[u] <_{\mathrm{lex}} [w] + [v]$, then it is easy to see that we cannot have $u \to w \cup v$, but it may be possible otherwise. We deduce that our product is given by:

$$w \mathbin{\overline{\sqcup\!\sqcup}} v = w \sqcup\!\sqcup v + \sum_{\substack{\mathrm{wt}(u) = \mathrm{wt}(w) + \mathrm{wt}(v) \\ [u] > _{\mathrm{lex}} [w] + [v]}} \beta_u u \tag{8}$$

for some non-negative integers β_u.

Now given $w = l_1^{r_1} \cdots l_k^{r_k}$ written as a (concatenation) product of decreasing Lyndon words, we can consider the complete shuffle product as we did for the normal shuffle product above:

$$\begin{aligned} \bar{S}(w) &\stackrel{\mathrm{def}}{=} \frac{1}{r_1! \cdots r_k!}\, l_1^{\overline{\sqcup\!\sqcup} r_1} \mathbin{\overline{\sqcup\!\sqcup}} \cdots \mathbin{\overline{\sqcup\!\sqcup}} l_k^{\overline{\sqcup\!\sqcup} r_k} \\ &= \frac{1}{r_1! \cdots r_k!}\, l_1^{\sqcup\!\sqcup r_1} \sqcup\!\sqcup \cdots \sqcup\!\sqcup l_k^{\sqcup\!\sqcup r_k} + \sum_{\substack{\mathrm{wt}(u) = \mathrm{wt}(w) \\ [u] > _{\mathrm{lex}} [w]}} \beta_u u \\ &= w + \sum_{\substack{[u] = [w] \\ u <_{\mathrm{lex}} w}} \alpha_u u + \sum_{\substack{\mathrm{wt}(u) = \mathrm{wt}(w) \\ [u] > _{\mathrm{lex}} [w]}} \beta_u u \\ &= w + \sum_{\substack{\mathrm{wt}(u) = \mathrm{wt}(w) \\ u > w}} \alpha_u u, \end{aligned} \tag{9}$$

where the α_u and the β_u are non-negative integers. To get the second line, we have repeatedly used equation (8) to reduce the complete shuffle product to a normal shuffle product. Observe that $\mathrm{wt}(l_1^{r_1} \cdots l_k^{r_k}) = \mathrm{wt}(w)$, hence the sum is

over words with $\mathrm{wt}(u) = \mathrm{wt}(w)$, and with $[u] >_{\mathrm{lex}} [w]$, since $>_{\mathrm{lex}}$ is transitive and $[u_1] >_{\mathrm{lex}} [u_2]$ implies $[u_1] + [u] >_{\mathrm{lex}} [u_2] + [u]$ for any word u. That the β_u are non-negative is easy to see, and it is not that much harder to see that they are integral, although we do not need this. In the third line, we have used equation (7), and in the last line, we have set $\alpha_u = \beta_u$ in the case that $[u] >_{\mathrm{lex}} [w]$, and used the relation on words (sequences) defined in the previous section, namely $u > w$ if $[u] >_{\mathrm{lex}} [w]$ or $[u] = [w]$ and $u <_{\mathrm{lex}} w$.

It is also important to note that in our case, the set $\{ u : \mathrm{wt}(u) = \mathrm{wt}(w) \}$ is finite, as there are only finitely many connected blocks of each weight, the same number as the number of orbits on sets of size $\mathrm{wt}(w)$, so that the sums in equation (9) are all finite.

We now see, as above, that the matrix relating $\{ w : w \in T^* \text{ and } \mathrm{wt}(w) = n \}$ to $\{ \bar{S}(w) : w \in T^* \text{ and } \mathrm{wt}(w) = n \}$ is unitriangular when the words of weight n are listed in the order we have defined. It follows that the $\bar{S}(w)$ form a vector space basis for $A(G) = K\langle T \rangle$, and hence the set of Lyndon words is a set of polynomial generators for $A(G)$. We summarise these results as a theorem.

Theorem 6.3. *If G is an oligomorphic wreath-A-like permutation group, then $A(G)$ is a polynomial ring, and the generators are those characteristic functions on orbits corresponding to Lyndon words as described above.* □

We can now deduce:

Corollary 6.4. *If G is an oligomorphic wreath-A-like permutation group, then the element $\varepsilon \in V_1(G)$ is prime in $A(G)$.*

Proof. We have $e = \Delta_1^{(1)} + \cdots + \Delta_1^{(r)}$, where the $\Delta_1^{(j)}$ are the orbits on 1-sets. As each of the $\Delta_1^{(j)}$ is a Lyndon word, $A(G) = K[\Delta_1^{(1)}, \ldots, \Delta_1^{(r)}, \Delta_2^{(1)}, \ldots]$. It follows that we can replace the polynomial generator $\Delta_1^{(1)}$ by ε (as they are linearly related), giving $A(G) = K[\varepsilon, \Delta_1^{(2)}, \ldots, \Delta_1^{(r)}, \Delta_2^{(1)}, \ldots]$. It is clear, since we then have $A(G)/(\varepsilon) \cong K[\Delta_1^{(2)}, \ldots, \Delta_1^{(r)}, \Delta_2^{(1)}, \ldots]$, that $A(G)/(\varepsilon)$ is an integral domain, so ε is prime in $A(G)$. □

6.3 Integer sequences, necklaces and free Lie algebras

Theorem 6.3 leads us to revisit some counting questions. Cameron [5] considered the following question. If the algebra $A(G)$ corresponding to an "interesting" oligomorphic group G were polynomial, what would be the sequence counting the number of polynomial generators of each degree? From knowledge of the dimension of each homogeneous component of $A(G)$, the answer can be determined using the inverse Euler transform. Now that we have an explicit description of the polynomial generators in the wreath-A-like case, an examination of the

sequences observed might yield some interesting new information about those sequences.

The two sequences we will consider are those arising from the groups S_2 Wr A and A Wr A, both of which appear in the On-Line Encyclopedia of Integer Sequences [12]. There are some obvious generalisations to other groups, as we observe below. The n-th homogeneous component of the group S_2 Wr A has dimension F_{n+1} (a Fibonacci number, where $F_0 = 0$ and $F_1 = 1$), and so the sequence counting the number of generators of degree n is A006206, beginning 1, 1, 1, 1, 2, 4, 5, 8, 11, 18, ... By our result, the n-th term of this sequence gives the number of Lyndon words of weight n (starting with $n = 1$) in the alphabet $T = \{\Delta_1, \Delta_2\}$, where Δ_1 and Δ_2 have respective weights 1 and 2.

Similarly, for the group A Wr A, the n-th homogeneous component has dimension 2^{n-1} for $n \geqslant 1$, and the sequence counting the number of generators of degree n is A059966, beginning 1, 1, 2, 3, 6, 9, 18, 30, ... (Note that the paper quoted above had sequence A001037 by mistake, this being the inverse Euler transform of the closely related sequence (2^n).) This sequence then counts the number of Lyndon words of weight n in the alphabet $T = \{\Delta_1, \Delta_2, \dots\}$, where Δ_i has weight i.

The Encyclopedia entry gives a different explanation, however: this sequence lists the dimensions of the homogeneous components of the free Lie algebra with one generator of each degree 1, 2, 3, etc. The connection between these two descriptions of this sequence is easy to describe, using [11, Thm. 4.9]. Let T be an alphabet whose letters each have a positive integral degree/weight (we use these terms interchangeably in this section), and where there are only finitely many letters of each possible weight. There is a basis of the free Lie algebra on the alphabet T (viewed as a vector space) given by $\{ P_w : w \in T^* \text{ Lyndon} \}$, where $P_a = a$ if $a \in T$, and $P_w = [P_u, P_v]$ otherwise, where $w = uv$ with v being the lexicographically smallest nontrivial proper right factor of w (see [11, Thm. 5.1]). Note that it trivially follows by induction that the degree of the homogeneous polynomial P_w is $\mathrm{wt}(w)$. Thus the dimension of the homogeneous component of degree n of the free Lie algebra on the alphabet T is the number of Lyndon words in T^* of weight n. It follows that we can also describe the two sequences above as either the number of Lyndon words of weight n in the alphabets $\{\Delta_1, \Delta_2\}$ and $\{\Delta_1, \Delta_2, \dots\}$ respectively, or as the number of primitive necklaces of weight n in these symbols, or as the dimension of the homogeneous component of degree n of the free Lie algebras on these sets. This obviously generalises to other wreath-A-like groups.

We may ask other counting questions based on these ideas. We start with an alphabet of weighted letters T (again with only finitely many letters of each

weight). The primary questions arising are how to transform between the three sequences:

$$\begin{aligned} a_n &= \text{number of letters of weight } n \text{ in } T, \\ w_n &= \text{number of words of weight } n \text{ in } T^*, \\ l_n &= \text{number of Lyndon words of weight } n \text{ in } T^*. \end{aligned}$$

(Of course, l_n can also be regarded as the number of primitive necklaces of weight n in this alphabet.) In our context, a_n is the number of connected blocks of weight n in our wreath-A-like group, w_n gives the dimension of the homogeneous component of weight n in $A(G)$ and l_n gives the number of polynomial generators of weight n in $A(G)$. We use the notation and some of the ideas presented in Bernstein and Sloane's paper on integer sequences [1].

The transformation between (a_n) and (w_n) can be effected by INVERT, as every word is an ordered sequence of letters:

$$1 + \sum_{n=1}^{\infty} w_n x^n = \frac{1}{1 - \sum_{n=1}^{\infty} a_n x^n}.$$

The transformation between (w_n) and (l_n) is performed using EULER, as every word is a product of a decreasing sequence of Lyndon words, so can be identified with a multiset of Lyndon words:

$$1 + \sum_{n=1}^{\infty} w_n x^n = \prod_{n=1}^{\infty} \frac{1}{(1 - x^n)^{l_n}}.$$

It follows that we can transform between (a_n) and (l_n) using a variant of WEIGH:

$$1 - \sum_{n=1}^{\infty} a_n x^n = \prod_{n=1}^{\infty} (1 - x^n)^{l_n}. \tag{10}$$

Most of the six possible conversions between (a_n), (w_n) and (l_n) are straightforward given these formulæ; the two which are harder are converting (w_n) and (a_n) to (l_n). Inverting the EULER transform is explained in [1]; we apply the same idea to convert from (a_n) to (l_n).

Given a sequence (a_n), we introduce the auxiliary sequence (c_n) defined by the equation $1 - \sum_{n=1}^{\infty} a_n x^n = \exp\bigl(-\sum_{n=1}^{\infty} c_n x^n/n\bigr)$. Using the generating functions $A(x) = \sum_{n=1}^{\infty} a_n x^n$ and $C(x) = \sum_{n=1}^{\infty} c_n x^n$, we can perform standard manipulations using the defining equation for (c_n) to deduce that $C(x) =$

$xA'(x) + C(x)A(x)$. It follows that

$$c_n = na_n + \sum_{k=1}^{n-1} c_k a_{n-k}. \tag{11}$$

Now substituting $\exp\bigl(-\sum c_n x^n/n\bigr)$ for $1 - \sum a_n x^n$ in equation (10), taking logarithms and expanding as a power series gives the coefficient of x^n/n to be $c_n = \sum_{d|n} d\, l_d$. Finally, Möbius inversion gives

$$l_n = \frac{1}{n} \sum_{d|n} \mu(n/d) c_d. \tag{12}$$

Thus we have an effective way of calculating the number of Lyndon words of a given weight given the number of letters of each possible weight.

As an interesting example of this process, let us consider our favourite group, $G = S_2$ Wr A. In this case, recall that we have $T = \{\Delta_1, \Delta_2\}$, so $a_1 = a_2 = 1$ and $a_n = 0$ for $n \geqslant 3$. Then the sequence (c_n) is calculated by equation (11): we have $c_1 = 1$ and $c_2 = 3$. For $n \geqslant 3$, we have $c_n = c_{n-1} + c_{n-2}$, so (c_n) is the standard Lucas sequence (L_n): 1, 3, 4, 7, 11, 18, ... We can now calculate the sequence (l_n): the first few terms are as we predicted: 1, 1, 1, 1, 2, 2, 4, 5, ..., and a general formula is $l_n = \frac{1}{n} \sum_{d|n} \mu(n/d) L_d$, as is given in the Encyclopedia entry for A006206. One interesting thing to observe is that if p is prime, then we have $l_p = (\mu(1)L_p + \mu(p)L_1)/p = (L_p - 1)/p$. It follows that the Lucas sequence satisfies $L_p \equiv 1 \pmod{p}$ for all primes p, a known result (see Hoggart and Bicknell [7]), but somewhat surprising in this context.

The description of our sequence A006206 in the Encylcopedia is "aperiodic binary necklaces [of length n] with no subsequence 00, excluding the sequence '0'." Our description is that it counts primitive necklaces of weight n in the alphabet $\{\Delta_1, \Delta_2\}$. These are easily seen to be equivalent: if we replace every Δ_1 by the symbol 1 and every Δ_2 by the symbols 10 (in clockwise order, say), then we will get a primitive (aperiodic) binary necklace with no subsequence 00 whose length equals the weight of the necklace we started with, and we can perform the inverse transformation equally simply (as we are excluding the necklace 0). We can do the same with the group S_n Wr A, enabling us to count the number of primitive binary necklaces of length n with no subsequence $00\cdots0$ (with n zeros) and excluding the necklace 0.

Now let us apply these ideas to the case $G = A$ Wr A. Firstly, the auxilary sequence turns out to be $c_n = 2^n - 1$, and the sequence (l_n) is given by $l_n = \sum_{d|n} \mu(n/d)(2^d - 1)$. This can be simplified using the result $\sum_{d|n} \mu(n/d) = [n = 1]$, where we are using Iverson's convention that if P is a predicate, then

$[P] = 1$ if P is true and 0 otherwise. So we have $l_n = \sum_{d|n} \mu(n/d)2^d - [n = 1]$. The sequence given by $\sum_{d|n} \mu(n/d)2^d$ is sequence A001037, and so our sequence differs from it by 1 in the $n = 1$ term only, yielding the observed sequence A059966. We can also give a necklace description of this sequence as above: it is the number of primitive binary necklaces of length n excluding the necklace 0—the sequence A001037 is essentially the same, but does not exclude the necklace 0, so it it also counts the number of binary Lyndon words of *length* n. (These are the descriptions of this sequence given in the Encyclopedia.) Finally, as above, if we consider the term l_p for p prime, we see that $l_p = ((2^p - 1) - 1)/p = 2(2^{p-1} - 1)/p$, so for $p > 2$, we deduce Fermat's little theorem for base 2, that is $2^{p-1} \equiv 1 \pmod{p}$.

An investigation of those sequences of non-negative integers (b_n) for which $\frac{1}{n}\sum_{d|n} \mu(n/d)b_d$ is a non-negative integer for all n has been undertaken by Puri and Ward [10], who call them exactly realizable. We can thus add to their work a class of exactly realizable sequences: those which are of the form (c_n), where (c_n) is given by equation (11) for some sequence of non-negative integers (a_n). A particular family of such sequences is given by $a_i = 1$ for $1 \leqslant i \leqslant n$ and $a_i = 0$ for $i > n$; these are sometimes known as "generalised Fibonacci sequences", and have been discussed by Du [6] (where this sequence is called ϕ_n). It would be interesting to know whether new congruence identities can be discovered by applying this technique to some of the sequences identified there or to sequences produced by other wreath-A-like groups.

7 Non-oligomorphic groups

Throughout this part of the thesis, we have mostly focused on oligomorphic groups, proving results in general where there was no problem in doing so. In this final section, we consider briefly the issues arising in the non-oligomorphic case.

As has already been pointed out above, the group $\mathbb{Z}$ acting regularly on $\mathbb{Z}$ does not have a Ramsey ordering on 2-sets, so much of what we did above will not help us to understand the algebra $A(\mathbb{Z})$. It is easy to construct other similar examples.

A more difficult question is whether we have even got the "right" definition of the algebra $A(G)$ in the non-oligomorphic case. The definition we have been using was introduced specifically to study the behaviour of oligomorphic groups. There are two finiteness conditions which can be imposed on the algebra we consider.

Firstly, we have taken the direct sum $A(G) = \bigoplus_{n=0}^{\infty} V_n(G)$, which is the direct limit as $N \to \infty$ of the vector spaces $\bigoplus_{n=0}^{N} V_n(G)$ (with the obvious direct maps). We could have instead taken the cartesian sum $\sum_{n=0}^{\infty} V_n(G)$, being the inverse limit of the same family of vector spaces (with the obvious inverse maps).

Secondly, and independently of the first choice, we could either take $V_n(G)$ to be the vector space of all functions from n-subsets of Ω to K which are fixed by G, as we have until now, or we could take it to be the subspace of this consisting of those functions which assume only finitely many distinct values on n-sets. (The latter idea was suggested to me by Peter Cameron.) Note, though, that if there are infinitely many orbits on n-sets, this vector space will still have uncountable dimension. It is not hard to check that if we use the latter definition, the multiplication in the algebra is still well-defined. Also, this distinction does not exist in the oligomorphic case. (Another seemingly plausible choice, those functions in $V_n(G)$ which are non-zero on only finitely many orbits of G, can fail to produce a well-defined multiplication: consider, for example, the case of e^2 with our favourite non-oligomorphic group, $\mathbb{Z}$: it takes the value 2 on every 2-set.)

Thus we have four plausible algebras to choose from, and it is not clear which is the "correct" one to use. More work is still required in this area.

Part II

Parking Functions, Valet Functions and Priority Queues

In which we present a new bijection between parking functions and priority queues, extend it to a bijection between valet functions and priority queues on multisets, and learn of the standard of driving in Boston

This is an edited version of the published paper: Julian D. Gilbey and Louis H. Kalikow, *Parking functions, valet functions and priority queues*, Discrete Mathematics **197/198** (1999), 351–373.

1 Introduction

The combinatorial properties of parking functions have attracted interest for some time. Much is known about these functions and how they relate to other combinatorial structures such as trees. Recently, allowable pairs of permutations of a priority queue have also been studied. In this part of the thesis, we study these two classes of objects, which turn out to be closely related.

After introducing some notation in section 2, we define parking functions in section 3, together with some background material on the subject. The same is done for priority queues and allowable pairs in section 4. In section 5 we define the notion of a "breakpoint" for both parking functions and allowable pairs, and in section 6 we present a new bijection between these objects. In section 7 we introduce valet functions, which turn out to correspond to allowable pairs of permutations of a multiset. We also note an interesting bijection between valet functions and k-way trees, which restricts to a new bijection between parking functions and labelled trees. In section 8 we present, with detailed proof, a bijection between valet functions and allowable pairs for a multiset. This bijection, of which our first bijection is a special case, has the property of being both output and breakpoint preserving. (The output of the various objects involved is defined in sections 3, 4 and 7.) In section 9 we give an alternative description of the bijection of section 6, and use this in section 10 to give an interpretation for allowable pairs of the inversion enumerator for trees, showing that our bijection preserves this too in a suitable sense. We conclude in section 11 by comparing our bijection to other bijections involving parking functions and priority queues.

2 Notation

We write $[n]$ for $\{1, 2, \ldots, n\}$ and $[n]_0$ for $[n] \cup \{0\}$, with the convention that $[0] = \varnothing$. We will often think of a function $p : [n] \to [n]$ as the sequence of its values $p(1), \ldots, p(n)$ (sometimes even omitting the commas). Similarly, we regard a permutation $\sigma \in S_n$ as either a bijection $\sigma : [n] \to [n]$ or as a sequence $\sigma_1\sigma_2 \ldots \sigma_n$ (writing σ_i for $\sigma(i)$). If (a_i) is a sequence, we will also use $\mathbf{a}$ to refer to it. In the case that each $a_i \in \mathbb{N}$, we write $M_{\mathbf{a}}$ for the multiset $\{1^{a_1}, 2^{a_2}, \ldots\}$. Note that 0 is considered a natural number! (Also, we are using standard set notation for multisets, which is different from that used in the first part of this thesis; this turns out to be more convenient here.)

From section 7 onwards, we will be considering functions $p : [k] \to \mathcal{P}([n])$ with $|p(i)| = a_i$ for each i, where $\mathcal{P}(\Omega)$ denotes the power set of Ω. We will list the elements of each $p(i)$ as $p_i(1)$, $p_i(2)$, $\ldots$, $p_i(a_i)$. The order in which we do so

turns out to be unimportant for our results, as we will show below, so without loss of generality, we will assume that they are listed in increasing order, unless stated otherwise. We will also write $p_1(1), \ldots, p_i(j-1)$ as shorthand for the initial subsequence of $p_1(1), \ldots, p_1(a_1), p_2(1), \ldots, p_k(a_k)$ up to, but excluding, $p_i(j)$, even in the case that $j = 1$.

3 Parking functions and major functions

Consider a one-way street with n empty parking spaces in a row. There are n drivers who wish to park in these spaces and they arrive one at a time. Each driver has a preferred parking space, to which she drives. If it is empty, she parks there, but if not, she parks in the next available parking space if there is one. If, however, the rest of the spaces are occupied, she leaves without parking. If all of the cars are able to park, we call the sequence of preferred positions a parking function.

Formalising this description, we define a *parking function* to be a function $p : [n] \to [n]$ for which the following algorithmic function returns `TRUE`, and we write P_n for the set of all parking functions on $[n]$. Our arrays are indexed starting at 1, and we follow the convention that the body of a loop headed by a condition such as "**for** $i := 1$ **to** 0 **do**" is never executed.

function *TestParking*(p, n)
  $L :=$ empty array of length $n + 1$
  for $i := 1$ **to** n **do**
    $l_0 := \min\{\, l : l \geqslant p(i)$ and $L[l]$ is empty $\}$
    if $l_0 = n + 1$ **then**
      return `FALSE`
    else
      $L[l_0] := i$
    fi
  od
  return `TRUE`

If the algorithm returns `TRUE`, we write $\pi_n(p)$ for the resulting permutation $(L[1], L[2], \ldots, L[n])$ of $[n]$, calling it the *output* of p. We note that if p is a parking function and $\tau = \pi_n(p)$, then $\tau^{-1}(i) \geqslant p(i)$ for each i.

Parking functions were introduced in computer science and combinatorics by Konheim and Weiss [12, Sec. 6] as a colourful way to study a hashing problem. (However, the original scenario used would no longer be considered politically correct!) In their paper, they proved that the number of parking functions

on $[n]$ is $(n+1)^{n-1}$. Further proofs of this fact followed, including a beautiful one by Pollak (see Riordan [18, Sec. 2] and Foata and Riordan [5, Sec. 2]), a simple extension of which is used to prove Theorem 7.2 below. (An alternative description of Pollak's proof in group-theoretic terms is given by Stanley in [22, Sec. 2].) Knuth [11, Sec. 6.4] surveys the results about parking functions known to computer science in the early 1970s. (His description is given in terms of a hashing algorithm, but see also exercises 6.4–29 through 6.4–31 in which the parking function description is presented.)

It was recently pointed out to me by Joseph Kung that parking functions have been known to statisticians for a long time, in the context of order statistics. This also leads to a natural generalisation of parking functions. For more information, see Kung and Yan [14].

Several bijections between parking functions on $[n]$ and other sets of combinatorial structures are known. The first published bijection between parking functions and acyclic functions on $[n]$ (which are trivially representable by labelled trees on $[n]_0$) was by Schützenberger [20]. Kreweras [13, Sec. 6] gives a bijection that maps labelled trees with k inversions to parking functions with k probes. (Inversions are described in section 10 below. Note also that our parking functions correspond to Kreweras's *suites majeures* under the bijection $p(i) \mapsto (n+1) - p(i)$.) Moszkowski [16, Sec. 3] gives another bijection, in which a node of the tree with i children corresponds to a parking space in which i cars prefer to park. Pollak (see Riordan [18, Secs. 3 and 4] and Foata and Riordan [5, Sec. 2]) also gives a bijection in which a parking function is associated with a code which, by Prüfer's correspondence, corresponds to a tree. Foata and Riordan [5] also present another bijection from parking functions on $[n]$ to acyclic functions on $[n]$, and Françon [6] has shown how their result may be generalised to a much larger class of selection procedures. Knuth [11, answer to exercise 6.4–31] describes two bijections which are based on those of Foata and Riordan [5] and Kreweras [13], but are in fact different from them. Finally, in section 7 below, we describe a bijection which satisfies the property described in part (a) of Knuth's answer. In addition to these, Stanley [21, 22, 23] has studied how parking functions relate to noncrossing partitions and to hyperplane arrangements. Parking functions have also proved to have interesting algebraic properties. See, for example, the series of conjectures concerning diagonal invariants and parking functions presented by Haiman [10].

We define a *probe* to be an attempt by a car to park in an already occupied space, and the number of probes of a parking function is the total number of probes made by all of the cars. For example, if a car prefers space 3, but parks in space 6 (because spaces 3, 4 and 5 were full), the car makes three probes. In the language of the algorithm *TestParking*, the number of probes of car i is

$l_0 - p(i)$. So, letting $\tau = \pi_n(p)$ as before, car i makes $\tau^{-1}(i) - p(i)$ probes. Thus the number of probes of p is given by

$$\begin{aligned}\sum_{i=1}^{n}(\tau^{-1}(i) - p(i)) &= \sum_{i=1}^{n}\tau^{-1}(i) - \sum_{i=1}^{n}p(i)\\ &= \sum_{j=1}^{n} j - \sum_{i=1}^{n}p(i)\\ &= \tfrac{1}{2}n(n+1) - \sum_{i=1}^{n}p(i),\end{aligned}$$

as τ is a permuation of $[n]$. In particular, the number of probes of a parking function $p \in P_n$ depends only upon the values which the function takes, not the order in which it takes them. This was known already; see for example Peterson [17, page 137] or Gessel and Sagan [7, Sec. 7].

In Konheim and Weiss [12, Sec. 3], an expression is also obtained for the size of the set $S(\tau) = \{\, p \in P_n : \pi_n(p) = \tau \,\}$, defined for any $\tau \in S_n$. Given τ, set $\tau(0) = n + 1$ and define

$$b_\tau(i) = \max\{\, j \in [i-1]_0 : \tau(j) > \tau(i) \,\}.$$

Then we have

$$|S(\tau)| = \prod_{i=1}^{n}(i - b_\tau(i)). \tag{1}$$

To see why this is true, notice that if car m parks in space j, its preferred space could have been any space numbered $i \leqslant j$ as long as the spaces i, $i+1$, …, $j-1$ were occupied before it attempted to park. This will be the case if and only if all of these spaces are occupied by cars numbered less than m.

We finish this section with a very important alternative characterisation of parking functions. We call a function $f : [n] \to [n]$ a *major function* if it satisfies the property

$$|\{\, i : f(i) \leqslant m \,\}| \geqslant m \qquad \text{for } m = 1, 2, \ldots, n.$$

Lemma 3.1. *p is a parking function if and only if p is a major function.*

This is the special case of Lemma 7.3 below with $\mathbf{a} = (1, 1, \ldots, 1)$. It is also straightforward to prove directly, and has been known for a long time. A direct proof can be found in Gessel and Sagan [7, Theorem 7.2].

4 Priority queues and allowable pairs

We follow Atkinson and Thiyagarajah [3] for the following definitions. A *priority queue* is an abstract data type supporting the operations INSERT and DELETEMIN. There is an input data stream $\sigma = \sigma_1\sigma_2\ldots$ and an output data stream $\tau = \tau_1\tau_2\ldots$, where the σ_i are (possibly repeated) elements of a totally ordered set. Each INSERT operation will insert the next element of σ into the queue, and each DELETEMIN operation will remove a minimal element of the queue, placing it in the output stream. We only allow a DELETEMIN operation when the queue is non-empty.

We restrict ourselves throughout this thesis to the case where σ is finite; it follows that τ is also. If σ has length n, then an allowable sequence of n INSERT's and n DELETEMIN's (that is, one with the property that any initial subsequence contains at least as many INSERT's as DELETEMIN's) will be called a *priority queue computation*. If σ is the input and τ is the output of some priority queue computation, we call (σ, τ) an *allowable pair*. We write Q_n for the set of allowable pairs on $[n]$, by which we mean those allowable pairs (σ, τ) for which $\sigma, \tau \in S_n$. The following algorithm from Atkinson and Beals [1] takes as input a pair (σ, τ) of data streams of length n and tests whether it is an allowable pair. (The use of the notation INSERT(σ_j) rather than simply INSERT is for convenience, as it allows us to refer to our location in σ.)

```
function TestPair((σ, τ), n)
    Q := empty priority queue
    i := 1
    for j := 1 to n do
(*)     while τ_j ∉ Q do
            INSERT(σ_i)
            i := i + 1
        od
        if τ_j ≠ min(Q) then
            return FALSE
        else
            DELETEMIN
        fi
    od
    return TRUE
```

If (σ, τ) is an allowable pair, then τ is called the *output* of (σ, τ), and the priority queue computation executed by this algorithm is called the *natural*

computation for (σ, τ).

Many properties of Q_n are known. Atkinson and Thiyagarajah [3, Thm. 1] found that the number of allowable pairs on $[n]$ is $(n+1)^{n-1}$. Moreover, they show in [3, Lemma 5] that the number of allowable pairs (σ, τ) having a given permutation $\tau \in S_n$ as output is given by the same expression as that which counts the number of parking functions having τ as output ($|S(\tau)|$ in equation (1) above). This suggests the possible existence of an interesting bijection between parking functions and allowable pairs on $[n]$ which is output preserving.

As with parking functions, bijections have been found between allowable pairs on $[n]$ and labelled trees on $n+1$ vertices. Atkinson and Beals [1, Sec. 3] define such a bijection inductively, and Gessel and Wang [8] give algorithms for this bijection. A variant of their bijection can be obtained by letting their $\gamma_{(i,m)}$ denote the result of inserting m within γ *before* the symbol i, where i is given the name "root" if m is inserted at the end of γ. A different bijection, also defined by induction, is given by Golin and Zaks [9]. This too has a variant obtained by connecting $*$ in $T_{\pi\to\sigma}$ to the *predecessor* of $\max(\pi_i)$ in π_i.

Atkinson, Linton and Walker [2] generalised the work on allowable pairs by permitting the input and output data streams to be permutations of a multiset $M_{\mathbf{a}} = \{1^{a_1}, 2^{a_2}, \ldots, k^{a_k}\}$. They found that the number of allowable pairs in this case is $\frac{1}{n+1}\prod_{i=1}^{k}\binom{n+1}{a_i}$. This was calculated by constructing a bijection between the allowable pairs and certain k-way trees. (A k-way tree is either an empty tree or a root node with a sequence of k k-way subtrees.) Their bijection, again defined by induction, is a natural extension of the bijection in Atkinson and Beals [1] for allowable pairs on $[n]$. We provide a corresponding extension of parking functions below (sections 7ff), and deduce an alternative way of counting these pairs.

5 Breakpoints

We now define a parallel concept for both functions $[n] \to [n]$ and pairs of permutations of $[n]$, which turns out to be invariant under our bijection and is crucial to our method of proof.

Let $p : [n] \to [n]$. We say that $b \in [n]_0$ is a *breakpoint* of p if we have $|\{\, i : p(i) \leqslant b \,\}| = b$. It is easily checked that in the case $p \in P_n$, this condition is equivalent to $\{L[1], \ldots, L[b]\} = \{\, i : p(i) \leqslant b \,\}$. (We always have $\{L[1], \ldots, L[b]\} \subseteq \{\, i : p(i) \leqslant b \,\}$; then consider the sizes of the sets.) In the car drivers description, this says that every driver who wishes to park in one of the first b spaces succeeds in doing so.

Now let $(\sigma, \tau) \in S_n \times S_n$. We say that $b \in [n]_0$ is a *breakpoint* of (σ, τ) if

$\{\sigma_1, \ldots, \sigma_b\} = \{\tau_1, \ldots, \tau_b\}$. In the case $(\sigma, \tau) \in Q_n$, this is equivalent to saying that, with the natural computation, the queue is empty after outputting τ_b. (This follows, for if b is a breakpoint, then once the first b elements of σ have been read into the queue, the body of the **while** loop in the *TestPair* algorithm will not be executed again until τ_b has been output. The converse is trivial.)

It is clear that 0 and n are always breakpoints of any $p \in P_n$ and any $(\sigma, \tau) \in Q_n$. The following lemma shows that at least one other breakpoint often exists in such cases.

Lemma 5.1. (a) *Let $p \in P_n$, $t = \pi_n(p)$ and $d = t^{-1}(n)$. Then d is a breakpoint of p.*

(b) *Let $(\sigma, \tau) \in Q_n$ and $\delta = \tau^{-1}(n)$. Then δ is a breakpoint of (σ, τ).*

This follows as a special case of Corollary 8.2 when $\mathbf{a} = (1, 1, \ldots, 1)$. It is also very straightforward to prove directly.

6 The bijection between parking functions and allowable pairs

We define functions $\phi_n : P_n \to Q_n$ and $\psi_n : Q_n \to P_n$ inductively. For $n = 0$, the functions are trivial, as the sets have only one element.

For $n \geqslant 1$, given $p \in P_n$, we define $(s, t) = \phi_n(p)$ as follows:

(ϕ1) Set $t = \pi_n(p)$ and $d = t^{-1}(n)$.

(ϕ2) Define $p' \in P_{n-1}$ by setting, for $i < n$,

$$p'(i) = \begin{cases} p(i) - 1 & \text{if } p(i) > d, \\ p(i) & \text{otherwise.} \end{cases}$$

(ϕ3) Set $(s', t') = \phi_{n-1}(p')$.

(ϕ4) We define s by inserting n into the $p(n)$-th position of s'.

And for $n \geqslant 1$, given $(\sigma, \tau) \in Q_n$, we define $q = \psi_n(\sigma, \tau)$ as follows:

(ψ1) Set $q(n) = \sigma^{-1}(n)$ and $\delta = \tau^{-1}(n)$.

(ψ2) Let σ' and τ' be, respectively, σ and τ with n deleted, so $(\sigma', \tau') \in Q_{n-1}$.

(ψ3) Set $q' = \psi_{n-1}(\sigma', \tau')$.

(ψ4) For $i < n$, set

$$q(i) = \begin{cases} q'(i) + 1 & \text{if } q'(i) \geqslant \delta, \\ q'(i) & \text{otherwise.} \end{cases}$$

Theorem 6.1. *The functions ϕ_n and ψ_n are well-defined, mutually inverse bijections between P_n and Q_n, and are output and breakpoint preserving.*

This follows as a special case of Theorem 8.1, where $\mathbf{a} = (1, 1, \ldots, 1)$. It can also be proved directly in a similar manner. Surprisingly, however, we have been unable to find a substantially simpler proof of this result, even when using the results of section 9 below.

7 Valet functions and multiset priority queues

From now on, $\mathbf{a} = (a_i)$ will be a finite sequence of positive integers with k terms, and we set $n = \sum_{i=1}^{k} a_i$. Furthermore, if $k \geqslant 1$, we will let the sequence $\mathbf{b} = (b_i)$ consist of the first $k-1$ terms of $\mathbf{a}$ and set $n' = \sum_{i=1}^{k-1} b_i = n - a_k$.

We define valet functions in a similar way to parking functions. There are again n cars, but this time, there are k types of car and k valets. Each valet is responsible for one type of car and has an appropriately sized preferred subset of the parking spaces in which to park those cars. Each valet tries in turn to park all of his cars, allocating one of his cars to each of his preferred spaces, and parking the cars one by one, using the same rules as before. If all of the cars are able to be parked, the chosen subsets form a valet function.

We again formalise this description. We define a *valet function* on $\mathbf{a}$ to be a function $p : [k] \to \mathcal{P}([n])$, with $|p(i)| = a_i$ for each i, for which the following algorithmic function returns `TRUE`. We write $P_{\mathbf{a}}$ for the set of valet functions on this $\mathbf{a}$. (We recall that we write $p(i) = \{p_i(1), \ldots, p_i(a_i)\}$, although we do not make any assumptions about the order of the elements $p_i(1)$, $\ldots$, $p_i(a_i)$ until after we have proved Lemma 7.1.)

```
function TestValet(p, k, a)
    n := Σ_{i=1}^{k} a_i
    L := empty array of length n + 1
    for i := 1 to k do
        for j := 1 to a_i do
(†)         l_0 := min{ l : l ⩾ p_i(j) and L[l] is empty }
            if l_0 = n + 1 then
                return FALSE
            else
                L[l_0] := i
            fi
        od
    od
    return TRUE
```

The next lemma guarantees that if the algorithm returns `TRUE`, it makes sense to speak of *the* permutation $(L[1], L[2], \ldots, L[n])$ of $M_{\mathbf{a}}$. As before, we write $\pi_{\mathbf{a}}(p)$ for this permutation, calling it the *output* of p. (The proof is delayed until the end of this section.)

Lemma 7.1. *The ordering chosen for the elements of each $p(i)$ does not affect either the return value of the algorithm TestValet or, if the return value is* `TRUE`*, the contents of array L when the algorithm terminates.*

Theorem 7.2. *The number of valet functions on* $\mathbf{a}$ *is*

$$\frac{1}{n+1}\prod_{i=1}^{k}\binom{n+1}{a_i}.$$

Proof. We extend Pollak's proof for the number of parking functions on $[n]$ (see section 3 above) to this case. Consider a circular car park with $n+1$ parking spaces labelled 1, 2, …, $n+1$ in order, and allow each valet to choose a subset of preferred spaces of size a_i from the $n+1$ spaces. As described above, each valet allocates one of their cars to each of their preferred spaces. Each valet now tries to park his cars in turn: for each car, he starts at their preferred space for that car and then, if necessary, drive around the circle (in order) until they find an empty space. (This is always possible as there are sufficiently many spaces available.) The number of possible choices of subsets is given by $\prod_{i=1}^{k}\binom{n+1}{a_i}$. A particular choice of subsets yields a valet function if and only if the empty space left after all n cars park is the $(n+1)$-th space. By symmetry, as there are $n+1$ possible choices for the empty space, this happens for precisely $1/(n+1)$ of the possibilities, giving the stated result. □

This result combined with the bijection in section 8 below yields another method of counting allowable pairs, which together with the bijection given by Atkinson, Linton and Walker [2] yields a new way of counting k-way trees (see Atkinson and Walker [4]). Similarly, Pollak's original proof together with the bijection of Kreweras [13] will yield a proof of Cayley's theorem for the number of labelled trees on $n+1$ vertices. Also, if we use the $(0,1)$ matrices introduced by Atkinson and Walker [4] to represent k-way trees, we can set $p(i) = \{\, l : m_{il} = 1 \,\}$ (where $M(\Gamma) = (m_{ij})$ is the matrix of the k-way tree Γ), giving a bijection between valet functions and k-way trees. This clearly restricts to a bijection between parking functions and labelled trees (treating a labelled tree on $n+1$ vertices as an n-way tree), and it satisfies the property described by Knuth [11] in part (a) of the answer to exercise 6.4–31. This bijection is distinct from all of those described in section 3 above, but it turns out that it is actually related to that of Moszkowski [16]; modifying his bijection by ordering

the vertices of the tree using a depth-first search (that is, preorder) instead of a breadth-first search gives our bijection. The proof of this is straightforward using Lemma 7.3 below and the well-known result that a sequence $f(1)$, …, $f(n+1)$ of natural numbers is the down-degree sequence of some tree on $[n]_0$ rooted at 0, traversed in preorder, precisely when $\sum_{i=1}^{m} f(i) \geqslant m$ for $m = 1, 2, \ldots, n$ and $\sum_{i=1}^{n+1} f(i) = n$. (This latter result is essentially due to Schröter; see Rosenbloom [19, pp. 152–156 and 205] for a proof and references.)

We can also extend the concept of a major function correspondingly. We say that a function $f : [k] \to \mathcal{P}([n])$ satisfying $|f(i)| = a_i$ for each i is a *major function* if it satisfies the property

$$\sum_{i=1}^{k} |f(i) \cap [m]| \geqslant m \qquad \text{for } m = 1, 2, \ldots, n.$$

Just as in the parking function case, we have the following lemma (which is also proved below).

Lemma 7.3. *p is a valet function if and only if p is a major function.*

We similarly define $Q_{\mathbf{a}}$ to be the set of all allowable pairs on the multiset $M_{\mathbf{a}}$, that is all allowable pairs (σ, τ) where σ and τ are (multiset) permutations of $M_{\mathbf{a}}$.

Next, we extend the definition of breakpoints to this case. We say that $b \in [n]_0$ is a breakpoint of a function $f : [k] \to \mathcal{P}([n])$, where $|f(i)| = a_i$ as usual, if $\sum_{i=1}^{k} |f(i) \cap [b]| = b$. If p is a valet function, it follows as before that b is a breakpoint if and only if $\{L[1], \ldots, L[b]\} = \{1^{|p(1)\cap[b]|}, \ldots, k^{|p(k)\cap[b]|}\}$ as multisets. Similarly we say that $b \in [n]_0$ is a breakpoint for a pair (σ, τ) of permutations of $M_{\mathbf{a}}$ if $\{\sigma_1, \ldots, \sigma_b\} = \{\tau_1, \ldots, \tau_b\}$ as multisets, and as before, b is a breakpoint of an allowable pair $(\sigma, \tau) \in Q_{\mathbf{a}}$ if and only if, with the natural computation, the queue is empty after outputting τ_b.

Before we prove Lemma 7.1, we introduce some notation which will make it easier to refer to the progress of the algorithms *TestValet* and *TestPair*. Given any function $p : [k] \to \mathcal{P}([n])$ with $|p(i)| = a_i$ for each i, we execute the algorithm *TestValet*$(p, k, \mathbf{a})$, setting

$$E_i(j) = \{\, l \in [n+1] : l \geqslant p_i(j) \text{ and } L[l] \text{ is empty at the start of loop } (i, j) \,\}$$

and

$$\hat{E}_i(j) = \{\, l \in [n+1] : L[l] \text{ is empty at the start of loop } (i, j) \,\},$$

so that

$$E_i(j) = \hat{E}_i(j) \cap \{p_i(j), \ldots, n+1\},$$

where by "the start of loop (i, j)", we mean the point (†) in the algorithm when

the values of i and j are as given. We will never refer to $E_i(j)$ or $\hat{E}_i(j)$ in cases that such a point is not reached. Note that, by construction, the (i,j)-th car will park in $\min E_i(j)$ if it is less than $n+1$, and will fail to park if $E_i(j) = \{n+1\}$.

Similarly, if (σ, τ) are a pair of permutations of $M_{\mathbf{a}}$, we execute the algorithm *TestPair*$((\sigma,\tau), n)$, and let $\mathcal{Q}(i,j)$ be the contents of the queue $\mathcal{Q}$ at the point $(*)$ where the values of i and j are as given. We will also never refer to $\mathcal{Q}(i,j)$ unless such a point is reached.

Proof of Lemma 7.1. It suffices to show that if we swap the values of $p_i(j)$ and $p_i(j+1)$ (where $1 \leqslant j < a_i$), the output is unaffected, since any permutation of $p(i)$ can be achieved by a sequence of transpositions of this form.

We use a prime to distinguish between the executions of *TestValet* with the original ordering of $p(i)$ and the ordering in which $p_i(j)$ and $p_i(j+1)$ have been swapped (the latter having a prime). We note that $L = L'$ at the start of the loop (i,j), as the algorithms are identical until this point; in particular, $\hat{E}_i(j) = \hat{E}'_i(j)$. Consider first the case $p_i(j) < p_i(j+1)$. Then $E'_i(j) \subseteq E_i(j)$ and one of the following holds:

(i) $E_i(j) = \{n+1\}$.

Thus $E'_i(j) = \{n+1\}$ as well and the algorithm returns `FALSE` in both cases.

(ii) $\min E_i(j) < n+1$ but $E_i(j+1) = \{n+1\}$.

Then we either have that $|\hat{E}_i(j) \cap \{p_i(j), \ldots, n\}| = 1$ or, if not, then $\hat{E}_i(j) \cap \{p_i(j+1), \ldots, n\} = \varnothing$. In the former case, if $\min E_i(j) < p_i(j+1)$, then $E'_i(j) = \{n+1\}$, otherwise $E'_i(j+1) = \{n+1\}$. In the latter case $E'_i(j) = \{n+1\}$. Thus in all of these cases the algorithm returns `FALSE` for both orderings.

(iii) $\min E_i(j) < n+1$ and $\min E_i(j+1) < n+1$.

Then we either have $\min E_i(j) < p_i(j+1)$, in which case $\min E'_i(j) = \min E_i(j+1)$ and $\min E'_i(j+1) = \min E_i(j)$, or $\min E_i(j) \geqslant p_i(j+1)$, in which case $\min E'_i(j) = \min E_i(j)$ and $\min E'_i(j+1) = \min E_i(j+1)$. In either case, neither algorithm returns `FALSE` at this point, and the arrays L and L' are identical after these two executions of the inner **for** loop. Since the rest of the algorithms run identically, the lemma holds in this case.

The case $p_i(j) > p_i(j+1)$ is entirely similar and the lemma is thus established. □

Proof of Lemma 7.3. We show that p is not a valet function if and only if p is not a major function.

Assume that p is not a major function. Then we can find an m satisfying $\sum_{i=1}^{k} |p(i) \cap [m]| < m$, so that $\sum_{i=1}^{k} |p(i) \cap \{m+1, \ldots, n\}| > n - m$.

Noting that each possible value of l_0 can be used at most once in the execution of the *TestValet* algorithm, and that $l_0 \geqslant p_i(j)$ for each (i, j), we see that there are more than $n - m$ values of l_0 greater than m when the algorithm runs, so for some (i, j), we must have $l_0 = n + 1$. Thus p is not a valet function.

Conversely, if p is not a valet function, let (i_0, j_0) be the value of (i, j) at which the algorithm returns `FALSE`, so that $\min E_{i_0}(j_0) = n + 1$. Let m be the last empty space in L (other than $n + 1$) when the algorithm terminates, so $m < p_{i_0}(j_0)$. Then for each (i, j) lexicographically less than (i_0, j_0) with $p_i(j) \leqslant m$, we have $\min E_i(j) < m$, as m remains unoccupied. But as the $n - m$ entries $L[m+1], \ldots, L[n]$ are all occupied, it follows that $n - m$ terms of $p_1(1), \ldots, p_{i_0}(j_0 - 1)$ are greater than m, as is $p_{i_0}(j_0)$.

So we see that $\sum_{i=1}^{k} |p(i) \cap \{m+1, \ldots, n\}| \geqslant n - m + 1$, or equivalently $\sum_{i=1}^{k} |p(i) \cap [m]| \leqslant m - 1$, proving that p is not a major function. □

8 Extending the bijection: valet functions and allowable pairs

This bijection is an extension of the one presented in section 6. We also prove here that this really is a bijection as claimed. Theorem 6.1 follows as a corollary of this theorem.

We define functions $\phi_{\mathbf{a}} : P_{\mathbf{a}} \to Q_{\mathbf{a}}$ and $\psi_{\mathbf{a}} : Q_{\mathbf{a}} \to P_{\mathbf{a}}$ inductively. For $k = 0$, the functions are trivial, as the sets only have one element.

For $k \geqslant 1$, given $p \in P_{\mathbf{a}}$, we define $(s, t) = \phi_{\mathbf{a}}(p)$ as follows:

(ϕ1) Set $t = \pi_{\mathbf{a}}(p)$ and $D = t^{-1}(k)$. We let $d_0 = 0$, $d_{a_k+1} = n + 1$ and $D = \{d_1, \ldots, d_{a_k}\}$, where $d_1 < d_2 < \cdots < d_{a_k}$.

(ϕ2) Define $p' \in P_{\mathbf{b}}$ by setting, for $i < k$,

$$p'(i) = \bigcup_{w=0}^{a_k} \{\, l - w : l \in p(i) \text{ and } d_w < l < d_{w+1} \,\}.$$

(ϕ3) Set $(s', t') = \phi_{\mathbf{b}}(p')$.

(ϕ4) We define s by inserting a_k terms labelled k into s' so that $s(j) = k$ if $j \in p(k)$.

And for $k \geqslant 1$, given $(\sigma, \tau) \in Q_{\mathbf{a}}$, we define $q = \psi_{\mathbf{a}}(\sigma, \tau)$ as follows:

($\psi 1$) Set $q(k) = \sigma^{-1}(k)$ and $\Delta = \tau^{-1}(k)$. Let $\delta_0 = 0$, $\delta_{a_k+1} = n+1$ and $\Delta = \{\delta_1, \ldots, \delta_{a_k}\}$, where $\delta_1 < \delta_2 < \cdots < \delta_{a_k}$.

($\psi 2$) Let σ' and τ' be, respectively, σ and τ with all k's deleted, so $(\sigma', \tau') \in Q_{\mathbf{b}}$.

($\psi 3$) Set $q' = \psi_{\mathbf{b}}(\sigma', \tau')$.

($\psi 4$) For $i < k$, set

$$q(i) = \bigcup_{w=0}^{a_k} \{\, \lambda + w : \lambda \in q'(i) \text{ and } \delta_w < \lambda + w < \delta_{w+1} \,\}.$$

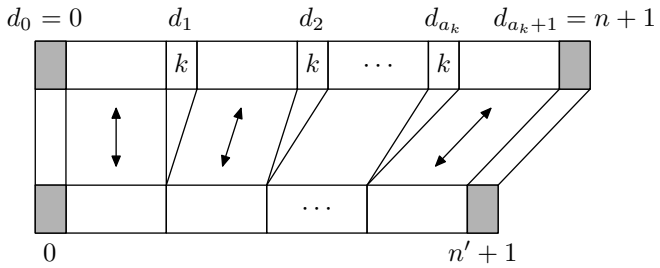
Theorem 8.1. *The functions $\phi_{\mathbf{a}}$ and $\psi_{\mathbf{a}}$ are well-defined, mutually inverse bijections between $P_{\mathbf{a}}$ and $Q_{\mathbf{a}}$, and are output and breakpoint preserving.*

Proof. We prove the result by induction on k, the case $k = 0$ being trivial. We must first show that the algorithms are well-defined. The only problematic parts here are the steps ($\phi 2$) and ($\psi 2$), where we must justify the claims that $p' \in P_{\mathbf{b}}$ and $(\sigma', \tau') \in Q_{\mathbf{b}}$. We then show that both functions preserve breakpoints and identify a special set of breakpoints, from which we deduce that $\phi_{\mathbf{a}}(p) \in Q_{\mathbf{a}}$ and $\psi_{\mathbf{a}}(\sigma, \tau) \in P_{\mathbf{a}}$. Finally, we show that $\phi_{\mathbf{a}}$ and $\psi_{\mathbf{a}}$ are mutually inverse and output preserving. The proof is quite technical in nature.

Throughout the proof we will assume, using Lemma 7.1, that the elements of $p(i)$, $p'(i)$ and the like are listed in increasing order. In particular, this allows us to make statements such as: $p'_i(j) = p_i(j) - w$ where $d_w < p_i(j) < d_{w+1}$.

It is also useful to note here that both $(d_w - w)$ and $(\delta_w - w)$ are non-decreasing sequences, as both (d_w) and (δ_w) are strictly increasing sequences.

We use the following figure to guide us in our thinking, for example when we consider how to obtain t' from t. The top row represents a permutation of $M_{\mathbf{a}}$ and the bottom row represents the corresponding permutation of $M_{\mathbf{b}}$. Alternatively, we can think of the top and bottom rows as representing L and L' respectively, suggesting the relationship between p and p', E and E' and the like. The shaded boxes in the rows represent 0 and $n+1$ or $n'+1$, which are sometimes needed. Many of the steps in the proof given are "obvious" in terms of this picture, but we prefer to give formal proofs in terms of the defining algorithms.



(i) The step ($\phi 2$) is well-defined and $\pi_{\mathbf{b}}(p')$ is $\pi_{\mathbf{a}}(p)$ with all k's deleted.

We could show that step ($\phi 2$) is well-defined by proving that p' is a major function. However, we prefer to show the result directly from the algorithm *TestValet*, for this also allows us to show that $\pi_{\mathbf{b}}(p')$ is $\pi_{\mathbf{a}}(p)$ with all k's deleted. More precisely, if we set $t = \pi_{\mathbf{a}}(p)$ and $t' = \pi_{\mathbf{b}}(p')$, we show that, for $1 \leqslant l' \leqslant n'$,

$$t'(l') = t(l' + w) \qquad \text{where } d_w < l' + w < d_{w+1}. \tag{2}$$

(Note that because of step ($\phi 1$) in the calculation of $\phi_{\mathbf{b}}(p')$, the t' of step ($\phi 3$) really is $\pi_{\mathbf{b}}(p')$.)

We compare the executions of *TestValet*$(p, k, \mathbf{a})$ and *TestValet*$(p', k-1, \mathbf{b})$, distinguishing the variables associated with the latter by using a prime. We claim that, for $i < k$,

$$\hat{E}'_i(j) = \{n' + 1\} \cup \bigcup_{w=0}^{a_k} \{\, l - w : l \in \hat{E}_i(j) \text{ and } d_w < l < d_{w+1} \,\}. \tag{3}$$

Before proving this claim, we show that given (3) for a particular (i, j), it follows that

$$E'_i(j) = \{n' + 1\} \cup \bigcup_{w=0}^{a_k} \{\, l - w : l \in E_i(j) \text{ and } d_w < l < d_{w+1} \,\} \tag{4}$$

for this (i, j). To show this, recall that $E'_i(j) = \hat{E}'_i(j) \cap \{p'_i(j), \ldots, n' + 1\}$. It is thus sufficient to show that for each w we have

$$\begin{aligned} &\{\, l - w : l \in \hat{E}_i(j) \text{ and } d_w < l < d_{w+1} \,\} \cap \{p'_i(j), \ldots, n' + 1\} \\ &\qquad = \{\, l - w : l \in E_i(j) \text{ and } d_w < l < d_{w+1}, \,\}. \end{aligned} \tag{5}$$

Let w_0 be such that $d_{w_0} < p_i(j) < d_{w_0+1}$, so that $p'_i(j) = p_i(j) - w_0$. We consider the three cases $w < w_0$, $w > w_0$ and $w = w_0$ separately. If $w < w_0$, then as $(d_{w+1} - 1) - w \leqslant d_{w_0} - w_0 < p'_i(j)$, the left hand side of (5) is empty, as is the right hand side, since $d_{w+1} \leqslant d_{w_0} < p_i(j) \leqslant \min E_i(j)$.

If $w > w_0$, then $(d_w + 1) - w \geqslant (d_{w_0+1} - (w_0 + 1)) + 1 > p'_i(j)$, so the left hand side is simply $\{\, l - w : l \in \hat{E}_i(j) \text{ and } d_w < l < d_{w+1} \,\}$. But as $p_i(j) < d_w$, it follows that $l \in \hat{E}_i(j)$ if and only if $l \in E_i(j)$ when $l > d_w$. Thus the right hand side is the same.

Finally, if $w = w_0$ we have

$$\begin{aligned}
&\{\, l - w_0 : l \in E_i(j) \text{ and } d_{w_0} < l < d_{w_0+1} \,\} \\
&\qquad = \{\, l - w_0 : l \in \hat{E}_i(j) \text{ and } l \geqslant p_i(j) \text{ and } d_{w_0} < l < d_{w_0+1} \,\} \\
&\qquad = \{\, l - w_0 : l \in \hat{E}_i(j) \text{ and } d_{w_0} < l < d_{w_0+1} \,\} \cap \{p'_i(j), \ldots, n'+1\},
\end{aligned}$$

where the last line follows as $p_i(j) - w_0 = p'_i(j)$, and for any $l < d_{w_0+1}$, we have the inequalities $l - w_0 \leqslant d_{w_0+1} - (w_0+1) \leqslant d_{a_k+1} - (a_k+1) = n'$. Thus our claim about $E'_i(j)$ follows from that about $\hat{E}'_i(j)$.

We now prove our claim about $\hat{E}'_i(j)$. We show that (3) holds every time (†) is reached in the execution of the algorithms. On the first occasion that (†) is reached, we have $(i,j) = (1,1)$, and as $\hat{E}'_i(j) = [n'+1]$ and $\hat{E}_i(j) = [n+1]$, the claim holds.

Assume that (3) holds at (†) when $(i,j) = (i_0, j_0)$, where $i_0 < k$. We have $l_0 = \min E_{i_0}(j_0) \leqslant n$, and we let w_0 be such that $d_{w_0} < l_0 < d_{w_0+1}$, noting that $l_0 \notin D$ when $i < k$. It follows easily from (4) that $l'_0 = \min E'_{i_0}(j_0) = l_0 - w_0$. Thus the next time (†) is reached, $\hat{E}_i(j) = \hat{E}_{i_0}(j_0) \setminus \{l_0\}$ and $\hat{E}'_i(j) = \hat{E}'_{i_0}(j_0) \setminus \{l'_0\}$ (where we have $(i,j) = (i_0, j_0+1)$ or $(i_0+1, 1)$, according to whether $j_0 < a_{i_0}$ or $j_0 = a_{i_0}$). Thus we have

$$\begin{aligned}
\hat{E}'_i(j) &= \hat{E}'_{i_0}(j_0) \setminus \{l'_0\} \\
&= \Big(\{n'+1\} \cup \bigcup_{w=0}^{a_k} \{\, l - w : l \in \hat{E}_{i_0}(j_0) \text{ and } d_w < l < d_{w+1} \,\}\Big) \\
&\qquad \setminus \{l_0 - w_0\} \\
&= \{n'+1\} \cup \bigcup_{w=0}^{a_k} \{\, l - w : l \in \hat{E}_i(j) \text{ and } d_w < l < d_{w+1} \,\},
\end{aligned}$$

proving that (3) holds for (i,j), and hence (3) holds for all (i,j) pairs.

It follows immediately from this that $p' \in P_{\mathbf{b}}$ and that $\pi_{\mathbf{b}}(p')$ is $\pi_{\mathbf{a}}(p)$ with all k's deleted: if $d_w < l' + w = l < d_{w+1}$, then for some (i,j) with $i < k$, we have $l = \min E_i(j)$, and for this (i,j), we see that $l_0 = l$ and $l'_0 = l'$. As $t(l_0) = t'(l'_0) = i$, we have $t'(l') = t(l'+w)$, proving (2). Also, the above showed that for each (i_0, j_0) with $i_0 < k$, we have $l'_0 = l_0 - w_0$, so $l'_0 < d_{w_0+1} - w_0 \leqslant d_{a_k+1} - a_k = n'+1$, so p' is a valet function.

(ii) The step ($\psi 2$) is well-defined.

Consider the natural priority queue computation for (σ, τ). Removing the i-th Insert for each $i \in \sigma^{-1}(k)$ and the j-th DeleteMin for each $j \in \tau^{-1}(k)$ yields a priority queue computation (actually the natural one)

which produces an output of τ' given an input of σ'. Thus $(\sigma', \tau') \in Q_{\mathbf{b}}$.

This argument can be formalised in terms of the algorithm *TestPair*, as in part (vii) below, but we shall not give details here.

(iii) $\phi_{\mathbf{a}}$ preserves breakpoints.

Let b be a breakpoint of p and let w be such that $d_w \leqslant b < d_{w+1}$, so that for $i < k$, $p_i(j) \leqslant b$ if and only if $p'_i(j) \leqslant b - w$. Also, $|p(k) \cap [b]| = w$ as $t^{-1}(k) = \{d_1, \ldots, d_{a_k}\}$ and b is a breakpoint of p. Thus

$$\begin{aligned}\sum_{i=1}^{k-1} |p'(i) \cap [b-w]| &= \sum_{i=1}^{k-1} |p(i) \cap [b]| \\ &= \sum_{i=1}^{k} |p(i) \cap [b]| \ - \ |p(k) \cap [b]| \\ &= b - w,\end{aligned}$$

so $b - w$ is a breakpoint of p'.

By the inductive hypothesis, $b - w$ is a breakpoint of $\phi_{\mathbf{b}}(p') = (s', t')$, so that $\{s'_1, \ldots, s'_{b-w}\} = \{t'_1, \ldots, t'_{b-w}\}$ as multisets. But we noted above that $|p(k) \cap [b]| = w$ and that $t_i = k$ for $i = d_1, d_2, \ldots, d_{a_k}$, so using step ($\phi 4$), we see that

$$\begin{aligned}\{s_1, \ldots, s_b\} &= \{s'_1, \ldots, s'_{b-w}\} \cup \{k^w\} \\ &= \{t'_1, \ldots, t'_{b-w}\} \cup \{k^w\} \\ &= \{t_1, \ldots, t_b\},\end{aligned}$$

showing that b is a breakpoint of (s, t).

(iv) $\psi_{\mathbf{a}}$ preserves breakpoints.

We use an argument similar to that of part (iii) above. Let b be a breakpoint of (σ, τ) and let w be such that $\delta_w \leqslant b < \delta_{w+1}$. Then we have $\{\tau_1, \ldots, \tau_b\} = \{\tau'_1, \ldots, \tau'_{b-w}\} \cup \{k^w\}$. But as b is a breakpoint of (σ, τ), we must have $\{\sigma_1, \ldots, \sigma_b\} = \{\sigma'_1, \ldots, \sigma'_{b-w}\} \cup \{k^w\}$ as well. Thus $\{\sigma'_1, \ldots, \sigma'_{b-w}\} = \{\tau'_1, \ldots, \tau'_{b-w}\}$ and $b - w$ is a breakpoint for (σ', τ'). By the inductive hypothesis, it follows that $b - w$ is a breakpoint for q'.

It is relatively straightforward to show that for $i < k$, $q'_i(j) \leqslant b - w$ if and

only if $q_i(j) \leqslant b$. Also, $|q(k) \cap [b]| = |\sigma^{-1}(k) \cap [b]| = w$, hence

$$\begin{aligned}\sum_{i=1}^{k} |q(i) \cap [b]| &= \sum_{i=1}^{k-1} |q(i) \cap [b]| + |q(k) \cap [b]| \\ &= \sum_{i=1}^{k-1} |q'(i) \cap [b-w]| + w \\ &= (b-w) + w = b,\end{aligned}$$

so b is a breakpoint of q as required.

(v) $d_w - w$ is a breakpoint of p' for each w.

In the execution of *TestValet*$(p, k, \mathbf{a})$, we have $\hat{E}_k(1) = D \cup \{n+1\}$, so that $d_w \in \hat{E}_i(j)$ for all (i, j) with $i < k$. Thus, for such pairs, $p_i(j) < d_w$ if and only if $\min E_i(j) < d_w$. It follows that $\sum_{i=1}^{k-1} |p(i) \cap [d_w]| = d_w - w$, as $\min E_i(j)$ is distinct for distinct (i, j) and $\{ \min E_i(j) : i < k \} = [n] \setminus D$.

Now for $i < k$, if $p_i(j) < d_w$ then $p'_i(j) \leqslant d_w - w$ by the definition of p' and the monotonicity of $d_w - w$. Also, if $p_i(j) > d_w$, then $p'_i(j) > d_w - w$. Thus $p_i(j) < d_w$ if and only if $p'_i(j) \leqslant d_w - w$, and

$$\begin{aligned}\sum_{i=1}^{k-1} |p'(i) \cap [d_w - w]| &= \sum_{i=1}^{k-1} |p(i) \cap [d_w]| \\ &= d_w - w,\end{aligned}$$

as required.

(vi) $\delta_w - w$ is a breakpoint of (σ', τ') for each w.

Consider the natural computation for (σ, τ). Remove the i-th Insert and the j-th DeleteMin for each $i \in \sigma^{-1}(k)$ and $j \in \tau^{-1}(k)$ to get a priority queue computation for (σ', τ'), as in part (ii) above.

Note that when k is output in the priority queue computation for (σ, τ), the queue $\mathcal{Q}$ contains only k's. Thus, in the priority queue computation for (σ', τ'), the queue will be empty at each point at which k would have been output in the corresponding computation for (σ, τ), that is, after each $(\delta_w - w)$-th DeleteMin.

As above, this argument can be formalised by comparing the executions of *TestPair*$((\sigma, \tau), n)$ and *TestPair*$((\sigma', \tau'), n')$. It is similar to, but easier than, the argument in part (vii) below.

(vii) $\phi_{\mathbf{a}}$ produces allowable pairs.

Given $p \in P_{\mathbf{a}}$, we show that $(s,t) = \phi_{\mathbf{a}}(p)$ is an allowable pair. By the inductive hypothesis, we know that $(s',t') = \phi_{\mathbf{b}}(p')$ is an allowable pair, and by step ($\phi 4$) and the result of (i) above, (s,t) is obtained from (s',t') by inserting k's into s' and t' in positions determined by $p(k)$ and D respectively.

To show that (s,t) is an allowable pair, we compare the execution of the algorithms *TestPair*$((s,t),n)$ and *TestPair*$((s',t'),n')$, distinguishing the variables in the two executions by using a prime. We set

$$u(i) = |s^{-1}(k) \cap [i-1]|$$

and

$$v(j) = |t^{-1}(k) \cap [j-1]|,$$

noting that $s_i = s'_{i-u(i)}$ if $s_i \neq k$ and $t_j = t'_{j-v(j)}$ if $t_j \neq k$. As $j \leqslant i$ throughout the execution of the algorithm, and $|p(k) \cap [j]| \geqslant |D \cap [j]|$ for all j, we see that $u(i) \geqslant v(j)$ and $u(i+1) \geqslant v(j+1)$ whenever $(*)$ is reached in the algorithm.

We claim that on each such occasion we have

$$\mathcal{Q}(i,j) = \mathcal{Q}'(i-u(i), j-v(j)) \cup \{k^{u(i)-v(j)}\}. \tag{6}$$

Recall that $\mathcal{Q}(i,j)$ is the content of the queue $\mathcal{Q}$ at the point $(*)$ when i and j are as given. It is certainly true when $(i,j) = (1,1)$. Given this result for $(i,j) = (i_0, j_0)$, we consider four possibilities for the next step in *TestPair*$((s,t),n)$, showing that in each case the claim is true the next time $(*)$ is reached. We assume that the corresponding execution of *TestPair*$((s',t'),n')$ has reached $(*)$ with $(i',j') = (i_0 - u(i_0), j_0 - v(j_0))$; it will follow from this induction argument that this point is indeed reached.

(a) $t_{j_0} \notin \mathcal{Q}$ and $s_{i_0} \neq k$.

We cannot have $t_{j_0} = k$ in this case, for if $k \notin \mathcal{Q}$, then $u(i_0) = v(j_0)$ from (6). As $u(i_0+1) \geqslant v(j_0+1) \geqslant v(j_0)$ but $s_{i_0} \neq k$, we must have $u(i_0+1) = u(i_0)$ and $v(j_0+1) = v(j_0)$, hence $t_{j_0} \neq k$. Thus $t'_{j_0-v(j_0)} \notin \mathcal{Q}'$, so $s_{i_0} = s'_{i_0-u(i_0)}$ is inserted in both algorithms, giving

$$\begin{aligned}
\mathcal{Q}(i_0+1, j_0) &= \mathcal{Q}(i_0, j_0) \cup \{s_{i_0}\} \\
&= \mathcal{Q}'(i_0 - u(i_0), j_0 - v(j_0)) \cup \{k^{u(i_0)-v(j_0)}\} \\
&\qquad \cup \{s'_{i_0-u(i_0)}\} \\
&= \mathcal{Q}'(i_0 + 1 - u(i_0+1), j_0 - v(j_0)) \cup \{k^{u(i_0+1)-v(j_0)}\},
\end{aligned}$$

as $u(i_0+1) = u(i_0)$ in this case.

(b) $t_{j_0} \notin \mathcal{Q}$ and $s_{i_0} = k$.

Then after INSERT(s_{i_0}) is executed in *TestPair*$((s,t),n)$, we have

$$\begin{aligned}\mathcal{Q}(i_0+1, j_0) &= \mathcal{Q}(i_0, j_0) \cup \{k\} \\ &= \mathcal{Q}'(i_0 - u(i_0), j_0 - v(j_0)) \cup \{k^{u(i_0)-v(j_0)}\} \cup \{k\} \\ &= \mathcal{Q}'(i_0 + 1 - u(i_0+1), j_0 - v(j_0)) \cup \{k^{u(i_0+1)-v(j_0)}\},\end{aligned}$$

as $u(i_0+1) = u(i_0)+1$ in this case.

(c) $t_{j_0} \in \mathcal{Q}$ and $t_{j_0} \neq k$.

As $t_{j_0} = t'_{j_0-v(j_0)}$, we see that $t'_{j_0-v(j_0)} \in \mathcal{Q}'(i_0 - u(i_0), j_0 - v(j_0))$ and thus $t'_{j_0-v(j_0)} = \min \mathcal{Q}'$ (as *TestPair*$((s',t'),n')$ does not return `FALSE`). It follows from (6) that $t_{j_0} = \min \mathcal{Q}(i_0, j_0)$, and therefore *TestPair*$((s,t),n)$ does not return `FALSE` at this point either. After the DELETEMIN is executed in each of the algorithms, we have removed $t_{j_0} = t'_{j_0-v(j_0)}$ from both $\mathcal{Q}$ and $\mathcal{Q}'$, so

$$\begin{aligned}\mathcal{Q}(i_0, j_0+1) &= \mathcal{Q}(i_0, j_0) \setminus \{t_{j_0}\} \\ &= \big(\mathcal{Q}'(i_0 - u(i_0), j_0 - v(j_0)) \cup \{k^{u(i_0)-v(j_0)}\}\big) \\ &\qquad \setminus \{t'_{j_0-v(j_0)}\} \\ &= \mathcal{Q}'(i_0 - u(i_0), j_0 + 1 - v(j_0+1)) \cup \{k^{u(i_0)-v(j_0+1)}\},\end{aligned}$$

as $v(j_0+1) = v(j_0)$ in this case.

(d) $t_{j_0} \in \mathcal{Q}$ and $t_{j_0} = k$.

Then $j_0 \in D$, say $j_0 = d_w$, so $v(j_0) = w-1$. Thus we have

$$\begin{aligned}\mathcal{Q}(i_0, j_0) &= \mathcal{Q}'(i_0 - u(i_0), j_0 - v(j_0)) \cup \{k^{u(i_0)-v(j_0)}\} \\ &= \mathcal{Q}'(i_0 - u(i_0), d_w - w + 1) \cup \{k^{u(i_0)-v(j_0)}\}\end{aligned}$$

We must have $u(i_0) > v(j_0)$ as $k \in \mathcal{Q}$, so to show that the execution of *TestPair*$((s,t),n)$ does not return `FALSE` at this point, it suffices to show that $\mathcal{Q}'(i_0 - u(i_0), d_w - w + 1) = \varnothing$. By (v), $d_w - w$ is a breakpoint of p', and by the inductive hypothesis, it follows that $d_w - w$ is a breakpoint of (s',t'). Thus at the point that t'_{d_w-w} was deleted from the queue in *TestPair*$((s',t'),n')$, $\mathcal{Q}'$ was empty. (This has already occurred, as now $j' = d_w - w + 1$.) Let i_1 be the smallest value of i satisfying $i - u(i) = d_w - w + 1$ for which (i_1, j_0) occurred as a value of (i,j) during the execution of *TestPair*$((s,t),n)$. Then $i_1 \leqslant i_0$ and $\mathcal{Q}'(i_1 - u(i_1), d_w - w + 1) = \varnothing$. Now if $u(i_1) - v(j_0) = u(i_1) - w + 1 > 0$,

it follows that $t_{j_0} = k \in \mathcal{Q}$ when $(i,j) = (i_1, j_0)$, hence $i_1 = i_0$ and $\mathcal{Q}'(i_0 - u(i_0), d_w - w + 1) = \varnothing$ as required. If not, then we have $\mathcal{Q}(i_1, j_0) = \varnothing$, which shows that $i_1 = j_0 = d_w$. Now since $v(d_w + 1) \leqslant u(d_w + 1)$, but $v(d_w) = u(d_w)$ and $d_w \in D$, we deduce that $d_w \in p(k)$. Hence $s_{i_1} = k$, so that $i_0 = i_1 + 1$ and $u(i_0) = u(i_1) + 1$, giving $\mathcal{Q}'(i_0 - u(i_0), d_w - w + 1) = \mathcal{Q}'(i_1 - u(i_1), d_w - w + 1) = \varnothing$ as required. Thus *TestPair*$((s,t), n)$ does not return `FALSE` at this point.

After this step, we have $j = j_0 + 1$ and $v(j) = v(j_0) + 1$, so

$$\begin{aligned}\mathcal{Q}(i_0, j_0 + 1) &= \mathcal{Q}(i_0, j_0) \setminus \{k\} \\ &= \big(\mathcal{Q}'(i_0 - u(i_0), j_0 - v(j_0)) \cup \{k^{u(i_0) - v(j_0)}\}\big) \setminus \{k\} \\ &= \mathcal{Q}'(i_0 - u(i_0), j_0 + 1 - v(j_0 + 1)) \cup \{k^{u(i_0) - v(j_0 + 1)}\}.\end{aligned}$$

It follows from the analysis of these four cases that our claim holds. It follows from our proof of cases (c) and (d) that every time the test $t_j \in \mathcal{Q}$ is carried out in *TestPair*$((s,t), n)$, the test succeeds, so (s,t) is an allowable pair.

(viii) $\psi_{\mathbf{a}}$ produces valet functions.

Given $(\sigma, \tau) \in Q_{\mathbf{a}}$, it suffices to demonstrate that $q = \psi_{\mathbf{a}}(\sigma, \tau)$ is a major function (appealing to Lemma 7.3), that is, given $m \in [n]$, we show that $\sum_{i=1}^{k} |q(i) \cap [m]| \geqslant m$. We note that by the inductive hypothesis, we already have $q' \in P_{\mathbf{b}}$, so q' is a major function.

Let w be such that $\delta_w \leqslant m < \delta_{w+1}$. For $i < k$, we can easily deduce that $q_i(j) \leqslant m$ if and only if $q'_i(j) \leqslant m - w$. Thus $\sum_{i=1}^{k-1} |q(i) \cap [m]| = \sum_{i=1}^{k-1} |q'(i) \cap [m - w]| \geqslant m - w$. But we also know that $|q(k) \cap [m]| = |\sigma^{-1}(k) \cap [m]| \geqslant |\tau^{-1}(k) \cap [m]| = w$, and hence $\sum_{i=1}^{k} |q(i) \cap [m]| \geqslant m$. Thus q is a valet function as required.

(ix) $\psi_{\mathbf{a}}\phi_{\mathbf{a}} = \mathrm{Id}_{P_{\mathbf{a}}}$.

Given $p \in P_{\mathbf{a}}$, we set $(s,t) = \phi_{\mathbf{a}}(p)$, then $(\sigma, \tau) = (s,t)$ and finally set $q = \psi_{\mathbf{a}}(\sigma, \tau) = \psi_{\mathbf{a}}\phi_{\mathbf{a}}(p)$. We wish to show that $p = q$.

As $\tau = t$, we have $\Delta = D$, so $\delta_w = d_w$ for each w. As $p_i(j) \notin D$ for $i < k$ and $q(k) = p(k)$, it is clear that if $p' = q'$, then $p = q$. But as $p' = \psi_{\mathbf{b}}(s', t')$ by the inductive hypothesis and $q' = \psi_{\mathbf{b}}(\sigma', \tau')$ by step ($\psi 3$), it suffices to show that $(s', t') = (\sigma', \tau')$. However, we showed in (i) that t' is t with all k's deleted, and clearly s' is s with all k's deleted by step ($\phi 4$). Also, step ($\psi 2$) tells us that σ' and τ' are respectively σ and τ with all k's

deleted. Thus, since $(s,t) = (\sigma,\tau)$, we have $(s',t') = (\sigma',\tau')$, so $p = q$ and $\psi_{\mathbf{a}}\phi_{\mathbf{a}} = \mathrm{Id}_{P_{\mathbf{a}}}$.

(x) $\phi_{\mathbf{a}}\psi_{\mathbf{a}} = \mathrm{Id}_{Q_{\mathbf{a}}}$ and $\pi_{\mathbf{a}}(\psi_{\mathbf{a}}(\sigma,\tau)) = \tau$.

Given $(\sigma,\tau) \in Q_{\mathbf{a}}$, we first set $q = \psi_{\mathbf{a}}(\sigma,\tau)$, then set $p = q$ and finally set $(s,t) = \phi_{\mathbf{a}}(p) = \phi_{\mathbf{a}}\psi_{\mathbf{a}}(\sigma,\tau)$. We show that $\pi_{\mathbf{a}}(q) = \tau$, and then use this to deduce that $(s,t) = (\sigma,\tau)$; these are the two results desired.

We proceed in a manner similar to that used in (i). We know by the inductive hypothesis that $(\sigma',\tau') = \phi_{\mathbf{b}}(q')$, so we also have $\tau' = \pi_{\mathbf{b}}(q')$ by step (ϕ1). Comparing the execution of *TestValet*$(q,k,\mathbf{a})$ with that of *TestValet*$(q',k-1,\mathbf{b})$, we claim that for $i < k$,

$$\hat{E}_i(j) = \{n+1\} \cup \Delta \cup \bigcup_{w=0}^{a_k} \{\, l+w : l \in \hat{E}'_i(j) \text{ and } \delta_w < l+w < \delta_{w+1} \,\}.$$

It follows immediately from this, as in (i), that

$$E_i(j) = \{n+1\} \cup \{\, \delta \in \Delta : \delta \geqslant q_i(j) \,\} \cup \bigcup_{w=0}^{a_k} \{\, l+w : l \in E'_i(j) \text{ and } \delta_w < l+w < \delta_{w+1} \,\}.$$

We prove the claim by showing that it holds each time (†) is reached in the algorithms. The result is trivial on the first occasion, as $(i,j) = (1,1)$, so that $\hat{E}_i(j) = [n+1]$ and $\hat{E}'_i(j) = [n'+1]$. Assume the result to be true at (†) when $(i,j) = (i_0,j_0)$, where $i_0 < k$. We let w_0 be such that $\delta_{w_0} < q_{i_0}(j_0) < \delta_{w_0+1}$, so that $q'_{i_0}(j_0) = q_{i_0}(j_0) - w_0$ satisfies $\delta_{w_0} - w_0 < q'_{i_0}(j_0) \leqslant \delta_{w_0+1} - (w_0+1)$. But $\delta_{w_0+1} - (w_0+1)$ is a breakpoint of q' by part (iv) and the inductive hypothesis, so it follows that $\delta_{w_0} - w_0 < l'_0 = \min E'_{i_0}(j_0) \leqslant \delta_{w_0+1} - (w_0+1)$. Thus we have

$$\begin{aligned} l_0 &= \min E_{i_0}(j_0) \\ &= \min\Big(\{n+1\} \cup \{\, \delta \in \Delta : \delta \geqslant q_{i_0}(j_0) \,\} \\ &\qquad \cup \bigcup_{w=0}^{a_k} \{\, l+w : l \in E'_{i_0}(j_0) \text{ and } \delta_w < l+w < \delta_{w+1} \,\}\Big) \\ &= \min\big(\{n+1\} \cup \{\, \delta \in \Delta : \delta \geqslant q_{i_0}(j_0) \,\} \cup \{l'_0 + w_0\}\big). \end{aligned}$$

But $\delta_{w_0} < l'_0 + w_0 \leqslant \delta_{w_0+1} - 1$, so $l_0 = l'_0 + w_0$. Thus the next time that

(†) is reached, we have $\hat{E}'_i(j) = \hat{E}'_{i_0}(j_0) \setminus \{l'_0\}$ and

$$\begin{aligned}\hat{E}_i(j) &= \hat{E}_{i_0}(j_0) \setminus \{l_0\} \\ &= \Big(\{n+1\} \cup \Delta \cup \bigcup_{w=0}^{a_k} \{\, l+w : l \in \hat{E}'_{i_0}(j_0) \text{ and } \delta_w < l+w < \delta_{w+1} \,\}\Big) \\ &\qquad \setminus \{l'_0 + w_0\} \\ &= \{n+1\} \cup \Delta \cup \bigcup_{w=0}^{a_k} \{\, l+w : l \in \hat{E}'_i(j) \text{ and } \delta_w < l+w < \delta_{w+1} \,\},\end{aligned}$$

as required, where $(i,j) = (i_0, j_0+1)$ or $(i_0+1, 1)$ according as $j_0 < a_{i_0}$ or $j_0 = a_{i_0}$.

In particular, this proof shows that at the end of the loop $i = k-1$, we have, for each w,

$$(L[\delta_w + 1], \ldots, L[\delta_{w+1} - 1]) = (L'[\delta_w - w + 1], \ldots, L'[\delta_{w+1} - (w+1)]),$$

and $L[\delta_w]$ is still empty. Thus during the loop $i = k$ in *TestValet*$(q, k, \mathbf{a})$, $\min E_k(j) \in \Delta$ for each j (using (viii)), so that $\pi_{\mathbf{a}}(q)$ is $\pi_{\mathbf{b}}(q') = \tau'$ with k's inserted into the a_k positions determined by Δ. Thus $\pi_{\mathbf{a}}(q) = \tau$ as stated.

We are now able to show that $(s,t) = (\sigma, \tau)$. Having shown that $\pi_{\mathbf{a}}(q) = \tau$, and noting that $t = \pi_{\mathbf{a}}(p)$, we deduce that $t = \tau$, as $p = q$. It follows that $D = t^{-1}(k) = \tau^{-1}(k) = \Delta$. By construction, $q_i(j) \notin \Delta$ for $i < k$, so steps ($\phi 2$) and ($\psi 4$) now yield $p' = q'$. But then, by the inductive hypothesis, $(s', t') = \phi_{\mathbf{b}}(p') = \phi_{\mathbf{b}}(q') = (\sigma', \tau')$, so $s' = \sigma'$. As s is s' with k's inserted in the positions determined by $p(k) = q(k)$, and σ is σ' with k's inserted in the positions determined by $\sigma^{-1}(k) = q(k)$, it follows that $s = \sigma$, hence $(s,t) = (\sigma, \tau)$ and $\phi_{\mathbf{a}}\psi_{\mathbf{a}} = \mathrm{Id}_{Q_{\mathbf{a}}}$.

(xi) $\phi_{\mathbf{a}}$ and $\psi_{\mathbf{a}}$ are both output preserving.

That $\phi_{\mathbf{a}}$ is output preserving is clear from step ($\phi 1$), and $\psi_{\mathbf{a}}$ is output preserving by the result of part (x) above. □

Corollary 8.2. (a) *Let $p \in P_{\mathbf{a}}$, $t = \pi_{\mathbf{a}}(p)$ and $D = t^{-1}(k)$. Then $\max D$ is a breakpoint of p.*

(b) *Let $(\sigma, \tau) \in Q_{\mathbf{a}}$ and $\Delta = \tau^{-1}(k)$. Then $\max \Delta$ is a breakpoint of (σ, τ).*

Proof. (a) In part (v) of the proof, we noted that $\sum_{i=1}^{k-1} |p(i) \cap [d_w]| = d_w - w$ for each w. In particular, when $w = a_k$, so that $d_w = \max D$, we have $|p(k) \cap [d_w]| = a_k = w$ (as all the cars in $p(k)$ park in the spaces in D), so $\sum_{i=1}^{k} |p(i) \cap [d_w]| = d_w$ as required.

(b) In part (vi) of the proof, we noted that when k is output in the computation of (σ, τ), the queue $\mathcal{Q}$ contains only k's. Thus when the final k is output, $\mathcal{Q}$ must be empty, so $\max \Delta$ is a breakpoint of (σ, τ). □

9 Alternative descriptions of the bijections

It is possible to calculate all of ϕ_n, ψ_n (as defined in section 6), $\phi_{\mathbf{a}}$ and $\psi_{\mathbf{a}}$ non-inductively, as we now demonstrate.

Given $(\sigma, \tau) \in Q_n$, we define for each $j \in [n]$

$$S(\sigma, j) = |\{\, l \in [j] : \sigma_l \leqslant \sigma_j \,\}|$$

and

$$T(\tau, j) = |\{\, l \in [j] : \tau_l > \tau_j \,\}|.$$

We then set $q(i) = S(\sigma, \sigma^{-1}(i)) + T(\tau, \tau^{-1}(i))$ and claim that $q = \psi_n(\sigma, \tau)$.

We can extend this to multisets as follows. Given $(\sigma, \tau) \in Q_{\mathbf{a}}$, for each $i \in [k]$ we list the elements of $\sigma^{-1}(i)$ and $\tau^{-1}(i)$ in increasing order as $\bar{\sigma}_i(1), \ldots, \bar{\sigma}_i(a_i)$ and $\bar{\tau}_i(1), \ldots, \bar{\tau}_i(a_i)$ respectively. Setting

$$q(i) = \{\, S(\sigma, \bar{\sigma}_i(j)) + T(\tau, \bar{\tau}_i(j)) : j \in [a_i] \,\} \tag{7}$$

gives $q = \psi_{\mathbf{a}}(\sigma, \tau)$, as we now show by induction.

The statement is vacuously true if $k = 0$. For $k \geqslant 1$, we assume this result to be true for $k - 1$, so using the notation of the previous section, we have, for $i < k$,

$$q'(i) = \{\, S(\sigma', \bar{\sigma}'_i(j)) + T(\tau', \bar{\tau}'_i(j)) : j \in [a_i] \,\}.$$

We consider the relationship between $S(\sigma, \bar{\sigma}_i(j))$ and $S(\sigma', \bar{\sigma}'_i(j))$, noting that $\sigma_{\bar{\sigma}_i(j)} = i$ by definition of $\bar{\sigma}_i(j)$. We have

$$S(\sigma, \bar{\sigma}_i(j)) = |\{\, l \in [\bar{\sigma}_i(j)] : \sigma_l \leqslant i \,\}|$$

and

$$S(\sigma', \bar{\sigma}'_i(j)) = |\{\, l \in [\bar{\sigma}'_i(j)] : \sigma'_l \leqslant i \,\}|.$$

But as σ' is just σ with all of the k's deleted, we see that $\{\sigma_1, \ldots, \sigma_{\bar{\sigma}_i(j)}\} = \{\sigma'_1, \ldots, \sigma'_{\bar{\sigma}'_i(j)}\} \cup \{k^r\}$ as multisets for some r. Thus $S(\sigma, \bar{\sigma}_i(j)) = S(\sigma', \bar{\sigma}'_i(j))$. This can be proven formally, but we do not do so here.

A similar argument also shows that

$$T(\tau, \bar{\tau}_i(j)) = |\{\, l \in [\bar{\tau}_i(j)] : \tau_l > i \,\}|$$

and

$$T(\tau', \bar{\tau}'_i(j)) = |\{\, l \in [\bar{\tau}'_i(j)] : \tau'_l > i \,\}|$$

differ by the number of k's in τ which appear before the $\bar{\tau}_i(j)$ position, and this is given by w, where w satisfies $\delta_w < \bar{\tau}'_i(j) + w < \delta_{w+1}$. Thus the $q(i)$ given by equation (7) satisfies $q_i(j) = q'_i(j) + w$ where $\delta_w < q'_i(j) + w < \delta_{w+1}$. Therefore the $q_i(j)$, and hence also the $q(i)$, are the same as those produced by step ($\psi 4$) of the bijection.

It remains to show that $q(k)$ is the same as in our original bijection. But this is easy: we have $S(\sigma, \bar{\sigma}_k(j)) = |\{\, l \in [\bar{\sigma}_k(j)] : \sigma_l \leqslant k \,\}| = \bar{\sigma}_k(j)$ and $T(\tau, \bar{\tau}_k(j)) = |\{\, l \in [\bar{\tau}_k(j)] : \tau_l > k \,\}| = 0$, so $q(k) = \{\, \bar{\sigma}_k(j) : j \in [a_k] \,\} = \sigma^{-1}(k)$ as required.

Thus this really is another description of $\psi_{\mathbf{a}}$.

Next, given $p \in P_n$, we can calculate $\phi_n(p) = (s, t)$ in the following way. We already know that $t = \pi_n(p)$, the output of p. To find s, we use a modified method of parking cars, which we will call *Boston parking*. As in the regular scenario, the cars wish to park on our one-way street, arriving in the same order as before. But now, when a car arrives, it *insists* on parking in its preferred space. If this space is empty, it simply parks there. If not, it displaces the car currently there to the next space, possibly setting off a chain of displacements until some car is pushed into an empty space or beyond the end of the row of spaces. A function $p : [n] \to [n]$ is called a *Boston parking function* if no car is displaced beyond the n-th space. It is trivial to check that a function is a Boston parking function if and only if it is a (normal) parking function, as at each step during the parking process, the same space is filled, albeit with a possibly different car. (The name is indicative of the perceived standards of driving etiquette in Boston; the legal aspects of this algorithm will be left to those better versed in that subject!)

As an example, consider the parking function 3, 1, 4, 4, 3, 2 in P_6. Car 1 parks in space 3. Then car 2 parks in space 1 and car 3 parks in space 4. When car 4 arrives, it pushes car 3 over to space 5 and parks in space 4. Subsequently, car 5 pushes cars 1, 3 and 4 along one space, parking itself in space 3. Finally, car 6 parks in space 2, which was still empty. The permutation of Boston-parked cars is 265143. Under the usual rules for parking cars, the permutation obtained is 261345. Therefore, $\phi_6(314432) = (265143, 261345)$.

This alternative description of ϕ_n can easily be extended to the valet functions

and multiset case. Here, each valet parks each of his cars following the Boston parking rules. However, unlike normal parking, the output here does depend upon the ordering of each $p(i)$. We require that the elements of each $p(i)$ are ordered in increasing order so that, for example, the cars of valet k end up parked in the spaces given by $p(k)$.

The proof that this bijection is the same as ϕ_n or $\phi_{\mathbf{a}}$ is then straightforward by induction, once we note that the breakpoints of Boston parking functions are identical to those of normal parking functions, and that $d_w - w$ is a breakpoint of p' for each w.

10 Tree inversions

Using the alternative description of the bijection ϕ_n, we can give an interpretation for allowable pairs of the inversion enumerator for trees, $I_n(x)$, which was first described by Mallows and Riordan [15]. An *inversion* in a rooted labelled tree is a pair (b, a) with $b > a$ for which the (unique) path from the root to vertex a passes through b. The coefficient of x^k in $I_n(x)$ is the number of trees on $[n]_0$ rooted at 0 with k inversions.

Kreweras [13] used his bijection between parking functions on $[n]$ and labelled trees on $[n]_0$ to prove that the coefficient of x^k in $I_n(x)$ is the number of parking functions on $[n]$ with k probes. (See section 3 above for the definition of a probe.) To interpret $I_n(x)$ for allowable pairs, we define an *inversion* of an allowable pair (σ, τ) to be a pair $(b, a) \in [n] \times [n]$ with $b > a$, where b appears before a in σ but after a in τ. It follows that the number of inversions of (σ, τ) is the number of inversions of σ (defined in the usual sense for a permutation) minus the number of inversions of τ. We show that our bijections ϕ_n and ψ_n map parking functions with k probes to allowable pairs with k inversions and vice versa.

Theorem 10.1. *The map ψ_n maps allowable pairs with k inversions to parking functions with k probes.*

Proof. Let $p = \psi_n(\sigma, \tau)$ and denote the number of probes of car i by $k(i)$. We prove the theorem by showing that for each i, the number of inversions of (σ, τ) of the form (i, j) is equal to $k(i)$. We use our alternative description of ψ_n in this proof.

We say that j moved after i if j appears before i in σ, but after i in τ; similarly, we say that j moved before i if j appears after i in σ, but before i in τ. It is clear that if j moved after i, then $j > i$, and if j moved before i, then $j < i$.

Given $(\sigma, \tau) \in Q_n$, note that

$$\begin{aligned}\tau^{-1}(i) = {} & |\{\, j \in [n] : j > i \text{ and } j \text{ is before } i \text{ in } \sigma \,\}| \\ & - |\{\, j \in [n] : j > i \text{ and } j \text{ moved after } i \,\}| \\ & + |\{\, j \in [n] : j = i, \text{ or } j < i \text{ and } j \text{ is before } i \text{ in } \sigma \,\}| \\ & + |\{\, j \in [n] : j < i \text{ and } j \text{ moved before } i \,\}|.\end{aligned}$$

From the results of section 9 above, we have $p(i) = S(\sigma, \sigma^{-1}(i)) + T(\tau, \tau^{-1}(i))$. By some simple manipulations, we see that

$$\begin{aligned}S(\sigma, \sigma^{-1}(i)) &= |\{\, l \in [\sigma^{-1}(i)] : \sigma_l \leqslant i \,\}| \\ &= |\{\, j \in [n] : j = i, \text{ or } j < i \text{ and } j \text{ is before } i \text{ in } \sigma \,\}|\end{aligned}$$

and

$$\begin{aligned}T(\tau, \tau^{-1}(i)) &= |\{\, l \in [\tau^{-1}(i)] : \tau_l > i \,\}| \\ &= |\{\, j \in [n] : j > i \text{ and } j \text{ is before } i \text{ in } \tau \,\}| \\ &= |\{\, j \in [n] : j > i \text{ and } j \text{ is before } i \text{ in } \sigma \,\}| \\ &\qquad - |\{\, j \in [n] : j > i \text{ and } j \text{ moved after } i \,\}|,\end{aligned}$$

since anything greater than i and before it in τ must have been before it in σ also. We then deduce that

$$\begin{aligned}\tau^{-1}(i) &= S(\sigma, \sigma^{-1}(i)) + T(\tau, \tau^{-1}(i)) \\ &\qquad + |\{\, j \in [n] : j < i \text{ and } j \text{ moved before } i \,\}| \\ &= p(i) + |\{\, j \in [n] : j < i \text{ and } j \text{ moved before } i \,\}| \\ &= p(i) + |\{\, j \in [n] : (i, j) \text{ is an inversion of } (\sigma, \tau) \,\}|.\end{aligned}$$

Recalling from section 3 that $k(i) = \tau^{-1}(i) - p(i)$ for each i, we deduce that $k(i)$ equals the number of inversions of (σ, τ) of the form (i, j), and the theorem is proven. □

Corollary 10.2. *The coefficient of x^k in $I_n(x)$ equals the number of allowable pairs in Q_n with k inversions.* □

This can also be proved directly using the recurrence for $I_n(q)$ given by Mallows and Riordan [15, p. 94] and the fact that any $(\sigma, \tau) \in Q_n$ can be written in the form $(\gamma_{i,n}\delta, \alpha n \beta)$, where (γ, α) and (δ, β) are allowable pairs, and $\gamma_{i,n}$ means γ with n inserted in the i-th position. (Note that this is different from the meaning of $\gamma_{(i,m)}$ in Atkinson and Beals [1].)

11 Comparison with other bijections

It is worth considering whether our bijection is simply the composition of a known bijection between parking functions and trees together with one between trees and allowable pairs. However, considering the parking function 3, 1, 4, 1, 5, 9, 2, 6, 5 in P_9, with $\phi_9(314159265) = (472193856, 241357896)$, we find that the trees produced by the bijections described in section 3 (not considering the family described by Françon [6]) and those produced by the bijections described in section 4 are all distinct. Thus our bijection cannot be written as a composition of any pair of the previously known bijections. It would be interesting to find some natural bijections between trees and parking functions or allowable pairs which provide such a composition.

It would also be interesting to find extensions of some of the known bijections between parking functions and trees to bijections between valet functions and k-way trees, and especially to find ones which preserve some generalisation of inversions and probes.

Asymptotics of Linear Recurrences with Rational Coefficients

Xavier Gourdon - Bruno Salvy

Xavier.Gourdon@inria.fr - Bruno.Salvy@inria.fr

Abstract:

We give algorithms to compute the asymptotic expansion of solutions of linear recurrences with rational coefficients and rational initial conditions in polynomial time in the order of the recurrence.

Introduction

We investigate sequences defined by a recurrence of the form

$$a_k u_{n+k} + a_{k-1} u_{n+k-1} + \cdots + a_0 u_n = 0, \tag{1}$$

where the coefficients a_k and the initial conditions belong to $\mathbb{Q}$. This is probably the most simple type of recurrence one may encounter. Recurrences of this type are ubiquitous in many fields of applications (see [3] for numerous examples and references). Among the approximately 2300 sequences listed in Sloane's book [18], one can estimate that about 13% are of this type [13]. In the rest of this paper ``linear recurrence" always means ``linear recurrence with rational coefficients" and we shall refer to u_n as a ``linear recurrent sequence".

Surprisingly, some problems related to linear recurrences remain open, and specially problems related to effectivity. Our aim in this paper is to describe an algorithm that computes an asymptotic expansion of a sequence obeying (1) in polynomial time in the order k of the recurrence. It is quite simple to find the asymptotic expansion of Fibonacci numbers with traditional tools, but these tools break down when the order of the recurrence gets large. The algorithm we describe works without any limitation on the value of k or those of the coefficients.

Given a recurrence such as (1), one usually computes its general term as a sum of *exponential polynomials* of the form $\sum_{k=0}^{N} p_k n^k \lambda^n$,where λ is an algebraic number. In Section 1 we shall describe an algorithm computing the coefficients p_k *without factoring any polynomial*. This general term does not solve the problem of asymptotic behaviour. To form a proper asymptotic expansion one has to order the moduli of the algebraic numbers λ occurring in the general terms. The problem which will occupy most of this paper is: How can one perform such an ordering *exactly*, i.e. we prove that the algorithms we propose work on the whole class of recurrences (1). We shall use techniques from computer algebra to free ourselves from problems of ill-conditioning related to the use of floating-point values. The result is an algorithm which, given a positive integer p and a linear recurrence (1)

together with its initial conditions--or equivalently a rational function in $Q(x)$ (see below)--outputs the p first exponential polynomials of the asymptotic expansion of the solution u_n of (1) as n tends to infinity.

We describe two essentially different decision procedures to compute this asymptotic expansion. The first approach, purely algebraic, completely avoids factorizations. It is made expensive by the increase of degrees due to resultant computations. Currently this is the most natural computer algebra approach to the problem, and the most easily implemented. However, as soon as $p \geq 2$,its cost becomes potentially exponential in the order of the recurrence. The second approach, based on guaranteed numerical approximations remains in polynomial time in the order of the recurrence. Numerical approximations have long been banned from computer algebra because of the reluctance inherited from fixed precision routines. However, with the arbitrary precision provided by most computer algebra systems, we feel that it is time for floating point numbers to be rehabilitated in computer algebra.

The first step of the algorithm is to compute a suitable partial fraction decomposition of the generating function of u_n. Since factorization of polynomials is known to be polynomial-time but depressingly expensive, we shall avoid factorization and rely instead on a recent decomposition algorithm [2]. This is described in Section 1. In Section 2 and 3, we address the problem of comparing the moduli of the singularities (corresponding to the roots of the characteristic polynomial). As opposed to what happens usually in most algorithms involving algebraic numbers, we have to distinguish between roots of a given polynomial. A first method is described in Section 2, based on an algorithm [6] for comparing real algebraic numbers. At this stage, we can produce the desired asymptotic expansion. Section 3 describes a numerical alternative to the algebraic algorithms of Section 2, where we show how to get exact information from numerical values. We prove that this can be done with a cost that is lower than that of the algebraic method. In Section 4, we study optimizations that can be applied to subparts of our algorithm in practical cases. In particular we show there how rough numerical estimates can be used fruitfully. We conclude in Section 5 with a few examples taken from classical combinatorics.

1 Outline of the algorithm

1.1 Generating function

One can translate (1) into the rational generating function $\sum u_n z^n$ with $O(k^2)$ rational operations: the generating function of the sequence (1) is

$$\frac{\sum_{i=0}^{k} a_i \sum_{j=0}^{i-1} u_j z^{k-i+j}}{\sum_{i=0}^{k} a_{k-i} z^i}.$$

The reciprocal conversion is also easy.

From the asymptotic point of view, the generating function approach enables us to use tools from complex analysis, like residue computation, which prove very effective. Because of the low cost of the conversion from a linear recurrence to the generating function, from now on we shall be concerned with rational functions only.

Thus the input of our algorithm is a function $f \in Q(z)$ regular at the origin, together with a positive integer *p*, and its output consists of the first *p* terms of the asymptotic expansion of $[z^n]f(z)$--the *n*th Taylor coefficient of *f* at the origin--as *n* tends to infinity.

1.2 Exact formula

In this section, we derive an exact formula for $[z^n]f(z)$, based on a partial fraction decomposition that does not require factorization. This allows for both an efficient implementation and possible future extensions to rational functions with parameters or non-rational coefficients.

Algorithm 1 (Exact formula)

Let $f(z) = P(z)/Q(z) \in Q(z)$, with *P* and *Q* two relatively prime polynomials and $\deg(P) < \deg(Q)$. To compute $[z^n]f(z)$,

1. Compute $Q = D_1 D_2^2 \cdots D_n^n$ the square-free decomposition of *Q*. (Each D_i is a square-free polynomial.)
2. Using the decomposition algorithm [2], compute polynomials $P_{i,j} \in Q[z]$ such that

$$f(z) = \frac{P(z)}{Q(z)} = \sum_{i=1}^{n} \sum_{j=1}^{i} \sum_{D_i(\alpha)=0} \frac{P_{i,j}(\alpha)}{(z-\alpha)^j}, \tag{2}$$

   with $\deg(P_{i,j}) < \deg(D_i)$. This requires only gcd computations.
3. For each (*i*,*j*) such that $\gcd(P_{i,j}, D_i) \neq 1$, write $D_i = G_i H_i$, where $G_i = \gcd(P_{i,j}, D_i)$ and rewrite all terms in (2) involving the polynomial D_i as

$$\sum_{D_i(\alpha)=0} \frac{P_{i,j}(\alpha)}{(z-\alpha)^j} = \sum_{G_i(\alpha)=0} \frac{A_{i,j}(\alpha)}{(z-\alpha)^j} + \sum_{H_i(\alpha)=0} \frac{B_{i,j}(\alpha)}{(z-\alpha)^j}$$

   where $A_{i,j}$ and $B_{i,j}$ are obtained by Euclidian division of $P_{i,j}$ by G_i and H_i. Repeat this process until all gcd's are units. This gives a factorization of each D_i in the form $D_i = D_{i,1} \cdots D_{i,n_i}$ and the partial fraction decomposition has the form

$$f(z) = \sum_{i=1}^{n} \sum_{j=1}^{n_i} \sum_{k=1}^{i} \sum_{D_{i,j}(\alpha)=0} \frac{P_{i,j,k}(\alpha)}{(z-\alpha)^k}, \tag{3}$$

   each $P_{i,j,k}$ being a polynomial with rational coefficients, $\deg(P_{i,j,k}) < \deg(D_{i,j})$.
4.

From this we get the value of $[z^n]f(z)$:

$$[z^n]f(z) = \sum_{i=1}^{n} \sum_{j=1}^{n_i} \sum_{k=1}^{i} \sum_{D_{i,j}(\alpha)=0} \frac{(n+1)\cdots(n+k-1)}{(k-1)!} \cdot \frac{P_{i,j,k}(\alpha)}{\alpha^{n+k}}. \tag{4}$$

Step 1 is computed by repetitively differentiating and computing gcd's. Step 3 guarantees that each $P_{i,j,k}(\alpha)$ in (3) is non zero. Step 4 is a consequence of the usual series expansion of $(\alpha - z)^{-k}$ .It is clear that Algorithm 1 runs in polynomial time. We do not worry about its complexity since the following algorithms are much more expensive.

Example Let $f(z)$ be the following input

$$\frac{z^2+2}{(1-z)^2(1+z-2z^2-z^3-2z^5)}.$$

In this case, the square-free decomposition of the denominator Q of f is given by D_2=1-z, D_1=1+z-2z^2-z^3-2z^5 (note that D_1 is not irreducible). Step (2) of the algorithm then produces the following decomposition

$$f(z) = -\frac{1}{(1-z)^2} - \frac{14/3}{1-z} + \sum_{D_2(\alpha)=0} \frac{h(\alpha)}{\alpha - z},$$

where $h(\alpha) = (11530\alpha^4 - 7778\alpha^3 + 11325\alpha^2 + 3889\alpha - 8080)/93$.Since h and D_2 are relatively prime, Step 3 does not do anything, and then Step 4 produces the result:

$$[z^n]f(z) = -(n+1) - \frac{14}{3} + \sum_{D_2(\alpha)=0} h(\alpha)\alpha^{-n-1}.$$

To get an asymptotic expansion from this, we have to compare the moduli of the roots of D_2 and compare them to 1. This is addressed in the following sections.

1.3 Specification of the algorithm

As already mentioned, the asymptotic expansion is governed by the successive ``layers" of singularities of the rational function, sorted by increasing moduli. We shall need several ways to describe these moduli.

Notation 1

For $P(z) \in Q[z]$, we note $\rho_1(P) < \rho_2(P) < \cdots < \rho_k(P)$ the *distinct* moduli of the roots of P in increasing order. When there is no ambiguity, we simply denote these numbers ρ_m, $1 \le m \le k$. We also note $Z_m(P)$ the

set of zeroes of P whose modulus is $\rho_m(P)$, and $Z_m^+(P)$ the subset of $Z_m(P)$ whose elements have positive imaginary part.

We first state the form of the output on the example of $f(z)$ from our previous section. The first four terms of the asymptotic expansion of $[z^n]f(z)$ as given by our algorithm are

together with the following information $\rho_1 = \rho_1(D_2)$, $\rho_2 = \rho_2(D_2)$, $\rho_3 = 1$, $\rho_4 = \rho_3(D_2)$ and $|Z_3^+(D_2)|=1$. If requested, we can also give numerical approximations of the ρ_i and β.

All the features of the general case are present in this example. We now state precisely the specification of the algorithm, which we encourage the casual reader to skip. The input of our algorithm consists of $f(z) = P(z)/Q(z) \in Q(z)$ and an integer $p \geq 1$.The output is the following asymptotic expansion of $[z^n]f(z)$:

$$[z^n]f(z) = \sum_{\ell=1}^{p} \frac{c_\ell(n)}{\rho_\ell^n} + o\left(\frac{1}{\rho_p^n}\right), \tag{5}$$

where

$$c_\ell(n) = H_{\ell,0}(n) + (-1)^n H_{\ell,1}(n) + \sum_{j\geq 2} \sum_{\beta \in Z^+_{n_{\ell,j}}(D_{\ell,j})} \sum_k \frac{H_{\ell,j,k}(n)}{\rho_\ell^k} \cos[(n+k)\arg(\beta)]$$

and explicit values are given for the coefficients of the polynomials $H_{\ell,0}$ and $H_{\ell,1}$ (in $Q(\rho_\ell)[z]$), $D_{\ell,j}$ (in $Q[z]$) and $H_{\ell,j,k}$ (in $Q(\beta,\overline{\beta})[z]$), as well as for the number of elements of the Z^+ involved and a definition of ρ_ℓ either explicit or as $\rho_\ell = \rho_{\ell'}(D_{i,j})$ for some divisor of Q.

In practice, the program will be able to give numerical approximations of the moduli and the roots implicitly defined. Note that, because of the trigonometric functions involved in the coefficients, the expansion (5) is not of Poincaré type. Instead, we resort to the extended definition of Schmidt [16] (see also [7]), according to which an asymptotic expansion is a sum of the form

$$f(x) = \sum_{k=1}^{p} a_k(n) \cdot f_k(n) + r(n) \tag{6}$$

where as n tends to infinity $f_{k+1}(n) = o[f_k(n)]$,$(1 \leq k \leq p-1)$; $r(n) = o[f_p(n)]$; and $a_k(n)$ are bounded functions of n that do not tend to zero.

1.4 Main algorithm

Starting from the partial fraction decomposition (3), we need to order the moduli of the roots of the $D_{i,j}$ in (4) and find those roots that are purely real along with their signs. Our algorithm is based on the resolution of the two following computational problems.

Task 1 (Ordering the moduli)

Given $Q = \prod_{i,j} D_{i,j}^i$ a square-free decomposition of $Q \in Q[z]$ and p a non-negative integer, compute for each (i,j) and for each k, $1 \le k \le p$, the number of roots of $D_{i,j}$ of modulus $\rho_k(Q)$.

Task 2 (Real roots and their signs)

Given $P \in Q[z]$ a square-free polynomial and k a non-negative integer, compute the number $p \in \{0,1\}$ (resp. $n \in \{0,1\}$) of positive (resp. negative) real roots of P of modulus $\rho_k(P)$.

Most of the rest of this paper is devoted to algorithmic solutions to these tasks. Based on these, our main algorithm is as follows.

Algorithm 2 (Main algorithm)

Let $f(z) = P(z)/Q(z) \in Q(z)$ be a rational function, with $\deg(P) < \deg(Q)$. Let p be a non-negative integer. To compute the p first terms of the asymptotic expansion of the coefficients of $f(z)$,

1. Compute the partial fraction decomposition (3) by Algorithm 1.
2. Perform Task 1 to compute, for each (i,j) and for each $\ell, 1 \le \ell \le p$, the number $m_{i,j,\ell}$ of roots of $D_{i,j}$ of modulus $\rho_\ell = \rho_\ell(Q)$.
3. Select those terms in the expansion (3) for which $|\alpha| \in \{\rho_1, \ldots, \rho_p\}$, and rewrite (3) in the form

$$[z^n]f(z) = \sum_{\ell=1}^{p} \sum_{\substack{(i,j) \\ m_{i,j,\ell} \neq 0}} \sum_{\substack{D_{i,j}(\alpha)=0 \\ |\alpha|=\rho_\ell}} \sum_{k=1}^{i} \binom{n+k-1}{n} \frac{P_{i,j,k}(\alpha)}{\alpha^{n+k}} + o\left(\frac{1}{\rho_p^n}\right). \qquad (7)$$

4. Perform Task 2 to compute, for each (i,j) and for each ℓ, $1 \le \ell \le p$, the number $p_{i,j,\ell} \in \{0,1\}$ (resp. $n_{i,j,\ell}$) of positive (resp. negative) real roots of $D_{i,j}$ of modulus ρ_ℓ.
5. Rewrite relation (7) in the following form which is exactly the sought expansion (5):

2 The algebraic method

To complete our main algorithm, there still remains to exhibit algorithms that perform Tasks 1 and 2. We describe in this section how this can be done purely algebraically. We rely principally on three tools:

(1) a method to order real algebraic numbers due to M. Coste and M.-F. Roy [6], based on Sturm sequences;

(2) a resultant computation that, given two polynomials *P* and *Q* produces a polynomial $P \otimes Q$ whose roots are the pairwise products of the roots of *P* and *Q*. In particular the smallest non-negative real root of $P \otimes P$ is the square of $\rho_1(P)$ the smallest modulus of the roots of *P*;

(3) the Graeffe process: $\mathcal{G}_k(P)$ has for roots the *k*th power of the roots of *P*;

(4) the construction of a polynomial $\mathcal{P}_k(P)$ whose roots are the products $\alpha_{i_1} \cdots \alpha_{i_k}$ for $i_1 < \cdots < i_k$, the α_i's being the roots of *P*.

Using (1) and (2) we can compare the smallest moduli $\rho_1(P)$ and $\rho_1(Q)$ of the roots of two polynomials *P* and *Q*. This will be done in Section 2.1.1. Using (2) and (3), we can produce the polynomials $\mathcal{P}_k(P)$ the modulus of the smallest root of which is $|\alpha_1| \cdots |\alpha_k|$. This in turn enables us to compare any pair of moduli $\rho_i(P)$ and $\rho_j(Q)$ as will be shown in Section 2.1.2.

Note that other methods than Coste-Roy's algorithm are known to compare real algebraic numbers (see, e. g. [14]). One of the reasons for our choice is that the complexity of Coste-Roy's algorithm is known [15].

The polynomials mentioned above are computed by the formulas:

$$P \otimes Q(y) = \mathrm{Resultant}_z\left(P(z), z^{\deg(Q)} Q(y/z)\right), \quad \mathcal{G}_k(P)(z^k) = \prod_{j=0}^{k-1} P(e^{2ij\pi/k} z),$$

$$\forall k,\ 1 \le k \le n, \qquad [\mathcal{P}_k(P)]^k = \frac{\prod_{i=0}^{\lfloor (k-1)/2 \rfloor} \mathcal{P}_{k-(2i+1)}(P) \otimes \mathcal{G}_{2i+1}(P)}{\prod_{i=1}^{\lfloor k/2 \rfloor} \mathcal{P}_{k-2i}(P) \otimes \mathcal{G}_{2i}(P)}, \tag{8}$$

where by convention we set $\mathcal{P}_0(P)(z) = z - 1$. Apart from the last one, these polynomials are well known. That the last polynomial has the roots we expect is not difficult to check. All these polynomials have coefficients in the same field as *P* and *Q*.

2.1 Sorting the moduli

Given the polynomial *Q*, its factors $D_{i,j}$ and an integer *p*, we need to determine the number of roots of these factors which belong to $Z_k(Q)$, $1 \leq k \leq p$. To simplify our description, we first concentrate on the case *p*=1, corresponding to the first order estimate of the asymptotic expansion.

2.1.1 First order estimate

In this case (*p*=1), our task can be performed in polynomial time in the degree of *Q* by Algorithm 4 below (which is an extension of an algorithm communicated to us by M.-F. Roy, taking into account multiplicities). We first describe an algorithm to compute the number of roots of smallest modulus of a polynomial.

Algorithm 3 (Number of roots of smallest modulus)

Let $P \in Q[z]$.

1. Compute $P_1 P_2^2 \cdots P_n^n$ the square-free decomposition of $P \otimes P$.
2. Using Coste-Roy's algorithm, find i_0 such that P_{i_0} has the smallest non-negative real root.
3. Then $|Z_1(P)|=i_0$.

Proof. By construction, the smallest non-negative real root of $P \otimes P(z)$ is $\rho_1^2(P)$. Moreover, its order of multiplicity is the number of roots of *P* of smallest modulus. Computing square-free decompositions in Step 1 ensures that only one of the polynomials P_i has the smallest non negative real root. □

Algorithm 4 (Smallest moduli comparison)

Let *P* and $Q \in Q[X]$.

1. Compute P_{i_0} and Q_{j_0} as in Algorithm 3. Their smallest non-negative real roots are $\rho_1^2(P)$ and $\rho_1^2(Q)$.
2.

Applying Coste-Roy's algorithm to P_{i_0} and Q_{j_0}, compare $\rho_1^2(P)$ and $\rho_1^2(Q)$.

3. The number of roots of P (resp. Q) of modulus $\rho_1(PQ) = \min(\rho_1(P), \rho_1(Q))$ is given by i_0 (resp. j_0) if $\rho_1(PQ)$ is equal to $\rho_1(P)$ (resp. $\rho_1(Q)$), and 0 otherwise.

Proof. This algorithm works for the same reason as Algorithm 3. □

Applying this algorithm to the polynomials $D_{i,j}$ and Q gives the result we are after. Task 1 is therefore solved for p=1. From the complexity estimates in [15], it follows that the complexity of Algorithm 4 is $O(n^{20}(n + \log|P| + \log|Q|)^2)$, where $n = \max(\deg(P), \deg(Q))$ and $|P|$ denotes the sum of the absolute values of the coefficients of the monic polynomial P.

2.1.2 Ordering the *p* smallest moduli

We now want to compute for each k, $1 \le k \le p$ and each (i,j), the number of roots of $D_{i,j}$ of modulus $\rho_k(Q)$. Although all the $|\alpha_i|^2$ are roots of $P \otimes P$, Algorithm 4 does not generalize well because in general $P \otimes P$ has other non-negative real roots. We first give a generalization of Algorithm 3.

Algorithm 5 (Number of roots of a given modulus)

Let $P \in Q[z]$. Given an integer $q \ge 1$, and m_i=$|Z_i(P)|$, for $1 \le i \le q$, such that $m_1 + \cdots + m_q < \deg(P)$, to compute m_{q+1}=$|Z_{q+1}(P)|$, apply Algorithm 3 to the polynomial $\hat{P} = P_{m_1+\cdots+m_q+1}(P)$.

Proof. If $P(z) = \prod_i (z - \alpha_i)$, then by (8) we have $\hat{P} = \prod_{i_1<\cdots<i_{k+1}} (z - \alpha_{i_1} \cdots \alpha_{i_{k+1}})$, where $k = m_1 + m_2 + \cdots + m_q$. Since $|\alpha_1| = \cdots = |\alpha_{m_1}| < |\alpha_{m_1+1}| = \cdots = |\alpha_{m_1+m_2}| < \cdots < |\alpha_{k+1}| = \cdots = |\alpha_{k+m_{q+1}}| < \cdots$, the roots of smallest modulus of $\hat{P}(z)$ are $\alpha_{k+j} \prod_{i=1}^{k} \alpha_i$, $1 \le j \le m_{q+1}$. □

We can now give the generalization of Algorithm 4:

Algorithm 6 ((*q*+1)st smallest moduli comparison)

Let P and $Q \in Q[z]$. Given an integer $q \ge 1$ and m_i (resp. n_i) the number of roots of P (resp. Q) of modulus $\rho_i(PQ)$ for $1 \le i \le q$, such that $(m_1 + \cdots + m_q) + (n_1 + \cdots + n_q) < \deg(P) + \deg(Q)$, to find the number m_{r+1} (resp. n_{r+1}) of roots of P (resp. Q) of modulus $\rho_{q+1}(PQ)$,

-
If $m_1 + \cdots + m_q = \deg(P)$ (resp. $n_1 + \cdots + n_q = \deg(Q)$), then m_{q+1} (resp. n_{q+1}) is 0 and n_{q+1} (resp. m_{q+1}) is given by Algorithm 5.
-
Otherwise, these values are obtained by applying Algorithm 4 to $\tilde{P} = \mathcal{P}_{m_1+\cdots+m_q+1}(P) \otimes \mathcal{P}_{n_1+\cdots+n_q}(Q)$ and $\tilde{Q} = \mathcal{P}_{n_1+\cdots+n_q+1}(Q) \otimes \mathcal{P}_{m_1+\cdots+m_q}(P)$.

Proof. The first part is obvious. Denote by α_i the roots of P and by β_j the roots of Q. Let M_p be the number of roots of P whose modulus is the smallest $\rho_i(P)$ strictly greater than $\rho_q(PQ)$ and define similarly M_q. The second part follows from noticing that the polynomial $\tilde{Q}$ has been built so that it has M_q roots of smallest modulus, namely $\beta_k \prod_{i=1}^{m_1+\cdots+m_q} \alpha_i \prod_{j=1}^{n_1+\cdots+n_q} \beta_j$, $m_1 + \cdots + m_q + 1 \le k \le m_1 + \cdots + m_q + M_q$. Writing similarly the M_p roots of smallest modulus of $\tilde{P}$, one deduces the result. □

By induction on $p \ge 1$, using Algorithm 6, it is now easy to find for each (i,j) the number of roots of $D_{i,j}$ of modulus $\rho_1(Q), \rho_2(Q), \ldots \rho_p(Q)$ with $Q = \prod_{i,j} D_{i,j}^i$. Task 1 is thus solved.

Because $k = m_1 + \cdots + m_q$ can take any value between 1 and n, and since the degree of $\mathcal{P}_{m_1+\cdots+m_q}$ is $\binom{n}{k}$, Algorithm 6 runs in exponential time as soon as $p \ge 2$.

2.2 Finding the real roots

We now attack Task 2: given an integer k, $1 \le k \le p$, we want to find for each $D_{i,j}$ the number and the sign of the real roots of $D_{i,j}$ of modulus $\rho_k(Q)$. The following algorithm solves this problem.

Algorithm 7 (Real roots and their sign)

Let $P \in Q[z]$ be a square-free polynomial. Given an integer q, the number $m_i = |Z_i(P)|$ and the number $n_i \in \{0,1\}$ of real negative roots of P of modulus $\rho_i(P)$ for $1 \le i \le q$, with $m_1 + \cdots + m_q < \deg(P)$; to compute the number $p_{q+1} \in \{0,1\}$ (resp. n_{q+1}) of real positive (resp. negative) roots of P of modulus $\rho_{q+1}(P)$,

1.
Compute the polynomial $\hat{P} = \mathcal{P}_{m_1+\cdots+m_q+1}(P)$ and m_{q+1} by Algorithm 5.
2.

If m_{q+1} is odd, then P has exactly one real root of modulus ρ_{q+1}. To find its sign, compare the smallest positive real roots r of $\hat{P}(z)$ and ρ of $\hat{P}(-z)$ by Coste-Roy's algorithm. If $r > \rho$ or if $\hat{P}(z)$ has no positive real roots, then $p_{q+1} \equiv n_1 + \cdots + n_q \pmod 2$ and $n_{q+1} \equiv 1 + n_1 + \cdots + n_q \pmod 2$. Otherwise, either $\rho > r$ or $\hat{P}(-z)$ has no positive real roots, and then $p_{q+1} \equiv 1 + n_1 + \cdots + n_q \pmod 2$ and $n_{q+1} \equiv n_1 + \cdots + n_q \pmod 2$.

3. If m_{q+1} is even, compute $R(z^2) = \gcd(\hat{P}(z), \hat{P}(-z))$. If its degree is 0 then $p_{q+1}=n_{q+1}=0$, otherwise use Coste-Roy's algorithm to compare the smallest positive real roots r of R and ρ of $\hat{P} \otimes \hat{P}$. If R has no positive real roots, then $p_{q+1}=n_{q+1}=0$. If $r = \rho$ then $p_{q+1}=n_{q+1}=1$. Otherwise we must have $r > \rho$ and so $p_{q+1}=n_{q+1}=0$.

Proof. First, note that P being square-free, $p_{q+1} \in \{0,1\}$ and $n_{q+1} \in \{0,1\}$. Let $P = \prod_i (z - \alpha_i)$. The roots of P being either real or coming by pairs of conjugates, the number $M = \prod_{i=1}^{m_1+\cdots+m_q} \alpha_i$ is real and its sign is the sign of $(-1)^{n_1+\cdots+n_q}$. The polynomial $\hat{P}$ has m_{q+1} roots of smallest modulus, namely

$$M \cdot \alpha_i, \qquad rm_1 + \cdots + rm_q + 1 \le i \le rm_1 + \cdots + rm_q + rm_{q+1}, \tag{9}$$

so that if m_{q+1} is odd, then P has exactly one real root of modulus $\rho_{q+1}(P)$ and $\hat{P}(z)$ has only one real root of smallest modulus. Step 2 is now obvious.

When m_{q+1} is even, either $p_{q+1}=n_{q+1}=0$ or $p_{q+1}=n_{q+1}=1$ for conjugacy reasons. The roots of $R(z^2)$ are the roots α of $\hat{P}$ such that $-\alpha$ is also a root of $\hat{P}$. Thus if $\deg(R) = 0$ we cannot have $p_{q+1}=n_{q+1}=1$ because of (9). Otherwise, the smallest positive real root of R is the square of the smallest real root β of $\hat{P}$ such that $-\beta$ is also a root of $\hat{P}$. The smallest positive real root of $\hat{P} \otimes \hat{P}$ being the square of the moduli of the roots (9), Step 3 is now clear. □

For the same reasons as Algorithm 6, Algorithm 7 runs in exponential time as soon as $p \ge 2$.

Tasks 1 and 2 have been solved, and we are now able to give the asymptotic expansion of the coefficients of a rational function by Algorithm 2.

3 The numerical method

In the last section, we solved Tasks 1 and 2 using only algebraic tools, which is currently the most natural

solution to our problem from the computer algebra point of view. We shall now present an alternative method showing that numerical tools can be used reliably to perform our task in polynomial time. We only need to order the moduli of the roots of a polynomial and find which of them are real. Although there exists algorithms which achieve these tasks (for instance, we could use Graeffe's method to approximate the moduli of the roots of *Q*), it is cheaper to find directly all the roots of *Q* with a sufficiently sharp bound on their errors. Our numerical method will depend on a complex root finding algorithm, that we first describe briefly.

3.1 A root finding algorithm

We want to find the complex roots of a polynomial with rational coefficients with arbitrary precision. Numerous algorithms exist to achieve this task, but only few of them are reliable. Newton's method does not always converge; Traub and Jenkins' method [9], usually used for root finding in computer algebra systems, converges theoretically but it turns out that precision control is badly handled in practical implementations. Besides, its complexity is not known to be polynomial. We present here a root finding algorithm for which the precision control has been carefully studied. In the following, $|P| = \sum_i |a_i|$ denotes the norm of the polynomial $P = a_0 + \cdots + a_n z^n$.An immediate consequence of a theorem from [12] is the following result.

Proposition 1 (Pan)

Let $P \in C[z]$ be a monic polynomial, $n = \deg(P) > 0$. All the zeros of *P* can be computed with absolute error $\epsilon > 0$using $O\left[n^2 \log n(n \log(n) + \log(|P|/\epsilon))\right]$ arithmetic operations.

Unfortunately, the constant term in front of the time bound is very high and therefore the result seems to be only of theoretical importance. For instance, this algorithm relies on FFT techniques, which makes it efficient only for very large degrees.

3.2 Necessary precision

The reason why we can rely on numerical methods to solve our task is that two different roots of a polynomial with integer coefficients cannot be too close. The following result [11] makes this precise.

Proposition 2 (Mahler)

Let $P(z) = a_0 + a_1 z + \cdots + a_n z^n = a_n \prod_{i=1}^{n} (z - \alpha_i)$ be a polynomial of degree *n*>0 with integer coefficients. Then

$$\alpha_i \neq \alpha_j \quad \Longrightarrow \quad |\alpha_i - \alpha_j| \geq \sqrt{3} n^{-(n+2)/2} M(P)^{1-n},$$

where $M(P) = |a_n| \prod_{i=1}^{n} \max(1, |\alpha_i|)$.

From this we deduce the following theorem.

Theorem 1

Let *P*(*z*) be a polynomial with integer coefficients, $n = \deg(P) > 0$ and $\alpha_1, \ldots, \alpha_n$ its roots. Define $\kappa(P)$ to be the following quantity

$$\kappa(P) = \frac{\sqrt{3}}{2}[n(n+1)/2]^{-[n(n+1)/4+1]} \cdot M(P)^{-n(n^2+2n-1)/2}, \tag{10}$$

then $|\alpha_i| \neq |\alpha_j| \Longrightarrow \big||\alpha_i| - |\alpha_j|\big| \geq \kappa(P)$ and $|\Im(\alpha_i)|$ is either 0 or larger than $\kappa(P)$.

Proof. Let *C* be the leading coefficient of *P*. We first prove that the polynomial $Q(z) = C^{n+1}\prod_{i \leq j}(z - \alpha_i\alpha_j)$ has integer coefficients. We can suppose that the polynomial *P* is primitive, i.e. the gcd of its coefficients is 1. The polynomial $P \otimes P$ has for roots $\alpha_i\alpha_j$, $1 \leq i, j \leq n$, its coefficients are integers, and from classical results on the resultant algorithm, its leading coefficient is C^{2n}. Since the polynomial $\mathcal{G}_2(P)(z) = C^2\prod_i(z - \alpha_i^2)$ has integer coefficients, is primitive and divides $P \otimes P$, we deduce that the quotient $C^{2(n-1)}\prod_{i \neq j}(z - \alpha_i\alpha_j) = [C^{n-1}\prod_{i<j}(z - \alpha_i\alpha_j)]^2$ has integer coefficients and therefore, so has its square root. Finally *Q*(*z*) is the product of this polynomial by $\mathcal{G}_2(P)(z)$ which implies it has integer coefficients.

Next, let *x* and *y* be two distinct roots of *Q*. Since $M(Q) \leq M(P)^{n+1}$, Mahler's result applied to *Q* yields

$$|x - y| \geq \gamma = \sqrt{3}\,[n(n+1)/2]^{-[n(n+1)/4+1]}\, M(P)^{(n+1)(1-n(n+1)/2)}. \tag{11}$$

If α_i and α_j are roots of *P* with distinct moduli, then $|\alpha_i|^2$ and $|\alpha_j|^2$ are two distinct roots of *Q* and we have $\big||\alpha_i|^2 - |\alpha_j|^2\big| \geq \gamma$,hence $\big||\alpha_i| - |\alpha_j|\big| \geq \gamma/(|\alpha_i| + |\alpha_j|)$. As $|\alpha_i|$ and $|\alpha_j|$ are smaller than *M*(*P*), we finally deduce

$$\big||\alpha_i| - |\alpha_j|\big| \geq \frac{\gamma}{2M(P)} = \kappa(P).$$

The last part of the theorem can be derived analogously from the inequality $|\alpha_i\overline{\alpha_i} - \alpha_i^2| \geq \gamma$.□

A sharper lower bound on $|\Im(\alpha_i)|$ can be derived by considering only the polynomial *P*. We do not need this sharper bound since we need to compute the roots with an absolute error $\kappa(P)$ to sort their moduli.

3.3 Numerical algorithm

Using these results, we now give an algorithm which performs reliably Tasks 1 and 2 by purely numerical methods.

Algorithm 8 (Numerical)

Let $Q = \prod_{i,j} D_{i,j}^{i}$ be a square-free decomposition of the polynomial Q. Our aim is to compute, for each (i,j) and for each q the number of roots of $D_{i,j}$ of modulus $\rho_q(Q)$ and the number of these that are real along with their signs.

1. For each (i,j), compute the number $\gamma_{i,j} = \inf_{(k,\ell)\neq(i,j)} \gamma(D_{i,j} D_{k,\ell})$ where $\gamma(D_{i,j} D_{k,\ell})$ is defined by

$$\gamma(D_{i,j} D_{k,\ell}) = \frac{\sqrt{3}}{2}[d(d+1)/2]^{-[d(d+1)/4+1]} \cdot |Q|^{-d(d^2+2d-1)/2},$$

with $d = \deg(D_{i,j}) + \deg(D_{k,\ell})$. (Take $D_{k,\ell} = 1$ if $D_{i,j}$ is the only polynomial).

2. Using Pan's Algorithm [12], compute for each (i,j) the roots of the polynomial $D_{i,j}$ with an absolute error $\epsilon_{i,j} = \gamma_{i,j}/4$.

3. Let α be a root of $D_{i,j}$, β a root of $D_{k,\ell}$, $\hat{\alpha}$ and $\hat{\beta}$ their approximations found at Step 2. If $\left||\hat{\alpha}| - |\hat{\beta}|\right| < \gamma_{i,j}/2$, then $|\alpha| = |\beta|$, else the inequality between $|\alpha|$ and $|\beta|$ is given by the inequality between $|\hat{\alpha}|$ and $|\hat{\beta}|$. This way, all the moduli of the roots of Q are sorted.

4. Let α be a root of some $D_{i,j}$. If its approximation $\hat{\alpha}$ satisfies $|\Im(\hat{\alpha})| > \gamma_{i,j}/2$, then α is not real. Otherwise α is real, and its sign is given by the sign of $\Re(\hat{\alpha})$.

Proof. The validity of this algorithm results from Theorem 1 applied to each of the polynomials $D_{i,j} D_{k,\ell}$ and $D_{i,j}$, and from the inequalities:

$$(i,j) \neq (k,\ell) \implies M(D_{i,j} D_{k,\ell}) \leq M(Q) \leq |Q|,$$

$$\forall (i,j), \qquad M(D_{i,j}) \leq M(Q) \leq |Q|.$$

The inequality $M(Q) \leq |Q|$ is due to Mahler [10]. In Step 4, the fact that the sign of α (when α is real) is the

sign of $\Re(\hat{\alpha})$ results from the inequality $|\alpha| \geq \gamma_{i,j}$. (This latter inequality can be derived, for example, from the inequality $|\alpha| \geq 1/M(D_{i,j})$ which is easily proved).□

Proposition 3

Algorithm 8 runs in time $O\left[n^5 \log n \log |Q|\right]$ where *n* is the degree of *Q*.

Proof. Apply Theorem 1 to each of the polynomials $D_{i,j}$ with $\epsilon = \epsilon_{i,j}$.□

4 Optimizations

In the last two sections, we presented two methods that achieve Tasks 1 and 2. In practice, these two methods are awfully expensive. We present here another algorithm, which works on most of the rational functions, and which is much quicker. Another advantage of this new algorithm is that we can know whether it works or not. When it does not, then we can revert to one of the previous methods. This method is essentially numerical. We compute approximations of the roots of $Q(z)$ using a root finding algorithm, with a relatively crude absolute error (compared to what it was in the previous section). In most cases though, everything can be deduced from these estimates.

In [17], A. Schönhage gave a root finding algorithm and demonstrated the following result.

Theorem 2 (Schönhage)

Let $P \in C[z]$ be a monic polynomial, $n = \deg(P)$, and $\epsilon > 0$. We can compute *n* complex numbers $v_1, \cdots, v_n$ such that

$$|P - (z - v_1) \cdots (z - v_n)| < \epsilon \tag{12}$$

within the time bound of $O\left[(n^3 \log(n) + \log(|P|/\epsilon) n^2) \log(n \log(|P|/\epsilon)) \log\log(n \log(|P|/\epsilon))\right]$.

Although this bound seems slightly weaker than the previous one in Proposition 1, this one is in terms of bit complexity. Note that this algorithm does not approach directly the roots with an absolute precision ϵ. But from inequality (12) one can derive absolute error bounds on the roots of *P*. This algorithm was optimized by Gourdon [8] who implemented it in MAPLE; the program gives the right result in a reasonable time. We shall rely on this method to approximate roots of polynomials.

Let $Q(z) = \prod_{i,j} D_{i,j}^i$ be a square-free decomposition of the polynomial *Q*. Using Schönhage's algorithm, we compute for each (*i*,*j*) approximations $\hat{\alpha}_1, \cdots, \hat{\alpha}_p$ of the roots of $D_{i,j}$ such that $|D_{i,j}(z) - \prod_k (z - v_k)| < \epsilon$ (we

can assume $D_{i,j}$ monic), with $\epsilon = 10^{-n}$, where $n = \deg(Q)$.We have already seen that from this we can compute for each root α_k of $D_{i,j}$ an absolute error bound $\tau_k > 0$ such that $|\hat{\alpha}_k - \alpha_k| < \tau_k$. Suppose that the absolute bounds τ_k determine which roots are conjugates, which roots are real and what their sign is. To achieve Tasks 1 and 2, it then remains to compare the moduli of the non-conjugate roots. If again, the absolute error bounds τ_k make it possible to decide these comparisons, then we have finished. Otherwise, we have a certain number of couples of non-conjugates and distinct roots (α, β) of Q such that, if $\hat{\alpha}$ and $\hat{\beta}$ are the approximations of α and β found and τ and τ' the absolute error bounds found for these approximations, $\left||\hat{\alpha}| - |\hat{\beta}|\right| < \tau + \tau'$. We call these couples candidates. In this case, we use Algorithm 9 (see below) to test the equality of the moduli of the candidates. If all the candidates have the same modulus (this is often the case), then we have solved Tasks 1 and 2. Else, this algorithm failed and we use one of the previous methods discussed in Sections 2 and 3. The underlying idea is that it is very unlikely that two non-real roots of distinct moduli have the same argument.

Algorithm 9 (Equality of candidates)

Let $P = \prod_{i=1}^{n}(z - \alpha_i)$ be a square-free polynomial $\in Q[z]$.We are given approximations $\hat{\alpha}_i$,absolute error bounds τ_i such that $|\hat{\alpha}_i - \alpha_i| < \tau_i$,and for each *j*, $1 \le j \le n$, the number s_j of elements of the set $\Gamma_j = \{i, \left||\hat{\alpha}_i| - |\hat{\alpha}_j|\right| < \tau_i + \tau_j\}$.

1. Compute the square-free decomposition $P \otimes P = P_1 P_2^2 \cdots P_r^r$.
2. By Sturm sequences [19], compute for each *k* the number m_k of non-negative real roots of P_k.
3. If (a) $rm_1 + 2rm_2 + \cdots + rrm_r = n$, (b) for all (*i*,*j*), either $\Gamma_i \cap \Gamma_j =$ or $\Gamma_i = \Gamma_j$, (c) for all ℓ, $\ell r m_\ell = |\cup_{s_i = \ell} \Gamma_i|$,then for all *j*, all the elements of Γ_j have the same modulus.

Proof. Since $P \otimes P = \prod_{i,j}(z - \alpha_i \alpha_j)$, the $|\alpha_i|^2$ are roots of it. If $rm_1 + 2rm_2 + \cdots + rrm_r = n$, then these are its only positive roots. The result is now obvious.□

5 Examples

Denumerants

[4, p. 108]: the number of ways to make *n* francs with coins of 1, 2, 5, and 10 francs has for generating function

$$f(z) = \frac{1}{(1-z)(1-z^2)(1-z^5)(1-z^{10})}.$$

The ten singularities have the same modulus, but 1 being a singularity of order 4 is isolated in the decomposition (3) produced by Algorithm 1:

From this we deduce easily the first terms of the asymptotic expansion of $[z^n]f(z)$:

$$\frac{n^3}{600}+\frac{9n^2}{200}+\left(\frac{421}{1200}+\frac{(-1)^n}{80}-\sum_{\alpha\in Z_1^+(x^4+x^3+x^2+x+1)}\frac{\alpha^3+\overline{\alpha}^3+2(\alpha+\overline{\alpha})+4}{250}\cos[(n+2)\arg(\alpha)]\right)n+O(1).$$

Sum of powers of Fibonacci numbers

Since rational functions (when they are regular at infinity) are closed under Hadamard product, and the sum of a sequence is obtained by multiplying its generating function by 1/(1-*z*), many operations that can be applied to a linear recurrent sequence yield another linear recurrent sequence. We consider here $\sum_{k=1}^{n} F_k^p$. It is not difficult (tedious, rather) to show that the generating function of F_n^p has the following expression for fixed *p*:

where L_n denote the Lucas numbers. From this we construct the generating function of the sum of the tenth powers of the Fibonacci numbers, which we give in compact form to our algorithm:

$$\frac{z^9-87z^8-4047z^7+42186z^6+205690z^5+42186z^4-4047z^3-87z^2+z}{z^{11}-89z^{10}-4895z^9+83215z^8+582505z^7-1514513z^6-1514513z^5+582505z^4+83215z^3-4895z^2-89z+1}.$$

The first stage of the algorithm produces the decomposition $f(z)=\sum_{Q(\alpha)=0}P(\alpha)/(\alpha-z)$,where *Q* is the denominator of *f* and *P* is the following polynomial: This decomposition implies that all the singularities are simple poles. The next stage of the algorithm is to determine the number of real and complex roots of each modulus for the first moduli of the roots. This is done by a numerical evaluation of the roots with error bound 10^{-4} which shows that all the roots are real, and yields their signs. For instance, the three first terms of the expansion are

$$[z^n]f(z)=\frac{P(\rho_1)}{\rho_1^{n+1}}+(-1)^{n+1}\frac{P(-\rho_2)}{\rho_2^{n+1}}+\frac{P(\rho_3)}{\rho_3^{n+1}}+o\left(\frac{1}{\rho_3^n}\right),$$

with $\rho_1\simeq 0.00812$, $\rho_2\simeq 0.0212$and $\rho_3\simeq 0.0753$.

A large problem

This combinatorial problem was considered in [5]. Starting with 1, we write down a sequence of words by counting the number of contiguous identical digits in the previous word. Thus the second word is 11 because

there is one 1 in ``1''. Then we have two 1s, hence the third word is 21, and so on. The first few words are: 1, 11, 21, 1211, 111221, 312211, 13112221,...We then consider the sequence of lengths of these words: 1, 2, 2, 4, 6, 6, 6, 8,.... What happens is that this sequence is rational of degree 72! From the table in [5, pp. 177-178], it is possible to compute this fraction by solving a linear system. The numerator is found to be and the denominator is One of the nice theorems in [5] states that this denominator is actually independent of the starting string, provided it different from ``22''. Thus in the leading term of the asymptotic expansion, only the constant factor depends on the initial string.

Despite the large degree of this denominator, it turns out that the asymptotic expansion is not too difficult to find. For the sequence we consider, the decomposition of P/Q is

$$\frac{P(z)}{Q(z)} = R(z) + \sum_{Q(\alpha)=0} \frac{F(\alpha)}{z-\alpha},$$

where R is a polynomial induced by the first terms, and F is a polynomial of degree 71 with 250-digit rational coefficients. This means that all the singularities are simple poles. If one is only interested in the first order estimate, it then remains to determine the number of roots of smallest modulus. As expected since the coefficients of the generating function are positive, one of these roots is a positive real number. Using the program of X. Gourdon based on A. Schönhage's algorithm [8], we get that the two smallest moduli are approximately 0.767 and 0.861, with error bounds of the order 10^{-40}, which shows that the root of smallest modulus is alone (and therefore real). Thus, $[z^n]f(z) \sim F(\rho_1)\rho_1^{-n-1}$, $\rho_1 \simeq 0.767119$ and $F(\rho_1) \simeq 1.566$. All the 72 moduli belong to the interval (0.767,1.151), showing the need for caution with numerical estimates.

Conclusion

Algorithm 8 should not be implemented blindly. Although its complexity is polynomial, the constant implied in the $O()$ of Proposition 1 is very large. Thus in our last example above, the precision needed to compute the roots would be approximately 522000 digits. Instead, one should use this algorithm as an upper bound in an adaptative program based on a good numerical program such as [8] and Algorithm 9, increasing the precision if necessary.

Note also that we have never used the fact that in combinatorial contexts, the generating functions have only positive coefficients and thus by Pringsheim's theorem (see [20]), one of their singularities of smallest modulus is real positive, the other ones having arguments commensurable with π. The computation of the first-order estimate could take advantage of this extra information.

This very simple problem of linear recurrences with rational coefficients is not yet completely solved. It would be useful in practice to have some control over the periodicities that may occur in the asymptotic expansions. This problem is exemplified with the following generating function:

$$\frac{z^2+2z-2}{(1-2z^2)(1-z)^2},$$

or equivalently $u_n=2u_{n-1}+u_{n-2}-4u_{n-3}+2u_{n-4}$, $u_0=u_1=2,u_2=5,u_3=4$. The first few terms are 2, 2, 5, 4, 9, 6, 15, 8, 25, 10, ... The first-order asymptotic approximation obtained from this generating function is $(1+\cos n\pi)2^{n-1}+o(2^n)$. What happens is that although valid for all positive n, this expression reduces to $o(2^n)$ when n is odd. Better precision necessitates to look for further terms in the expansion. The ideal algorithm outputs a list of asymptotic expansions depending on arithmetic properties of n. Cancellation in this context is not a trivial problem. For instance, no algorithm is known to determine whether a linear recurrent sequence takes the value 0 for some index. It is known that when such a sequence cancels infinitely often, the indices where it cancels asymptotically form a finite union of arithmetic progressions that can be computed [1], but our problem is different since we are only concerned with indefinite cancellation of the dominant part, which does not satisfy a linear recurrence in general.

Abstract

We look at binary strings of length n which contain no odd run of zeros and express the total number of such strings, the number of zeros, the number of ones, the total number of runs, and the number of levels, rises and drops as functions of the Fibonacci and Lucas numbers and also give their generating functions. Furthermore, we look at the decimal value of the sum of all binary strings of length n without odd runs of zeros considered as base 2 representations of decimal numbers, which interestingly enough are congruent (mod 3) to either 0 or a particular Fibonacci number. We investigate the same questions for palindromic binary strings with no odd runs of zeros and obtain similar results, which generally have different forms for odd and even values of n.

Keywords: Binary Strings, Fibonacci numbers, Lucas numbers, Runs
A.M.S. Classification Number: 05A99

1 Introduction

Binary sequences are of great importance in computer science, where they encode instructions as well as decimal numbers using just the digits 0 and 1. Thus, most questions regarding binary sequences relate to their decimal values. However, one can also regard them as an "abstract" string of digits, very much like compositions. A composition of n is an ordered sequence of numbers whose sum is n, whereas a binary string of length n is an ordered sequence of n zeros and ones. Actually, there is a one-to-one correspondence between compositions of $n+1$ with odd summands and binary strings of length n without odd runs of zeros. The latter will be investigated in this article.

Alladi and Hoggatt [1] have studied compositions of n with summands 1 and 2, and found many connections to the Fibonacci sequence. Besides counting the number of such compositions, they looked at the number of occurrences of the individual summands and the number of levels (a summand followed by itself), rises (a summand followed by a larger summand) and drops (a summand followed by a smaller summand). Chinn et. al. [2, 3] have looked at these questions for compositions that allow all integers as summands, and Grimaldi has examined compositions without 1's [4] and compositions with odd summands [5], where he also looked at congruence questions.

In this paper we will explore similar questions for binary strings of length n without odd runs of zeros. Such a string is a sequence of n zeros and ones, where no odd number of zeros occur consecutively. A consecutive string (of maximal length) of either zeros or ones is called a *run*. Even though there is a one-to-one correspondence between the compositions of $n+1$ with odd summands and the binary strings of length n without odd runs of zeros, this one-to-one correspondence does not extend to quantities such as the number of levels, rises and drops.

We derive recurrence equations for several characteristics and express these quantities as functions of the Fibonacci and Lucas numbers, and also give their respective generating functions. In Section 2 we introduce our notation and state some basic facts about the Fibonacci and Lucas numbers that will be used in subsequent sections. Section 3 contains results on the total number of binary strings of length n without odd runs of zeros, the number of zeros and ones, the total number of runs, and the number of levels, rises and drops in all such strings. In addition, we show that the sum of the decimal values of all such binary strings of length n is congruent to 0 (mod 3) for even n, and F_{n+1} (mod 3) for odd n. Section 4 contains the corresponding results for palindromic binary strings of length n without odd runs of zeros. These are strings that read the same from left to right as from right to left. For the palindromic binary strings the results are similar

as for the binary strings, but there are always separate formulas for odd and even n.

2 Notation and general observations

a_n	=	the total number of binary strings of length n without odd runs of zeros
$a_{n,0}, a_{n,1}$	=	the total number of binary strings of length n without odd runs of zeros ending in 0 and 1, respectively
z_n	=	the total number of zeros in all binary strings of length n without odd runs of zeros
w_n	=	the total number of ones in all binary strings of length n without odd runs of zeros
t_n	=	the total number of runs in all binary strings of length n without odd runs of zeros
v_n	=	the value of the sum of the a_n strings considered as the base 2 representation of decimal (base 10) integers

We use the same variable names with a $\tilde{}$ to denote the corresponding quantities for palindromic binary strings. The notation $G_{a_n}(x)$ is used for the generating function $\sum_{n=1}^{\infty} a_n x^n$ of the sequence $\{a_n\}_1^\infty$. F_n and L_n denote the n^{th} Fibonacci and Lucas number, respectively. Recall that explicit formulas for the n^{th} Fibonacci and Lucas numbers are given by the Binet forms

$$F_n = \frac{\alpha^n - \beta^n}{\alpha - \beta} = \frac{\alpha^n - \beta^n}{\sqrt{5}} \quad \text{and} \quad L_n = \alpha^n + \beta^n,$$

where

$$\alpha = \frac{1+\sqrt{5}}{2} \text{ and } \beta = \frac{1-\sqrt{5}}{2},$$

and that the generating functions are

$$G_{F_n}(x) = \frac{x}{1-x-x^2} \quad \text{and} \quad G_{L_n}(x) = \frac{x+2x^2}{1-x-x^2}.$$

Note that the sequence for the Lucas numbers starts with L_1, which is reflected in the generating function G_{L_n} - it does not contain the term for $L_0 = 2$. We will also need the generating functions of $\{nF_n\}_1^\infty$, $\{nL_n\}_1^\infty$, $\{2^nF_n\}_1^\infty$, and $\{2^nL_n\}_1^\infty$.

Lemma 1 *1.* $G_{nF_n}(x) = \frac{x+x^3}{(1-x-x^2)^2}$ *and* $G_{nL_n}(x) = \frac{x+4x^2-x^3}{(1-x-x^2)^2}$.
2. $G_{2^nF_n}(x) = G_{F_n}(2x) = \frac{2x}{(1-2x-4x^2)}$ *and* $G_{2^nL_n}(x) = G_{L_n}(2x) = \frac{2x+8x^2}{(1-2x-4x^2)}$.

Proof: 1. $G_{nF_n}(x) = x \cdot \frac{d}{dx}G_{F_n}(x)$ and $G_{nL_n}(x) = x \cdot \frac{d}{dx}G_{L_n}(x)$. (See for example [8], Eq. (2.2.2), p. 34.)
2. $G_{2^nF_n}(x) = \sum_{n=1}^{\infty} 2^n F_n x^n = \sum_{n=1}^{\infty} F_n(2x)^n = G_{F_n}(2x)$. Likewise for $G_{2^nL_n}(x)$. □

Both binary strings and palindromic binary strings without odd runs of zero can be created recursively from those of a shorter length. We will use these creation methods to derive recursions for the quantities of interest. For easier readability, we will leave out the specification "without odd runs of zeros" in the remainder of this article.

3 Results for binary strings

To create a binary string of length n, we can either append a 1 to a binary string of length $n-1$, or the string 00 to a binary string of length $n-2$. We will refer to this process as the *creation process*. First we look at the total number of such binary strings, and also count how many of these end in either 0 or 1.

Theorem 2 *1.* $a_n = F_{n+1}$ *for* $n \geq 1$.
2. $a_{n,0} = F_{n-1}$ *and* $a_{n,1} = F_n$.

Proof: From the creation process it is clear that $a_n = a_{n-1} + a_{n-2}$, the Fibonacci recurrence. Since $a_1 = 1$ and $a_2 = 2$, it follows that $a_n = F_{n+1}$. In addition, $a_{n,0} = a_{n-2} = F_{n-1}$ and $a_{n,1} = a_{n-1} = F_n$. □

Next we look at the total number of zeros that occur in the binary strings of length n. We will express z_n as a function of the n^{th} Fibonacci and Lucas numbers.

Theorem 3 *1.* $z_n = \frac{2}{5}nL_n - \frac{2}{5}F_n$ *for* $n \geq 1$ *and* $G_{z_n}(x) = \frac{2x^2}{(1-x-x^2)^2}$.
2. $w_n = \frac{2}{5}F_n + \frac{1}{10}nL_n + \frac{1}{2}nF_n$ *for* $n \geq 1$ *and* $G_{w_n}(x) = \frac{x}{(1-x-x^2)^2}$.

Proof: 1. We will show this proof in more detail, as many of the later proofs use the same argument and will only be sketched. From the creation process we get the following recurrence relation:

$$z_n = z_{n-1} + z_{n-2} + 2a_{n-2} = z_{n-1} + z_{n-2} + 2\frac{\alpha^{n-1} - \beta^{n-1}}{\sqrt{5}}. \tag{1}$$

When appending the 1, no new zeros are created, while two additional zeros are created for each of the a_{n-2} binary strings of length $n-2$. This difference equation has a solution of the form $z_n = z_n^{(h)} + z_n^{(p)}$. Since the associated homogeneous recurrence is the Fibonacci recurrence, it follows that $z_n^{(h)} = c_1\alpha^n + c_2\beta^n$ for some constants c_1 and c_2. The inhomogeneous part contains powers of α and β, hence $z_n^{(p)} = An\alpha^n + Bn\beta^n$ for some constants A and B (see for example [6]). Substituting $z_n^{(p)}$ into Eq. (1) and collecting only the terms that contain powers of α results in the following equation:

$$An\alpha^n = A(n-1)\alpha^{n-1} + A(n-2)\alpha^{n-2} + (2/\sqrt{5})\alpha^{n-1}. \tag{2}$$

Since α is a root of the Fibonacci recurrence, $An(\alpha^n - \alpha^{n-1} - \alpha^{n-2}) = 0$, and Eq. (2) simplifies to

$$0 = -A\alpha^{n-1} - 2A\alpha^{n-2} + (2/\sqrt{5})\alpha^{n-1}.$$

Dividing by α^{n-1}, substituting the value for α and solving for A gives $A = 2/5$. A similar computation for the terms that contain powers of β results in $B = 2/5$. Thus,

$$z_n = c_1\alpha^n + c_2\beta^n + \frac{2}{5}n(\alpha^n + \beta^n).$$

Using the initial conditions $z_1 = 0$ and $z_2 = 2$ results in $c_1 = -\frac{2\sqrt{5}}{25}$ and $c_2 = \frac{2\sqrt{5}}{25}$. Expressing sums and differences of powers of α and β as Lucas and Fibonacci numbers gives the desired result. From the expression for z_n it follows that $G_{z_n}(x) = (2/5)G_{nL_n}(x) - (2/5)G_{F_n}(x) = \frac{2x^2}{(1-x-x^2)^2}$ after simplification.
2. This can be proved similarly to part 1. Alternatively, $w_n + z_n = nF_{n+1}$. Substituting the solution for z_n and using $L_n - F_n = 2F_{n-1}$ (which can be easily shown by induction, or follows readily from the Binet forms for F_n and L_n) gives the result for w_n. The generating function G_{w_n} is computed in the same manner as G_{z_n}. □

Another quantity of interest is the number of runs in all binary strings of length n. Again, this can be expressed as a function of the Fibonacci and Lucas numbers.

Theorem 4 *$t_n = \frac{1}{10}(5L_n - 3F_n) + \frac{n}{5}(5F_n - L_n)$ for $n \geq 1$ and $G_{t_n}(x) = \frac{x-x^4}{(1-x-x^2)^2}$.*

Proof: Again we utilize the creation process. When creating the binary strings of length n, an additional run is created for every binary string of length $n-1$ that ends in 0, and also for every binary string of length $n-2$ that ends in 1, i.e. $a_{n-1,0} + a_{n-2,1} = F_{n-2} + F_{n-2}$ additional runs. Thus,

$$t_n = t_{n-1} + t_{n-2} + 2F_{n-2}, \text{ for } n \geq 3 \text{ with } t_1 = 1, t_2 = 2.$$

With the same method as in Theorem 3, we get $A = (-1 + \sqrt{5})/5$ and $B = (-1 - \sqrt{5})/5$. Using the initial conditions gives $c_1 = \frac{25-3\sqrt{5}}{50}$ and $c_2 = \frac{25+3\sqrt{5}}{50}$. Substituting the constants and expressing sums and differences of powers of α and β as Lucas and Fibonacci numbers gives the desired result, which also holds for $n = 1$ and $n = 2$. G_{t_n} is computed as the corresponding linear combination of G_{L_n}, G_{F_n}, G_{nL_n} and G_{nF_n}. □

In connection with runs, we can look at the total number of rises (switch from a 0 run to a 1 run), levels (within a run) and drops (switch from a 1 run to a 0 run). Since there are $n-1$ rises, levels or drops per binary string of length n, we get that

$$r_n + l_n + d_n = (n-1)F_{n+1}. \tag{3}$$

Furthermore, since the reverse of a binary string without odd runs of zeros is also a binary string without odd runs of zeros, we have that $r_n = d_n$. Thus we only need to derive the recurrence for the number of levels.

Theorem 5 *$l_n = \frac{1}{10}(3F_n - 5L_n) + \frac{n}{10}(7L_n - 5F_n)$ for $n \geq 1$ and $G_{l_n}(x) = \frac{2x^2+x^4}{(1-x-x^2)^2}$.*

Proof: For $n \geq 3$, it follows from the creation process that

$$l_n = (l_{n-1} + a_{n-1,1}) + (l_{n-2} + 2a_{n-2,0} + a_{n-2,1})$$

because we get all the previous levels, plus one additional one whenever we append either a 1 to a sting of length $n-1$ that ends in 1, or a 00 to a string of length $n-2$ that ends in 1. Appending 00 to a string of length $n-2$ that ends in 0 gives rise to two additional levels. Using Theorem 2, we get

$$l_n = l_{n-1} + F_{n-1} + l_{n-2} + 2F_{n-3} + F_{n-2} = l_{n-1} + l_{n-2} + 3F_{n-3} + 2F_{n-2}.$$

This recurrence relation again has a solution of the form given in the proof of Theorem 3, and we get $A = (7-\sqrt{5})/10$ and $B = (7+\sqrt{5})/10$. Initial conditions $l_1 = 0$ and $l_2 = 2$ give $c_1 = -\frac{1}{2} + \frac{3\sqrt{5}}{50}$ and $c_2 = -\frac{1}{2} - \frac{3\sqrt{5}}{50}$. Collecting sums and differences of powers of α and β gives the desired result, which also holds for $n = 1$ and $n = 2$. The generating function is computed by simplifying the associated linear combination of the respective generating functions. □

Corollary 6 *$r_n = d_n = \frac{1}{2}[(n-1)F_{n+1} - \frac{1}{10}(3F_n - 5L_n) - \frac{n}{10}(7L_n - 5F_n)]$ for $n \geq 1$ and $G_{r_n}(x) = \frac{x^3}{(1-x-x^2)^2}$.*

Proof: The formula for r_n follows immediately from Eq. (3). Since $r_n = [(n-1)F_{n+1} - l_n]/2 = (n+1)F_{n+1}/2 - F_{n+1} - l_n/2$,we get

$$\begin{aligned} G_{r_n}(x) &= \frac{1}{2}\sum_{n=1}^{\infty}(n+1)F_{n+1}x^n - \sum_{n=1}^{\infty}F_{n+1}x^n - \frac{1}{2}\sum_{n=1}^{\infty}l_n x^n \\ &= \frac{1}{2x}\sum_{k=2}^{\infty}kF_k x^k - \frac{1}{x}\sum_{k=2}^{\infty}F_k x^k - \frac{1}{2}G_{l_n}(x) \\ &= \frac{1}{2x}[G_{nF_n}(x) - x] - \frac{1}{x}[G_{F_n}(x) - x] - \frac{1}{2}G_{l_n}(x) \\ &= \frac{x^3}{(1-x-x^2)^2}. \end{aligned}$$

□

Note that the generating function for r_n can be expressed as $G_{r_n}(x) = x(G_{F_n}(x))^2$, thus, the sequence for r_n is a shifted convolution of the Fibonacci sequence with itself.

Now we change focus a little and consider these stings as base 2 representations of decimal (base 10) integers. We will look at the sum of all the decimal values of the binary strings of length n, and look at their congruences mod 3. Instead of functions involving nL_n and nF_n we now get expressions that involve 2^nL_n and 2^nF_n.

Theorem 7 *$v_n = \frac{2^n}{11}(L_n + 7F_n) - \frac{1}{11}(L_n + 4F_n)$ for $n \geq 1$ and $G_{v_n}(x) = \frac{x}{(1-x-x^2)(1-2x-4x^2)}$.*

Proof: Again we look at the creation process. We now have to determine what effect appending a 1 or a 00 has on the decimal value. Appending a 1 shifts the string to the left, hence results in a multiplication of the decimal

value by 2, and then an addition of 1 from the appended 1. Appending 00 results in a shift to the left of two positions, hence results in multiplication of the decimal value by 4. As there are F_n binary strings of length $n-1$, we get the following recurrence:

$$v_n = 2v_{n-1} + F_n + 4v_{n-2}, \quad \text{with} \quad v_1 = 1 \text{ and } v_2 = 3.$$

In this case, the homogeneous recurrence relation has characteristic roots 2α and 2β. Thus, the general solution is of the form

$$v_n = c_1(2\alpha)^n + c_2(2\beta)^n + An\alpha^n + Bn\beta^n.$$

Now we proceed as in the proof of Theorem 3, which results in $A = -(5 + 4\sqrt{5})/55$ and $B = -(5 - 4\sqrt{5})/55$. Substituting the initial conditions and solving the resulting system of equations gives $c_1 = \frac{1}{11} + \frac{7\sqrt{5}}{55}$ and $c_2 = \frac{1}{11} - \frac{7\sqrt{5}}{55}$. Substituting these constants and grouping into sums and differences of powers of α and β gives the result for $n \geq 3$. However, this formula also holds for $n = 1$ and $n = 2$. The generating function is computed by taking the appropriate linear combination of the respective generating functions. □

Finally, we examine the following.

Theorem 8 *For even n, the decimal value of each individual binary string of length n is congruent to 0 (mod 3), and $v_n \equiv 0$ (mod 3) also. For odd n, the decimal value of each individual binary string of length n is congruent to 1 (mod 3), and $v_n \equiv F_{n+1}$ (mod 3).*

Proof: We show the congruence for the individual strings by induction. The result for v_n follows because there are F_{n+1} binary strings of length n. For $n = 1$, there is only one string, 1, whose value is congruent to 1 (mod 3). For $n = 2$, the only strings are 11 and 00 with decimal values of 3 and 0, respectively, and both of these are congruent to 0 (mod 3). We now assume the induction hypothesis and use the creation process. If we append a 1, then this corresponds to multiplication by 2 of the value of the string of length $n-1$ and addition of 1. Thus the string's value is (using the hypothesis) congruent to 2·1 (mod 3) + 1 (mod 3) $\equiv$ 0 (mod 3) for even n, and congruent to 2·0 (mod 3) + 1 (mod 3) $\equiv$1 (mod 3) if n is odd. If we append 00, then this corresponds to multiplication by $4 \equiv 1$ (mod 3) of the value for a string of length $n-2$ and the result follows. □

4 Results for palindromic binary strings without odd runs of zeros

We now derive the corresponding results for palindromic binary strings. Palindromic binary strings of length n can be created by either attaching a 1 to both ends of a palindromic binary string of length $n-2$ or 00 to both ends of a palindromic binary string of length $n-4$. We will refer to this way of creating palindromic binary strings as the *palindromic creation process.*

For odd n, we note that the middle digit must be a 1, as otherwise there would be an odd run of zeros in the center. Thus, a palindromic binary string of length $2k+1$ can also be thought of as a binary string of length k, concatenated with a 1, concatenated with the reverse of the binary string. This viewpoint will be referred to as the *explicit representation.*

Theorem 9 *1.* $\tilde{a}_{2k} = F_{k+2}$ *for* $k \geq 1$ *and* $\tilde{a}_{2k+1} = F_{k+1}$ *for* $k \geq 0$ *and* $G_{\tilde{a}_n}(x) = \frac{x+2x^2+x^4}{(1-x^2-x^4)}$.

2. $\tilde{a}_{n,0} = \tilde{a}_{n-4}$ *and* $\tilde{a}_{n,1} = \tilde{a}_{n-2}$.

Proof: 1. If $n = 2k$, then from the palindromic creation process we get

$$\tilde{a}_{2k} = \tilde{a}_{2k-2} + \tilde{a}_{2k-4} = \tilde{a}_{2(k-1)} + \tilde{a}_{2(k-2)},$$

which is once more the Fibonacci recurrence. Using the initial values, $\tilde{a}_2 = \tilde{a}_{2\cdot 1} = 2$ (for the strings 00 and 11), and $\tilde{a}_4 = \tilde{a}_{2\cdot 2} = 3$ (for the strings 0000, 1001, and 1111) gives that $\tilde{a}_{2k} = F_{k+2}$. If $n = 2k+1$, then the explicit representation gives $\tilde{a}_{2k+1} = a_k = F_{k+1}$, where the second equality follows from Theorem 2. For the generating function, we have to split up the series into odd and even terms, use the result of part 1, re-index, and simplify:

$$\begin{aligned} G_{\tilde{a}_n}(x) &= \sum_{k=0}^{\infty} \tilde{a}_{2k+1}x^{2k+1} + \sum_{k=1}^{\infty} \tilde{a}_{2k}x^{2k} = \sum_{k=0}^{\infty} F_{k+1}x^{2k+1} + \sum_{k=1}^{\infty} F_{k+2}x^{2k} \\ &= \frac{1}{x}\sum_{l=1}^{\infty} \tilde{F}_l(x^2)^l + \frac{1}{x^4}\sum_{l=3}^{\infty} \tilde{F}_l(x^2)^l \\ &= \frac{1}{x}G_{F_n}(x^2) + \frac{1}{x^4}[G_{F_n}(x^2) - (x^2) - (x^2)^2] = \frac{x+2x^2+x^4}{(1-x^2-x^4)}. \end{aligned}$$

2. This follows from the palindromic creation process. □

Next we look at the number of zeros and ones in the palindromic binary strings of length n.

Theorem 10 *1.* $\tilde{z}_{2k} = -\frac{2}{5}F_k + 2kF_{k-1} + \frac{6}{5}kL_{k-1}$ *for* $k \geq 2$*;* $\tilde{z}_2 = 2$ *and* $\tilde{z}_{2k+1} = -\frac{4}{5}F_k + \frac{4}{5}kL_k$ *for* $k \geq 0$.
2. $\tilde{w}_{2k} = \frac{2}{5}F_k + 4kF_k - \frac{6}{5}kL_{k-1}$ *for* $k \geq 1$ *and* $\tilde{w}_{2k+1} = (2k+1)F_{k+1} + \frac{4}{5}F_k - \frac{4}{5}kL_k$ *for* $k \geq 0$.
3. $G_{\tilde{z}_n}(x) = \frac{2(x^2+x^4+2x^5+x^6)}{(1-x^2-x^4)^2}$ *and* $G_{\tilde{w}_n}(x) = \frac{x+2x^2+x^3+2x^4-x^5}{(1-x^2-x^4)^2}$.

Proof: 1. From the palindromic creation process, we get the following recursion:

$$\tilde{z}_{2k} = \tilde{z}_{2k-2} + \tilde{z}_{2k-4} + 4\tilde{a}_{2k-4} \text{ for } k \geq 3,$$

where the first two terms account for the "old" zeros, and the last term accounts for the four additional zeros for each palindromic binary string of length $n-4$. Defining $x_k = \tilde{z}_{2k}$ and using Theorem 9, part 1, we get

$$x_k = x_{k-1} + x_{k-2} + 4F_k.$$

Following the steps in the proof of Theorem 3 and using the initial conditions $x_1 = \tilde{z}_2 = 2$ and $x_2 = \tilde{z}_4 = 6$, we get the result for $x_k = \tilde{z}_{2k}$. Note that the formula also holds for $k = 2$.
If $n = 2k+1$, we get $\tilde{z}_{2k+1} = 2z_k$ from the explicit representation for $k \geq 1$. The result then follows from Theorem 3 and also holds for $k = 0$.
2. This follows from $\tilde{z}_n + \tilde{w}_n = n \cdot \tilde{a}_n$.
3. To compute $G_{\tilde{z}_n}(x)$, we split the series into odd and even terms, substitute the formulas from part 1 and adjust for the fact that the formula for even n only holds for $n \geq 4$:

$$\begin{aligned}
G_{\tilde{z}_n}(x) &= \sum_{l=0}^{\infty} \tilde{z}_{2l+1}x^{2l+1} + \sum_{l=1}^{\infty} \tilde{z}_{2l}x^{2l} = x\sum_{l=0}^{\infty} \tilde{z}_{2l+1}(x^2)^l + \sum_{l=1}^{\infty} \tilde{z}_{2l}(x^2)^l \\
&= x(-\frac{4}{5}G_{F_n}(x^2) + \frac{4}{5}G_{nL_n}(x^2)) \\
&\quad + \sum_{l=1}^{\infty}(-\frac{2}{5}F_l + 2lF_{l-1} + \frac{6}{5}lL_{l-1})(x^2)^l + \frac{12}{5}x^2 \\
&= x(-\frac{4}{5}G_{F_n}(x^2) + \frac{4}{5}G_{nL_n}(x^2)) - \frac{2}{5}G_{F_n}(x^2) \\
&\quad + 2x^2\sum_{l=1}^{\infty}((l-1)F_{l-1} + F_{l-1})(x^2)^{l-1} \\
&\quad + \frac{6}{5}x^2\sum_{l=1}^{\infty}((l-1)L_{l-1} + L_{l-1})(x^2)^{l-1} + \frac{12}{5}x^2.
\end{aligned}$$

Changing the summation index, replacing the series by the corresponding generating function, and then simplifying, gives the result.

Since $\tilde{w}_n = n \cdot \tilde{a}_n - \tilde{z}_n$, we get that $G_{\tilde{w}_n}(x) = x \cdot \frac{d}{dx} G_{\tilde{a}_n}(x) - G_{\tilde{z}_n}(x)$ (See for example [8], Eq. (2.2.2), p. 34.) □

As with the binary strings, we can ask about the total number of runs of zeros and ones in the palindromic binary strings of length n.

Theorem 11 *For $k \geq 1$, $\tilde{t}_{2k} = \frac{4}{5} k L_k - \frac{1}{10}(17F_k + 5L_k)$ and $\tilde{t}_{2k+1} = \frac{1}{10}(15L_k - 21F_k) + \frac{k}{5}(10F_k - 2L_k)$, with $\tilde{t}_1 = 1$ and generating function $G_{\tilde{t}_n}(x) = \frac{1+x^3+2x^5+x^6+2x^8-3x^9}{(1-x^2-x^4)^2}$.*

Proof: With an argument similar to that in Theorem 4, and using Theorem 9, we get

$$\begin{aligned} \tilde{t}_n &= \tilde{t}_{n-2} + \tilde{t}_{n-4} + 2(\tilde{a}_{n-2,0} + \tilde{a}_{n-4,1}) \\ &= \tilde{t}_{n-2} + \tilde{t}_{n-4} + \begin{cases} 4F_{k-1} & \text{for } n = 2k \\ 4F_{k-2} & \text{for } n = 2k+1 \end{cases}, \end{aligned}$$

where the factor of two for the additional runs comes from the fact that we append on both sides. Making the substitution $x_k = \tilde{t}_{2k}$ or $x_k = \tilde{t}_{2k+1}$, we can now proceed as in the proof of Theorem 3. For $n = 2k$, we get $A = B = 4/5$, and using the initial conditions $\tilde{t}_2 = x_1 = 2$, $\tilde{t}_4 = x_2 = 5$ results in $c_1 = -\frac{1}{2} + \frac{17}{50}\sqrt{5}$ and $c_2 = -\frac{1}{2} - \frac{17}{50}\sqrt{5}$. For $n = 2k+1$, we get $A = \frac{2}{5}(\sqrt{5}-1)$ and $B = -\frac{2}{5}(\sqrt{5}+1)$, and using the initial conditions $\tilde{t}_3 = x_1 = 1$, $\tilde{t}_5 = x_2 = 4$ results in $c_1 = \frac{3}{50}(25-7\sqrt{5})$ and $c_2 = \frac{3}{50}(25+7\sqrt{5})$. The generating function is computed as in the proof of Theorem 10, with an adjustment for the value of $\tilde{t}_1$. □

We now look at the total number of rises, levels and drops in all palindromic binary strings of length n. As before, we have $\tilde{r}_n = \tilde{d}_n$ and

$$\tilde{r}_n + \tilde{l}_n + \tilde{d}_n = (n-1)\tilde{a}_n = \begin{cases} (n-1)F_{k+2} & \text{for } n = 2k \\ (n-1)F_{k+1} & \text{for } n = 2k+1 \end{cases}. \qquad (4)$$

Theorem 12 *For $k \geq 1$, $\tilde{l}_{2k} = \frac{1}{10}(5L_k - 17F_k) + \frac{k}{5}(L_k + 15F_k)$ and $\tilde{l}_{2k+1} = \frac{1}{5}(13F_k - 5L_k) + \frac{k}{5}(7L_k - 5F_k)$, with $\tilde{l}_1 = 0$ and generating function $G_{\tilde{l}_n}(x) = \frac{x^2(2+2x+3x^2+2x^3+3x^4-2x^5-x^6+2x^7)}{(1-x^2-x^4)^2}$.*

Proof: Similar to the proof of Theorem 5, and with the additional factors of 2 as in the proof of Theorem 11, we get for $n \geq 5$:

$$\tilde{l}_n = (\tilde{l}_{n-2} + 2\tilde{a}_{n-2,1}) + (\tilde{l}_{n-4} + 4\tilde{a}_{n-4,0} + 2\tilde{a}_{n-4,1}).$$

Using Theorem 9 and the Fibonacci recurrence, this reduces to

$$\tilde{l}_n = \tilde{l}_{n-2} + \tilde{l}_{n-4} + \begin{cases} 4F_k + 2F_{k-2} & \text{for } n = 2k \\ 4F_{k-1} + 2F_{k-3} & \text{for } n = 2k+1 \end{cases}.$$

Making the substitution $x_k = \tilde{l}_{2k}$ or $x_k = \tilde{l}_{2k+1}$, we can now proceed as in the proof of Theorem 3. For $n = 2k$, we get $A = \frac{4(4+\sqrt{5})}{5(1+\sqrt{5})}$ and $B = \frac{-4(4-\sqrt{5})}{5(1-\sqrt{5})}$. Using the initial conditions $\tilde{l}_2 = x_1 = 2$, $\tilde{l}_4 = x_2 = 7$ results in $c_1 = \frac{1}{2} - \frac{17}{50}\sqrt{5}$ and $c_2 = \frac{1}{2} + \frac{17}{50}\sqrt{5}$. For $n = 2k+1$, we get $A = \frac{4(4+\sqrt{5})}{5(3+\sqrt{5})}$ and $B = \frac{4(4-\sqrt{5})}{5(3-\sqrt{5})}$. Using the initial conditions $\tilde{l}_3 = x_1 = 2$, $\tilde{l}_5 = x_2 = 6$ results in $c_1 = -1 + \frac{13}{25}\sqrt{5}$ and $c_2 = -1 - \frac{13}{25}\sqrt{5}$, which gives the result for $\tilde{l}_n$ for $n \geq 5$. Note that the formula also holds for $2 \leq n \leq 4$. The generating function $G_{\tilde{l}_n}(x)$ is computed as

$$\begin{aligned} G_{\tilde{l}_n}(x) &= x\left(\frac{13}{5}G_{F_n}(x^2) - G_{L_n}(x^2) + \frac{7}{5}G_{nL_n}(x^2) - G_{nF_n}(x^2)\right) \\ &\quad + \frac{1}{2}G_{L_n}(x^2) - \frac{17}{10}G_{F_n}(x^2) + \frac{1}{5}G_{nL_n}(x^2) + 3G_{nF_n}(x^2) \end{aligned}$$

and simplification yields the result. □

Corollary 13 *For $k \geq 1$, $\tilde{r}_{2k} = \tilde{d}_{2k} = \frac{1}{2}(2k-1)F_{k+2} - \frac{1}{20}(5L_k - 17F_k) - \frac{k}{10}(L_k + 15F_k)$ and $\tilde{r}_{2k+1} = \tilde{d}_{2k+1} = kF_{k+1} - \frac{1}{10}(13F_k - 5L_k) - \frac{k}{10}(7L_k - 5F_k)$, with $\tilde{r}_1 = 0$ and generating function $G_{\tilde{r}_n}(x) = \frac{x^4(1+x+x^2+x^3+x^4-x^5)}{(1-x^2-x^4)^2}$.*

Proof: Follows immediately from Theorem 12 and Eq. (4). Since $\tilde{r}_n = \frac{1}{2}(n\tilde{a}_n - \tilde{a}_n - \tilde{l}_n)$, the generating function can be computed as $G_{\tilde{r}_n}(x) = \frac{1}{2}[x \cdot \frac{d}{dx}G_{\tilde{a}_n}(x) - G_{\tilde{a}_n}(x) - G_{\tilde{l}_n}(x)]$. □

Finally, we look at the palindromic binary strings as base 2 representations of decimal integers. First we give a formula for the sum of all the decimal values of the palindromic binary strings of length n.

Theorem 14 *For $k \geq 1$, $\tilde{v}_{2k} = \frac{3}{22}2^k(F_k - L_k) + \frac{2}{11}4^k(2L_k + 3F_k) - \frac{1}{22}(5L_k + 9F_k)$ and $\tilde{v}_{2k+1} = \frac{9}{22}2^k(F_k + L_k) + \frac{2}{11}4^k(L_k + 7F_k) - \frac{1}{11}(L_k + 4F_k)$ with*

$\tilde{v}_1 = 1$ *and generating function*
$G_{\tilde{v}_n}(x) = \frac{x(1+3x+3x^3-21x^4-30x^5-24x^7+16x^8)}{(1-x^2-x^4)(1-2x^2-4x^4)(1-4x^2-16x^4)}$.

Proof: We proceed as in the proof of Theorem 7, except that now we also have to take into account the changes on the left side. When appending a 1 to the right and left sides of a palindromic binary string of length $n-2$, we get an additional 2^{n-1} from the left side. When appending 00 on the right and left sides of a palindromic binary string of length $n-2$, the left side does not contribute anything to the decimal value. Thus, we get the following recursion for $n \geq 5$:

$$\tilde{v}_n = (2\tilde{v}_{n-2} + \tilde{a}_{n-2} + 2^{n-1} \cdot \tilde{a}_{n-2}) + 4 \cdot \tilde{v}_{n-4},$$

with initial conditions $\tilde{v}_1 = 1$, $\tilde{v}_2 = 3$, $\tilde{v}_3 = 7$, and $\tilde{v}_4 = 24$. Using Theorem 9, this reduces to

$$\tilde{v}_n = 2\tilde{v}_{n-2} + 4\tilde{v}_{n-4} + (2^{n-1}+1) \cdot \begin{cases} F_{k+1} & \text{for } n = 2k \\ F_k & \text{for } n = 2k+1 \end{cases}.$$

Making the usual substitution $x_k = \tilde{v}_{2k}$ and $x_k = \tilde{v}_{2k+1}$, respectively, we get a general solution of the form

$$x_k = c_1(2\alpha)^k + c_2(2\beta)^k + A\alpha^k + B\beta^k + C(4\alpha)^k + D(4\beta)^k$$

due to the factor of 2^{n-1} for the Fibonacci term. We proceed as in the proof of Theorem 3. For $n = 2k$, we get $A = -\frac{25+9\sqrt{5}}{110}$, $B = -\frac{25-9\sqrt{5}}{110}$, $C = \frac{40+12\sqrt{5}}{110}$, and $D = \frac{40-12\sqrt{5}}{110}$. The initial conditions give $c_1 = -\frac{3\sqrt{5}}{110}(1-\sqrt{5})$ and $c_2 = -\frac{3\sqrt{5}}{110}(1+\sqrt{5})$. For $n = 2k+1$, $A = -\frac{5+4\sqrt{5}}{55}$, $B = -\frac{5-4\sqrt{5}}{55}$, $C = \frac{10+14\sqrt{5}}{55}$, and $D = \frac{10-14\sqrt{5}}{55}$. Here, the initial conditions give $c_1 = \frac{9}{110}(5+\sqrt{5})$ and $c_2 = \frac{9}{110}(5-\sqrt{5})$. The generating function is computed as in the proof of Theorem 12. In particular,

$$\begin{aligned} G_{\tilde{v}_n}(x) &= x\left[\frac{9}{22}(G_{F_n}(2x^2) + G_{L_n}(2x^2)) + \frac{2}{11}(G_{L_n}(4x^2) + 7G_{F_n}(4x^2))\right. \\ &\quad \left. -\frac{1}{11}(G_{L_n}(x^2) + 4G_{F_n}(x^2))\right] + \left[\frac{3}{22}(G_{F_n}(2x^2) - G_{L_n}(2x^2))\right. \\ &\quad \left. +\frac{2}{11}(2G_{L_n}(4x^2) + 3G_{F_n}(4x^2)) - \frac{1}{22}(5G_{L_n}(x^2) + 9G_{F_n}(x^2))\right] \end{aligned}$$

which gives the result after substitution and simplification. □

Finally, we examine the following.

Theorem 15 *For $n = 2k$, the decimal value of each individual palindromic binary string of length n is congruent to 0 (mod 3), and $\tilde{v}_{2k} \equiv 0$ (mod 3) also. For $n = 2k+1$, the decimal value of each individual palindromic binary string of length n is congruent to 1 (mod 3), and $\tilde{v}_{2k+1} \equiv F_{k+1}$ (mod 3).*

Proof: The proof follows along the lines of the proof of Theorem 8. We show the congruence for the individual terms by induction. The basic step for the induction follows from Theorem 8. We now assume the induction hypothesis and utilize the palindromic creation process. If we append 00 on both sides, then this corresponds to multiplication by $4 \equiv 1 \pmod 3$ of the value for a string of length $n-4$ and the result follows. If we append a 1 on each side of a palindromic binary string of length $n-2$, then this corresponds to multiplication by 2 of the value of the string of length $n-2$ and addition of $2^{n-1}+1$. Since $2^{2k} \pmod 3 \equiv 4^k \pmod 3 \equiv 1 \pmod 3$, we get for $n = 2k$, that the string's value is (using the hypothesis) congruent to $2 \cdot 0 \pmod 3 + (2^{2k-1}+1) \pmod 3 \equiv (0+2 \cdot 2^{2(k-1)}+1) \pmod 3 \equiv (0+2 \cdot 1+1) \pmod 3 \equiv 0 \pmod 3$. For $n = 2k+1$, the string's value is (using the hypothesis) congruent to $2 \cdot 1 \pmod 3 + (2^{2k}+1) \pmod 3 \equiv (2+1+1) \pmod 3 \equiv 1 \pmod 3$. The result for $\tilde{v}_{2k+1}$ follows because there are F_{k+1} palindromic binary strings of length $2k+1$. □

5 Connection to Compositions with Odd Summands

We now discuss the connection between binary strings of length $n-1$ and compositions of n with odd summands. We can visualize a composition of n as a board of size 1-by-n inches with potential cutting sites after each inch. At each potential cutting site, we either cut or do not cut, and the lengths of the resulting pieces will determine the summands in the composition. The cutting instruction for a composition of n can be given by a binary string of length $n-1$, where a 0 indicates "no cut", and a 1 indicates "cut", as shown in Figure 1.

Since an even number of "no cuts" results in a piece of odd length, there is a one-to-one correspondence between the compositions of n with only odd summands and the binary strings of length $n-1$ with no odd runs of zeros. Grimaldi [5] has investigated compositions with odd summands, and looked at the occurrences of individual summands, and the number of summands, "+"-signs, levels, rises and drops. However, the one-to-one correspondence between the total number of compositions of $n+1$

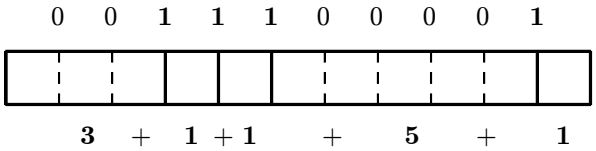

Figure 1: A composition and its binary string cutting instruction

with odd summands and the binary strings of n with no odd runs of zero does not extend automatically to these quantities. The only one-to-one correspondence is between s_{n+1}, the number of "+" signs in compositions of $n+1$ with odd summands and w_n, the number of 1's in binary strings of n. This can be easily seen since every 1 results in a cut which creates two pieces and therefore has to correspond to a "+" sign. The two formulas look somewhat different (Section 3 [5] and Theorem 3):

$$s_{n+1} = (-1/5)F_{n+1} + (1/5)(n+1)L_{n+1} \text{ for } n \geq 1$$

and

$$w_n = (2/5)F_n + (1/10)nL_n + (1/2)nF_n \text{ for } n \geq 1,$$

but can be shown to be equivalent by first using the fact that $L_{n+1} - F_{n+1} = 2F_n$ (see proof of Theorem 3, part 2) and then showing the remaining equality using the Binet forms for F_n and L_n.

Acknowledgements The authors would like to thank Phyllis Chinn, who pointed out the equivalence between the binary strings of length n and the compositions of $n+1$ with only odd summands, and the anonymous referee who provided an incredibly fast turnaround!

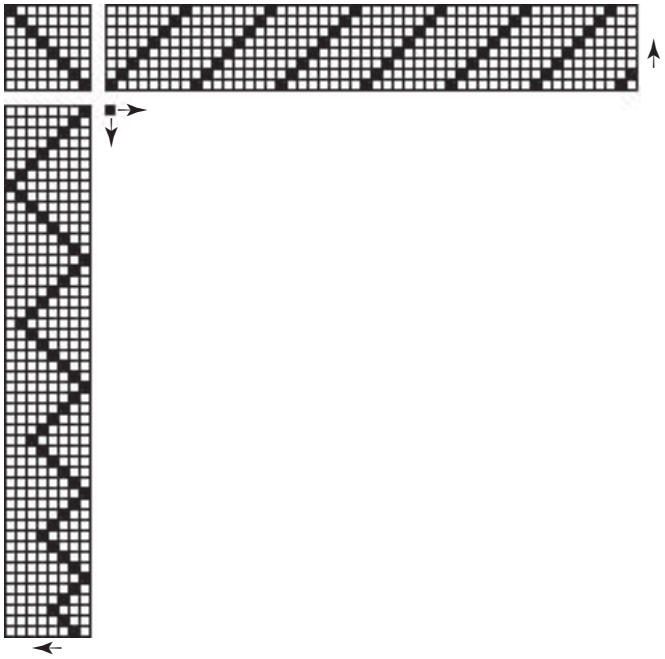
Drafting with Sequences

Shafts and treadles in drafts are numbered for identification. The numbers of the shafts through which successive warp threads pass form a sequence, as do the numbers of the treadles for successive picks. Consider the following draft, in which the arrows indicate the orientation:



The threading is an upward straight draw. The sequence is:

1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, 1, 2

The treadling sequence is more complicated:

1, 2, 3, 4, 5, 6, 7, 8, 7, 6, 5, 4, 3, 2, 1, 2, 3, 4, 5, 6, 7, 6, 5, 4, 3, 2, 1, 2, 3, 4, 5, 6, 5, 4, 3, 2, 1, 2, 3, 4, 5, 4, 3, 2, 1, 2, 3, 4, 3, 2

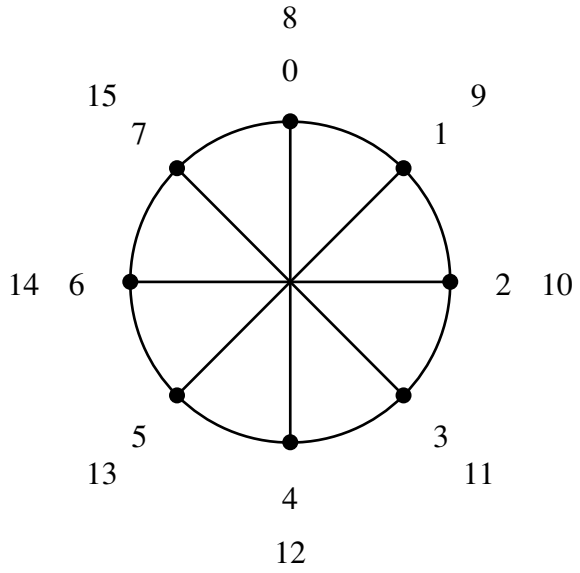
These two sequences, in combination with the tie-up, define the structure of the weave.

Threading and treadling sequences often have distinctive patterns, as in the repeat for the threading sequence above. In the case of a repeat, it's only necessary to know the basic unit, which we'll indicate by brackets:

[1, 2, 3, 4, 5, 6, 7, 8]

Modular Arithmetic

Since looms have a fixed number of shafts and treadles, the sequences usually are most easily understood in terms of modular arithmetic, sometimes called clock or wheel arithmetic, in which numbers go around a circle clockwise, starting with 0. If there are 8 shafts, there are 8 equally spaced points on the circle from 0 to 7:

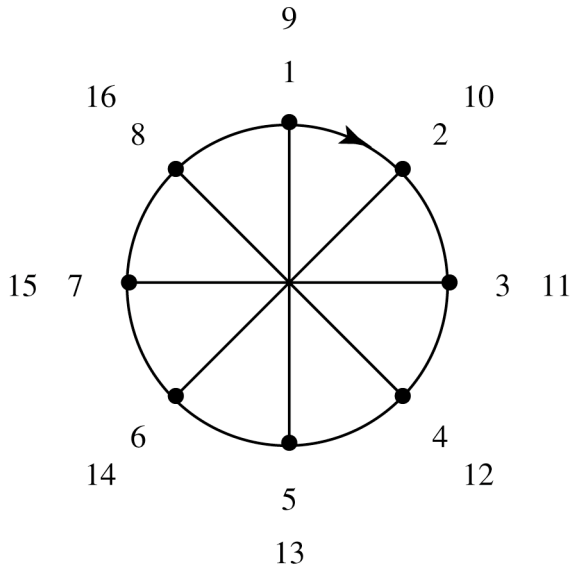


The numbers on the inner circle are those that exist in the modular arithmetic. If we continue beyond 7, as shown in the outer ring, the numbers wrap around the wheel. Numbers on the same spoke are equivalent. For example, 0 and 8 are equivalent, 1 and 9 are equivalent, 2 and 10 are equivalent, and so on. Another way to look at it is that when 9 is introduced into modular arithmetic with 8 shafts, it *becomes* 1, and so on.

Shaft Arithmetic

Although modular arithmetic uses the number 0 as a starting point, most persons count from 1. We'll keep this convention, which is used for numbering shafts and treadles. This is easily accomplished by rotating the wheel counterclockwise by one position:

July 8, 1999; last modified December 3, 2002



Notice that 1 and 9 are still equivalent, as are 2 and 10, and so on. If there are 8 shafts, there are 8 positive numbers. 0 has gone away, but it will be back.

For sequences, shafts and treadles are handled the same way, so we'll call this *shaft arithmetic*, with the understanding that it applies to treadles also. Of course, most facts about shaft arithmetic hold for ordinary modular arithmetic.

In shaft arithmetic, an upward straight draw for 8 shafts is described by the positive integers in sequence:

1, 2, 3, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, …

and wrapped around the shaft circle to produce

1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, …

The point is that an upward straight draw comes from the most fundamental of all integer sequences, the positive integers in order. (We'll discuss downward straight draws later.)

Drafting with Sequences

The idea behind drafting with sequences is that many sequences have interesting patterns, which often become more interesting in shaft arithmetic. In fact, many sequences show repeats when cast in shaft arithmetic. When this is the case, the entire sequence can be represented by the repeat. For example, the shaft sequence for an upward straight draw for 8 and 10 shafts are represented by

[1, 2, 3, 4, 5, 6, 7, 8]

and

[1, 2, 3, 4, 5, 6, 7, 8, 9, 10]

respectively.

Note: Not all sequences produce repeats in shaft arithmetic. For example, the prime numbers, which are divisible only by 1 and themselves, do not show a repeat in shaft arithmetic (or in any other arithmetic).

Patterns in Sequences

Sequences may produce interesting woven patterns when they are used for threading and treadling.

There are many, many well-known integer sequences. The Fibonacci sequence, which has many connections in nature, design and mathematics, is one of the best known and most thoroughly studied of all integer sequences. The Fibonacci sequence starts with 1 and 1. Then each successive number (*term*) is the sum of the preceding two:

1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89,…

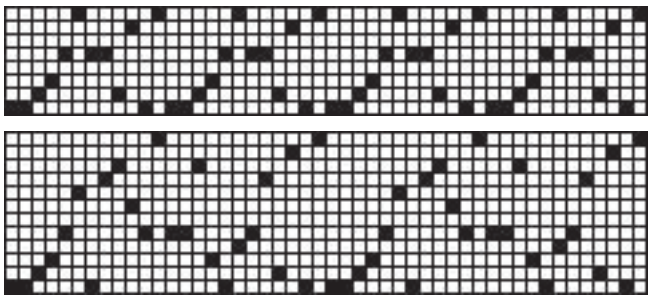
As the sequence continues, the numbers get very large. For example, the 50th term in the Fibonacci sequence is more than 12 billion. Shaft arithmetic brings this sequence under control. For 8 shafts, the result is

1, 1, 2, 3, 5, 8, 5, 5, 2, 7, 1, 8, 1, 1, 2, 3, 5, 8, 5, 5, 2, 7,
1, 8, 1, 1, 2, 3, 5, 8, 5, 5, 2, 7, 1, 8, …

As you can see, there is a repeat, so the entire sequence can be represented by

[1, 1, 2, 3, 5, 8, 5, 5, 2, 7, 1, 8]

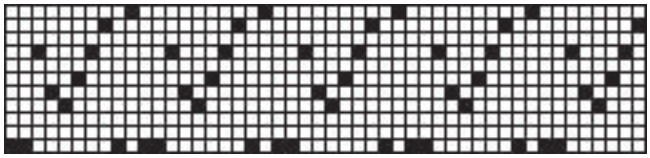
Patterns in sequences are more easily seen if they are plotted, as in the grids used in weaving drafts. For 8 and 12 shafts, the Fibonacci sequence looks like this:



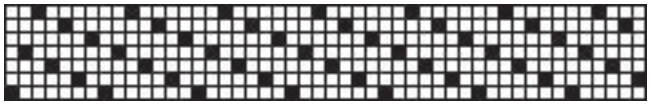
Here are some other simple sequences and what they look like for various numbers of shafts.

The squares for 5 shafts:

The cubes of the Fibonacci numbers for 11 shafts:

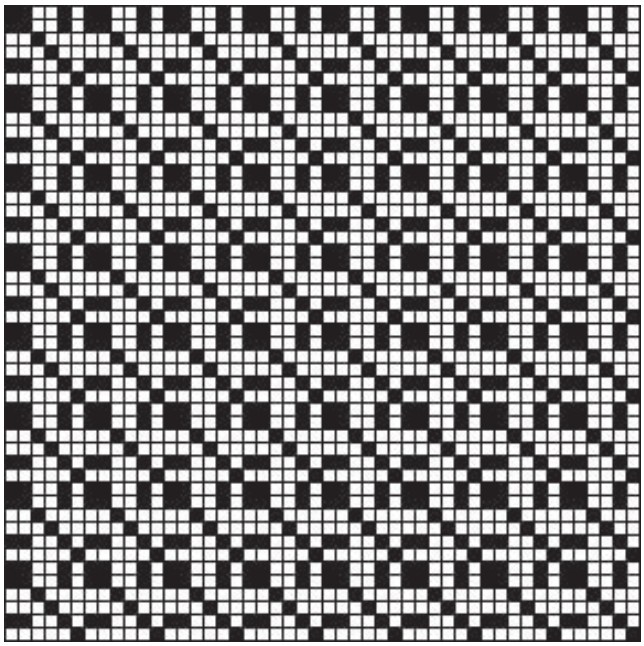


Every third positive integer for 7 shafts:

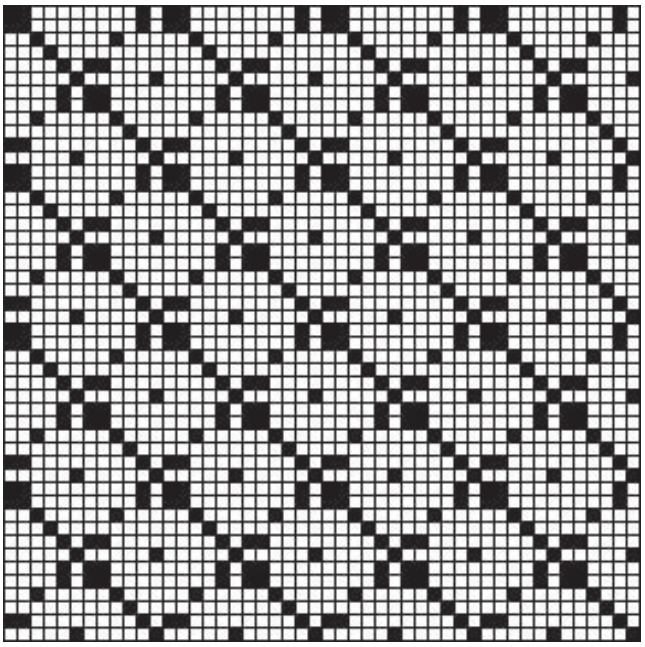


The patterns such sequences produce in weaves depend on many factors. To keep things simple to begin with, we'll use direct tie-ups and treadling as drawn in (that is, the same sequence for the threading and the treadling). Even in this very limited framework, interesting woven patterns abound.

Here is a drawdown for a few repeats of the Fibonacci sequence for 4 shafts.



The pattern lookss quite different for 8 shafts, although you'll notice structures in common:

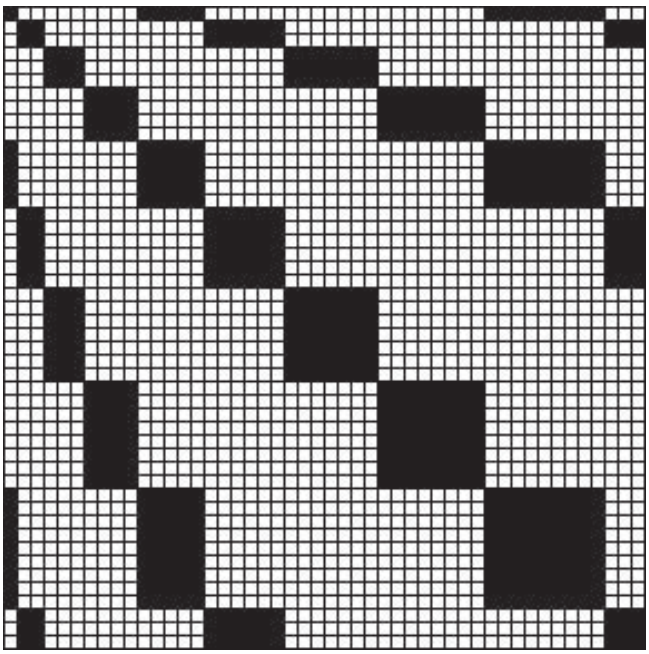


A simple sequence that produces interesting patterns is the "multi" sequence, which starts with a single 1 and is followed by 2 copies of 2, 3 copies of 3, and so on:

1, 2, 2, 3, 3, 3, 4, 4, 4, 4, 5, 5, 5, 5, 5, 6, 6, 6, 6, 6, 6, …

Note that there are no repeats in shaft arithmetic for this sequence, since the "width" of the repeated integer blocks constantly increases.

The drawdown for the multi sequence for 4 shafts is:

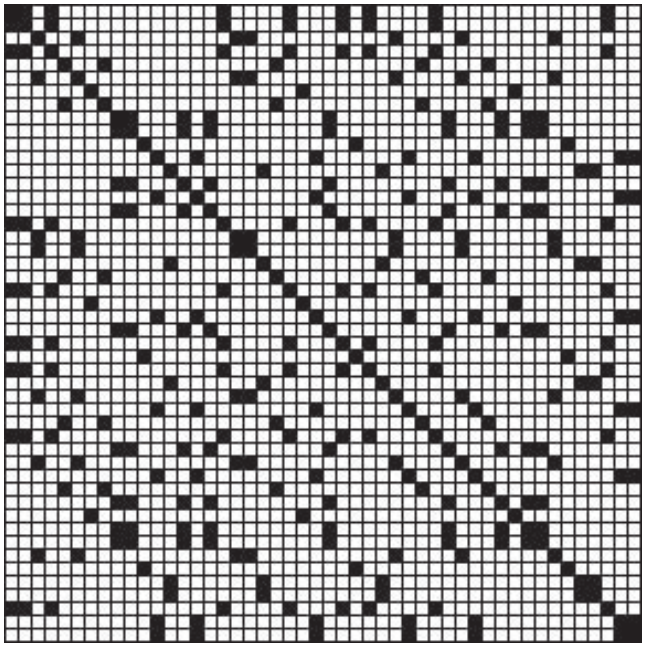


One way to produce interesting sequences is to combine other sequences, such as interleaving the terms of two sequences. For example, interleav-

ing the positive integers and the Fibonacci sequence produces

1, 1, 2, 1, 3, 2, 4, 3, 5, 5, 6, 8, 7, 5, 8, 5, 1, 2, 2, 7, 3, 1, 4, 8, 5, 1, 6, 1, 7, 2, 8, 3, 1, 5, 2, 8, 3, 5, 4, 5, 5, 2, 6, 7, 7, 1, 8, 8 …

The drawdown for 8 shafts is:



Other tie-ups and threading sequences and treadling sequences that are different produce all kinds of interesting results.

Creating interesting weaves by drafting with sequences requires judicious selection and combination of sequences, the number of shafts and treadles, and tie-ups. An understanding of the properties of the sequences used may help, but a little luck and some experimentation also can lead to pleasant surprises. The process is a nice combination of artistic sense, creative talent, a modicum of arithmetic, and finding the hidden structures that abound in integer sequences.

Finding Interesting Integer Sequences

Interesting integer sequences can come from many sources. It helps if you have a computer with a program that can do simple arithmetic so that you can invent your own. There also are many online sources of sequences. By far the most extensive one is the "Encyclopedia of Integer Sequences" (EIS):

http://www.research.att.com/~njas/sequences/

Beware, though — this site contains a lot of esoteric mathematical material and its vastness can be overwhelming. It's like a "Haystack from Hell", but the needles to be found within are made of precious metals.

Getting Shaft Sequences

There are shaft sequences for a few integer sequences and various numbers of shafts at

http://www.cs.arizona.edu/patterns/weaving/sequences.html

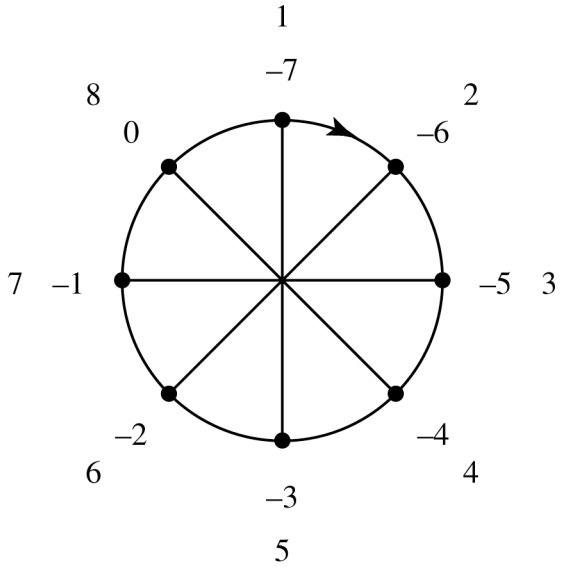
These sequences provide an easy way to start, but you'll want more if you decide you're really interested in drafting with sequences.

You can find many integer sequences ready made, but in order to do your own drafting, you need to be able to convert them to shaft sequences for different numbers of shafts. The method is simple: Divide each term by the number of shafts and take the reminder. For example, for 8 shafts, the reminder of 13 divided by 8 is 5, which is the shaft number for 13. That gives you the corresponding term in the shaft sequence. It helps if you have a program or calculator that can do integer arithmetic and produce remainders.

There's one more complication — 0 and negative numbers. The way to deal with these is indicated by looking at what happens when you have negative integers in increasing sequence as they cross over to the positive integers:

…, –7, –6, –5, –5, –3, –2, –1, 0, 1, 2, 3, 4, 5, 6, 7, 8, …

Now think of the modular wheel and what happens if you wrap this sequence of numbers around it. For 8 shafts, it looks like this:



In other words, –1 becomes 7, –2 becomes 6, and so on. Note that 0, which we've been hiding, becomes 8.

Perhaps you now see the integer sequence that produces a downward straight draw:

0, –1, –2, –3, –4, –5, –6, –7, –8, –9, –10, …

All that's needed to convert a non-positive remainder to a shaft number is to add it to the number of shafts. For –1, for example,

$$8 + (-1) = 7$$

Despite this long-winded discussion, getting shaft sequences from integer sequences is not difficult at all.

The interesting part remains — trying it and designing drafts.

What's on the Horizon

As you might imagine if you've checked out my background, my approach to drafting with sequences relies heavily on programming — making things easy enough that experiments and refinements to them can be done quickly. I'll have more to say about this later.

Patterns from Term-Replication Sequences

You probably have seen patterns like the one in Figure 1 and its mirrored extension in Figure 2.

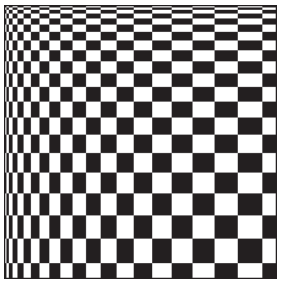

Figure 1. Pattern

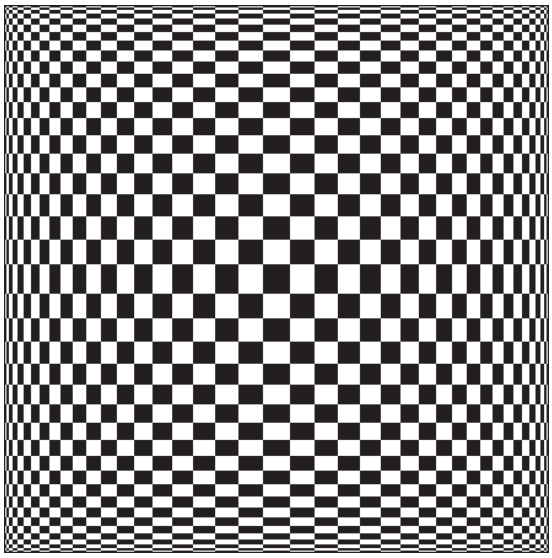

Figure 2. Mirrored Pattern

These patterns come from a very simple sequence:

1 2 2 3 3 3 4 4 4 4 5 5 5 5 5 …

For example, if this sequence is used for the threading and treadling sequences in a weaving draft with a tabby tie-up, the resulting drawdown is as shown in Figure 1.

In the sequence above, each term is replicated according to its value. We know of no good name for this sequence. We have called it the multi sequence in previous articles [1] and the On-Line Encyclopedia of Integer Sequences [2] refers to it as "*n* appears *n* times", which is descriptive but far from elegant.

The sequence above is one of a class of sequences obtained by applying *term replication functions* to *bases sequences*.

For the example above, the base sequence is the positive integers, $I^+ = 1\,2\,3\,4\,5\,\ldots$ and the replication function is $r(v) = v$, where v is the value of the term.

If the base sequence is the Fibonacci numbers, $F = 1\,1\,2\,3\,5\,8\,\ldots$, then this rule yields

1 1 2 2 3 3 3 5 5 5 5 5 8 8 8 8 8 8 8 8 …

Compact Represention of Term Replication

Sequences in which terms are replicated may be difficult to understand if terms are written out in the usual fashion.

One way to reduce visual clutter is to list replicated terms only once along with their replication factor. We'll use the notation

$$\underline{i}_j$$

to indicate that there are j copies of i. Thus, the result of applying $r(v) = v$ to I^+ and the primes, $P = 2\,3\,5\,7\,\ldots$, can be written as

$$1\ \underline{2}_2\ \underline{3}_3\ \underline{4}_4\ \underline{5}_5\ \ldots$$
$$\underline{2}_2\ \underline{3}_3\ \underline{5}_5\ \underline{7}_7\ \ldots$$

We use 1 rather than $\underline{1}_1$, and similarly for other non-replicated terms, to further reduce visual clutter.

Another way to represent the results of applying a replication function to a base sequence is to write the base sequence above the replication sequence, with a bar separating the two. For the examples above, the representations are

$$\frac{1\,2\,3\,4\,5\,\ldots}{1\,2\,3\,4\,5\,\ldots}$$

$$\frac{2\,3\,5\,7\,\ldots}{2\,3\,5\,7\,\ldots}$$

For named sequences, a simpler, linear typographical form can be used, as in P/F.

March 11, 2002; last modified December 16, 2002

Value-Based Replication Functions

Replication functions whose values are determined solely by term values are called value-based.

Many kinds of value-based replication functions are possible, such as the following:

$$r(v) = 1 \quad [1]$$

$$r(v) = v \quad [2]$$

$$r(v) = v + 2 \quad [3]$$

$$r(v) = v \text{ smod } 5 \quad [4]$$

$$r(v) = \begin{matrix} 1 & v \text{ even} \\ 2 & v \text{ odd} \end{matrix} \quad [5]$$

$$r(v) = \begin{matrix} 1 & v \text{ even} \\ 0 & v \text{ odd} \end{matrix} \quad [6]$$

Eqn. 1 leaves the base sequence unchanged. Eqn. 2 produces the results described previously. Eqn. 3 is like Eqn. 2 except that 2 replications are added. In Eqn. 4, the replication factor is reduced shaft-modulo 5 [1], so that values whose residues are 1 smod 5 are not replicated, values whose residues are 2 smod 5 are replicated two times, and so on.

In Eqns. 5 and 6, the result depends on the parity of the value. In Eqn. 5 even values are not replicated, while odd ones are duplicated. In Eqn. 6, even values are not replicated and odd values are discarded (being replicated 0 times).

Note that in Eqns. 2 and 3, replication factors increase without limit as v does. In the other equations, the replication factors are bounded regardless of how large v is.

Position-Based Replication Functions

Replication factors can be based on the positions of terms instead of their values, position being the number of the term in the sequence. For example, in P, 2 is term 1, 3 is term 2, 5 is term 3, 7 is term 4, and so on.

For example, if p is the position of a term in a sequence, the replication function

$$r(p) = \begin{matrix} 1 & p \text{ odd} \\ 2 & p \text{ even} \end{matrix} \quad [7]$$

doubles even-numbered terms but not the odd-numbered terms.

The replication function

$$r(p) = p \quad [8]$$

replicates by the position of the term. For I^+, Eqn. 8 produces the same results as Eqn. 2. For P, it produces

$$2\ \underline{3}_2\ \underline{5}_3\ \underline{7}_5 \ldots$$

Value- and Position-Based Replication Functions

Replication functions can depend both on value and position. An example is

$$r(v, p) = \begin{matrix} v & p \text{ odd} \\ p & p \text{ even} \end{matrix} \quad [9]$$

For F, Eqn. 9 produces

$$\underline{1}_3\ \underline{2}_2\ \underline{3}_3\ \underline{5}_5\ \underline{8}_6 \ldots$$

Replication Sequences

Replication factors can be determined independently of the base sequence. For example, for the base sequence I^+ and the replication sequence P, we have

$$I^+ / P =$$

$$\frac{1\ 2\ 3\ 4\ \ldots}{2\ 3\ 5\ 7\ \ldots} =$$

$$\underline{1}_2\ \underline{2}_3\ \underline{3}_5\ \underline{4}_{7\ \ldots} =$$

$$1\ 1\ 2\ 2\ 2\ 3\ 3\ 3\ 3\ 4\ 4\ 4\ 4\ 4\ 4\ 4 \ldots$$

As another example, consider the 1-based Morse-Thue sequence [3], $M = 1\ \ 2\ \ 2\ \ 1\ \ 2\ \ 1\ \ 1\ \ 2 \ldots$ as the base sequence and I^+ as the replication sequence:

$$M / I^+ =$$

$$\frac{1\ \ 2\ \ 2\ \ 1\ \ 2}{1\ \ 2\ \ 3\ \ 4\ \ 5}\ \underset{6.}{1}\ \underset{7}{1}\ \ 2 \ldots$$

$$1\ \underline{2}_5\ \underline{1}_4\ \underline{2}_5\ \underline{1}_{13}\ \underline{2}_8 \ldots =$$

$$1\ 2\ \ 2\ \ 2\ \ 2\ \ 2\ \ 1\ \ 1\ \ 1\ \ 1\ \ 2\ \ 2\ \ 2\ \ 2\ \ 2\ \ 1\ \ 1\ \ 1$$
$$1\ \ 1\ \ 1\ \ 1\ \ 1\ \ 2\ \ 2\ \ 2\ \ 2\ \ 2\ \ 2\ \ 2\ \ 2 \ldots$$

Term-Replication Sequence Patterns

Patterns derived from term-replication sequences may not be suitable, as-is, for interlacement patterns in weaving for structural reasons. Such patterns, however, may make good block patterns for profile drafting.

As in all such things, designing good patterns based on term replication requires a combination of experience, skill, and creativity.

The Appendix A shows some examples that can be used as a basis for experimentation. Appendix B shows some examples of mirrored patterns based on term replication sequences.

All the examples in the appendices are produced using tabby tie-ups with treadling as drawn in. Hint, hint … .

Floats

An aspect of weaving that is of great practical importance is the strength and durability of the fabric produced, which depends not only on the kind of threads used and how tight the weave is but also on the manner of interlacing.

The interlacing that gives the strongest fabric is the one used in plain weave, also called tabby, which has a strict 1-over, 1-under interlacement pattern. Figure 1 shows an example.

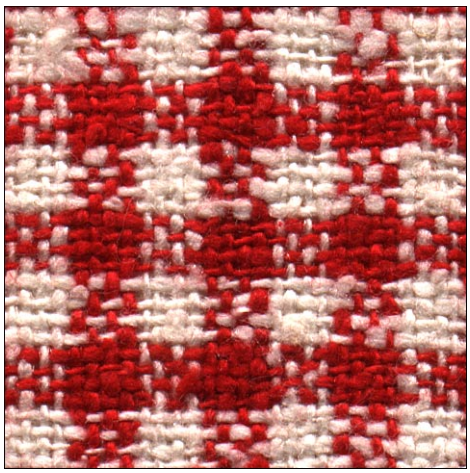

Figure 1. A Plain Weave Fabric

When a thread passes over or under more than one perpendicular thread, the result is called a *float*.

A fabric with long floats does not have the strength and durability of one with short floats or none at all. Not only is there less interlacement, but floats tend to snag.

The importance of snagging depends on the use to which a fabric is put. Long floats sometimes appear on the back of upholstery fabrics, where they cause few problems.

On the other hand, floats allow the creation of textures and patterns that cannot be achieved otherwise. Floats also produce a surface that feels smoother and drapes better than a float-free one. The sheen and luxurious texture of satins is due to their floats.

Figure 2 shows an example in which floats are used to achieve a decorative effect. Notice that one thread has pulled loose where there is a float.

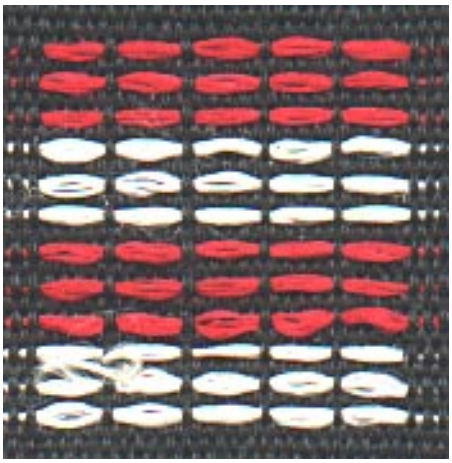

Figure 2. Floats on a Decorative Fabric

Drafts that produce very long floats are undesirable or even unweavable. Unintended floats can occur when designing drafts. For example, in the drawdown shown in Figure 3, there are places where weft threads float all the way across the fabric.

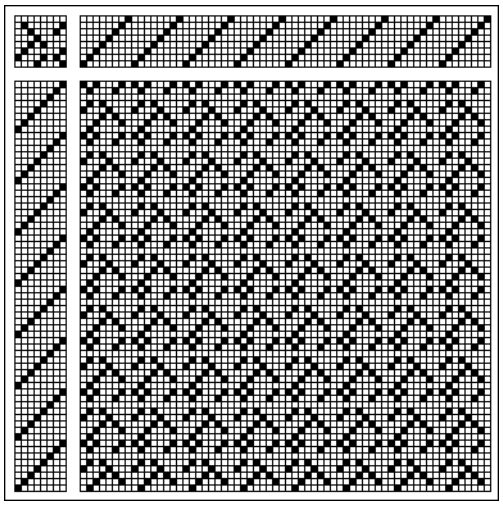

Figure 3. An Unweavable Draft

If an attempt were made to weave this fabric, these weft threads would not be interfaced with the warp at all and would not be attached to the fabric — the fabric would be unweavable.

Weavers avoid such extremes intuitively, but they have to watch for float problems nonetheless. Weavers have methods of modifying drafts with this kind of problem without affecting the appearance of the woven fabric [1]. For example, tiny threads, which are too fine to be noticed, can be used as "incidentals" to add interlacement.

We've ignored the problem of floats in the drafts we've shown in previous articles, since it's not a problem in creating images. Our "virtual" weaving is much easier than real weaving. (There is an interpretation of weaving drafts as patterns in which the interlacement is not a concern. That's on our agenda for a future article.)

Weaving programs have various ways of showing floats. WeaveMaker One uses "float indicators" — over-and-under diagrams for selected warp and weft threads. See Figure 4. The selected threads are indicated by small markers at the top and right edges of the drawdown. We've added arrows to help locate them. The markers can be moved to show the floats for other threads.

A fabric surface simulation, such as the one shown in Figure 5 (also from WeaveMaker One), provides a more intuitive but less precise view of floats.

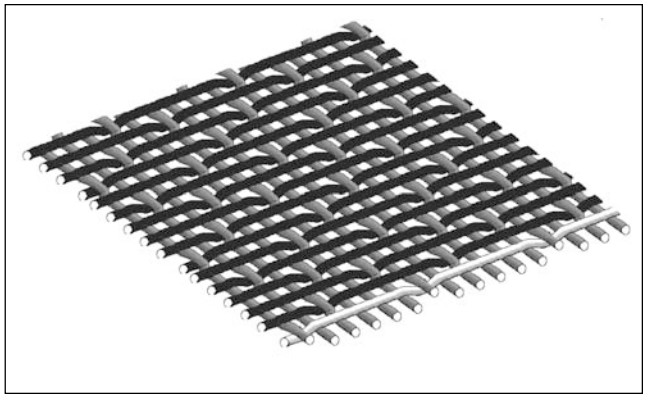

Figure 5. Fabric Surface Simulation

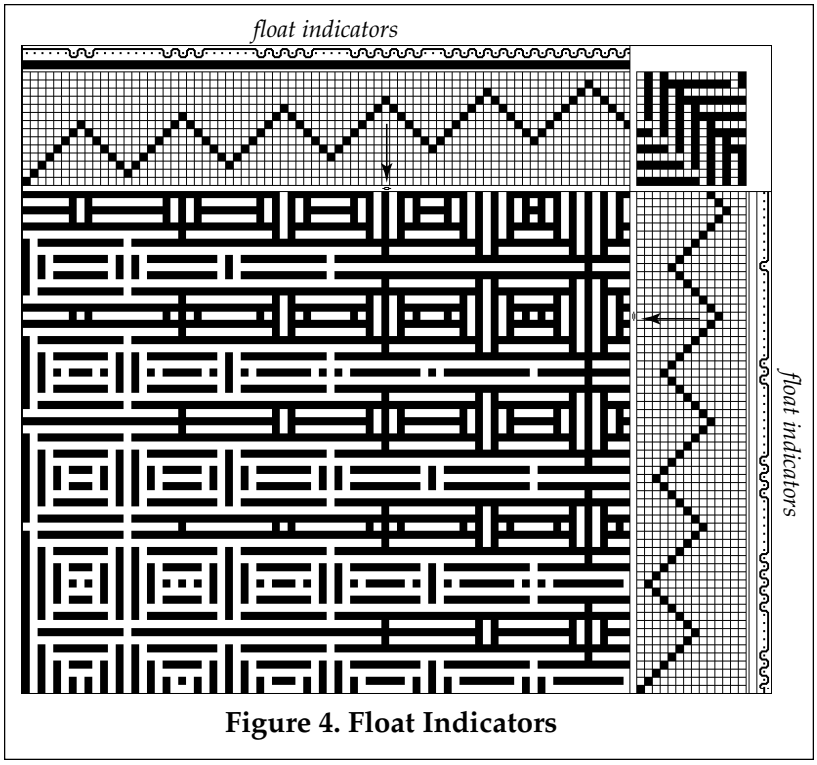

Figure 4. Float Indicators

Creating such diagrams is fairly difficult and few weaving programs attempt it. Realistic rendering of fabric surfaces is in another class altogether.

Most weaving programs can produce tabulations or histograms of the number of floats by length. Figure 6 shows a WeaveMaker One histogram for the draft shown in Figure 3:

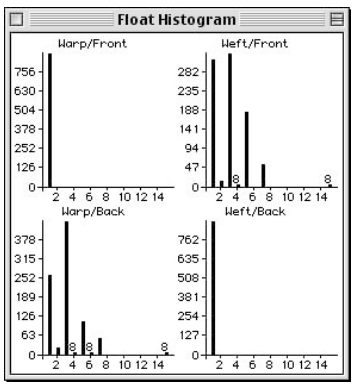

Figure 6. Float Histogram

Floats of length 15 and longer are lumped together without comment. Note that 1 is included, although strictly speaking it is not a float.

Here's a program to produce a float tabulation. It works from an image string of a drawdown. A drawdown image for the back of the fabric is created by exchanging black and white pixels — where a thread is on top on the face of the fabric, it is in back on the back of the fabric. Weft floats are determined by rotating the fabric by 90°.

```
link imrutils

procedure main()
   local front, back, black, white

   front := imstoimr(read()) |
      stop("***cannot create image record")

   black := PaletteKey(front.palette, "black")
   white := PaletteKey(front.palette, "white")

    analyze("Front weft floats", front, white)

   front := imrrot90cw(front)

   analyze("Front warp floats", front, black)

   back := imrcopy(front)
   back.pixels := map(back.pixels,
      white || black, black || white)

   analyze("Back weft floats", back, white)

   back := imrrot90cw(back)

   analyze("Back warp floats", back, black)

end
```

```
procedure analyze(caption, imr, color)
   local counts, length, row

   counts := table(0)

   imr.pixels ? {
      while row := move(imr.width) do {
         row ? {
            while tab(upto(color)) do {
               length := *tab(many(color))
               if length > 1 then
                  counts[length] +:= 1
               }
            }
         }
      }

   if *counts = 0 then fail          # no output

   write(caption)

   counts := sort(counts, 3)

   write()

   while write(right(get(counts), 6),
      right(get(counts), 6))

   write()

   return

end
```

The output for the drawdown shown in Figure 3 is:

```
Front weft floats
                2      16
                3     328
                4       8
                5     184
                7      56
               64       8

Back warp floats
                2      24
                3     440
                4       8
                5     112
                6       8
                7      56
               64       8
```

Satin

Satin usually is thought of as a kind of silk fabric that is characterized by a glossy surface and a smooth texture. Weavers, on the other hand, consider satin to be a weave structure — a system for interlacement — that is not associated with any particular kind of fiber.

The conflict of meaning came into focus with the introduction of fabrics called satins but made with rayon. This use of the word led to a legal dispute, which eventually was settled (in the United States, at least) in 1930 by the Circuit Court of Appeals, which ruled satin was the name of a weave construction and not the name of a textile made from any particular fiber [1].

The common perception remains largely unchanged, however.

As a weave structure, satin is characterized by long floats (which gives satin fabrics their smoothness) and a system of interlacing that avoids the regularity of twills [2].

This is accomplished by having only one warp interlacement with the weft per shaft. These interlacements are arranged so that no two are adjacent on successive treadlings. Figure 1 shows an example of a satin tie-up.

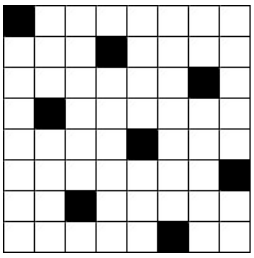

Figure 1. A Satin Tie-Up

The location of interlacement points is determined by a *counter* that depends on the number of shafts used.

Weaving literature is not noted for its clarity and precision. Here are four quotations on the subject from sources dating from 1888 to 1994:

> 1. *Divide the number of harness for the satin into two parts, which must neither be equal nor the one a multiple of the other; again it must not be possible to divide both parts by a third number.* [3]

Harness is used as a collective noun and corresponds to shafts in current terminology.

> 2. *Divide the number of ends (or shafts) on which the satin … is to be woven into two unequal parts, so that one shall not be a measure of the other, nor shall it be divisible by a common number.* [4]

The word ends means the number of warp threads. "Measure of the other" is British English and means (we think) "divisible by the other".

> 3. *Find two numbers which give a sum equal to the number of frames. None of these numbers can be 1; the two numbers cannot divide one another, or by any other number at the same time.* [5]

The word frames is synonymous with shafts.

> 4. *The satin counter cannot be 1, or the interlacement forms a twill. It cannot be one fewer than the number in the unit … , or the interlacement forms a twill in the opposite direction. The counter cannot share a divisor with the number in the unit, or some warp threads interlace more than once and others not at all.* [6]

Grammatical errors, tortured prose, questionable meaning, and definition by elimination aside, it comes down to this:

> Given n shafts, find i and j such that $i > 1$, $i + j = n$, and the greatest common divisor of i and $j = 1$.

Either i or j can be used as the counter; the smaller one usually is chosen.

Well, that wouldn't make sense to most weavers either, and it's no wonder most of them rely on tables of satin counters. In one sense, tables aren't that bad: there are not that many different counters for the number of shafts that are available for hand looms. Here is a table for 2 to 24 shafts:

shafts	*small counters*	*number*
2		0
3		0
4		0
5	2	1
6		0
7	2 3	2
8	3	1
9	2 4	2
10	3	1
11	2 3 4 5	4
12	5	1
13	2 3 4 5 6	5
14	3 5	2
15	2 4 7	3

16	3 5 7	3
17	2 3 4 5 6 7 8	7
18	5 7	2
19	2 3 4 5 6 7 8 9	8
20	3 7 9	3
21	2 4 5 8 10	5
22	3 5 7 9	4
23	2 3 4 5 6 7 8 9 10 11	10
24	5 7 11	3

Notice that satin requires at least five shafts and cannot be woven with six shafts. By the way, if the number of shafts is a prime, $p > 2$, any number $2 \le i \le p-1$ is a valid counter: If $i + j = p$, gcd(i, j) must be 1 — otherwise the common factor would divide p.

But a weaver who just uses a table of counters, and who doesn't understand the formula or the reason for it, is limited to the designs of others.

Computing satin counters is easy. Here's a procedure that generates the smaller counter from each pair for a given number of shafts:

```
procedure satin_counter(shafts)
   local candidate

   every candidate := 2 to shafts / 2 do
      if gcd(candidate, shafts – candidate) = 1
         then suspend candidate

end
```

The procedure gcd() is in the Icon program library module numbers.

Once the counter is chosen, the tie-up is constructed starting with first position of the first row, adding the counter to that value modulo the number of shafts, using shaft arithmetic [7], to get the position in the second, and so on. Refer to Figure 1 on the previous page.

Here's a procedure that produces a satin tie-up as a row array:

```
procedure satin_tieup(counter, shafts, treadles)
   local rows, m, k

   rows := list(shafts, repl("0", treadles))

   m := 1
   rows[1, 1]  := "1"

   every k := 2 to shafts do
      rows[k, residue(m +:= counter, shafts, 1)] := "1"

   return rows

end
```

The procedure residue() is in the Icon program library module numbers.

Tie-Ups

Depending on what you read, the tie-up in a weaving draft is the essence of the draft or it's just something that is produced mechanically after a weave structure is designed. Both are true in different contexts.

We've shown how to derive the threading, treadling, and tie-up from a drawdown — an interlacement pattern. This is a case when the tie-up follows as a matter of course.

On the other hand, as we've shown for twills and satins (see the article **Satins** that starts on page 4), tie-ups can be fundamental to design and work for many kinds of threadings and treadlings.

A tie-up also can serve as a motif, such as a diagram of a leaf, that is replicated in the drawdown. Geometric designs also are used in tie-ups to achieve certain kinds of effects. Some tie-ups are specific to certain kinds of weaving.

Many tie-ups are derived from others. And there's the ever-present miscellaneous category.

Basic Tie-Ups

The basic tie-ups are direct, tabby, twill, and satin.

The figures that follow are for eight shafts and treadles. The principles apply equally well to

other numbers of shafts and treadles.

A direct tie-up consists of tie-up points in a diagonal line. See Figure 1.

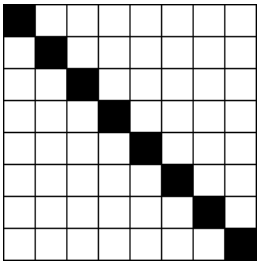

Figure 1. Direct Tie-Up

Direct tie-ups always are square, with the same numbers of shafts and treadles.

We'll consider the effect of direct tie-ups in a later article on the interaction of tie-ups with threading and treadling sequences.

A tabby tie-up, used to produce plain weaves, is a simple checkerboard as shown in Figure 2 .

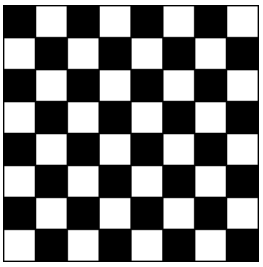

Figure 2. Tabby Tie-Up

We covered twill tie-ups in an earlier article [1]. Figure 3 shows an example for reference.

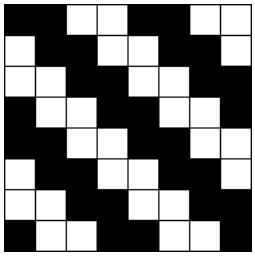

Figure 3. A /2/2 Twill Tie-Up

For classification purposes, tabby might be considered to be a /1/1 twill, but weavers think in terms of texture, and plain weave does not have the diagonal texture associated with twill.

Satin tie-ups break the diagonal effect of twills. See the article **Satin**, which begins on page 4. Figure 4 provides an example to compare with the other types here.

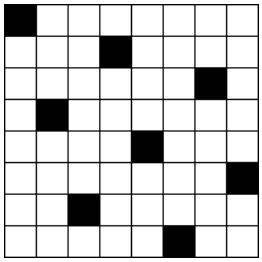

Figure 4. A Satin Tie-Up

Satin can be thought of as a kind of twill in which the shift is greater than one. But, again, it does not have the diagonal appearance expected of twill; it fact, it is designed *not* to have such an appearance.

The basic tie-ups shown above can be characterized by a "under-and-over" row pattern that is circularly shifted by a fixed number of columns for each successive row. A positive shift is to the right; negative to the left. If the sum of the numbers in a pattern is less than the number of treadles, the pattern is extended to fill out the row.

Direct, tabby, and twill tie-ups are circularly shifted by one column for each successive row (in twill tie-ups, positive and negative shifts produce different but complementary effects). In satin tie-ups the shift is chosen to break the diagonal regularity of twills.

Here are the values for the tie-ups in the figures given previously:

figure	*pattern*	*shift*	*type*
1	/1/7	1	direct
2	/1/1	1 (or –1)	tabby
3	/2/2	1	twill
4	/3/5	11	satin

We can represent such tie-ups by strings in which the pattern is separated from the shift by a colon:

- direct: "1/*n*–1:1", where *n* is the number of shafts
- tabby: "/1/1:1"
- twill: "*p*:1"
- satin: "1/*n*–1:*n*+*c*" where *n* is the number of shafts and *c* is the counter

This form of characterization invites the design of other tie-ups that do not fall into any of the basic types given above. Figures 5 through 8 show some examples.

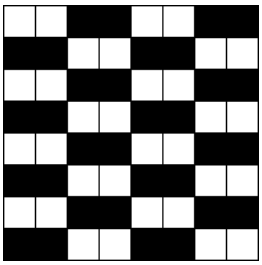

Figure 5. /2/2:2 Tie-Up

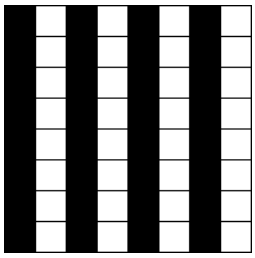

Figure 6. /1/1:0 Tie-Up

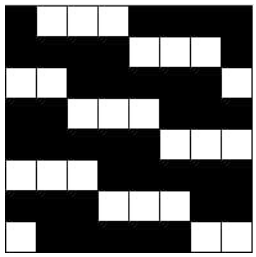

Figure 7. /1/3/4:3 Tie-Up

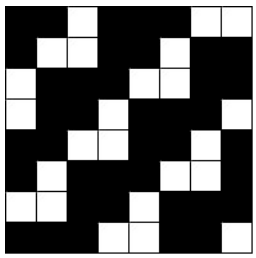

Figure 8. /2/1/3/2:5 Tie-Up

Be aware that simply coming up with a new tie-up using this formula does not insure a weave using it will be interesting or structurally sound.

More to Come

In the next article on tie-ups, we'll consider derivatives of the basic ones.

Classical Cryptography

Cryptography deals with methods for encoding messages to hide their meaning, decoding the results to recover the messages, and "cracking" coded messages when the encoding method is not known.

Classical cryptography deals with the subject from ancient times until approximately World War I. It does not include sophisticated devices developed this century or more recent mathematical methods like public-key encryption.

In our articles on the subject, we'll restrict ourselves to methods that manipulate strings and not attempt to cover various mechanical devices that have been used.

Terminology

Before going on, we need to define some terms. Some of these terms are used inconsistently in the literature; what follows are the meanings we will use.

A message in its unencoded form is called *plain text*. The coded form is called a *cryptogram*. A *cipher* is a method of coding. The process of encoding plain text is called *enciphering*, while the process of decoding a cryptogram is called *deciphering*. Ciphers often use a *key* to parameterize the basic method.

Decryption is the process of decoding a message without knowing the cipher and/or key. We'll be concerned primarily with ciphers and deal with decryption only tangentially.

The Nature of Ciphers

Abstractly, deciphering is the inverse of enciphering — recovering the plain text from the cryptogram. In practice, many ciphers discard information that is not essential to the message or add material that is not relevant or even intended to be confusing to a would-be decryptor. We'll generally deal with the ideal situation in which no

Downloading Icon Material

Implementations of Icon are available for downloading via FTP:

ftp.cs.arizona.edu (cd /icon)

information is lost in the process of enciphering and deciphering; that is, when deciphering is the inverse of ciphering:

```
decipher(encipher(pt, key), key) == pt
```

Figure 1 shows the situation schematically.

Kinds of String Ciphers

Most string ciphers fall into one of two categories or a combination of them [1]:

- substitution
- transposition

Substitution replaces characters or combinations of characters with others in plain text. Transposition rearranges the characters.

Substitution Ciphers

Substitution raises the question of the *alphabets* used in the enciphering and deciphering processes. In most textbook examples, the alphabet for the plain text and cryptograms is restricted to the uppercase letters. In practice, there is no reason to be so limited: numbers, spaces, and punctuation often are needed and most methods place no inherent restriction on the characters used.

Another way of dealing with this issue is to leave unchanged characters in plain text that are not in the alphabet used.

In our description of substitution ciphers, we'll use an alphabet limited to letters and just not make substitutions for other characters.

In any event, an alphabet is an *ordered* sequence of characters — a string.

Simple Monoalphabetic Substitution Ciphers

A simple substitution cipher is one in which plain text characters in an *input* alphabet are replaced on a one-to-one basis by characters in *output* alphabets to form a cryptogram. The keys for the cipher are the alphabets.

A monoalphabetic substitution cipher uses only one output alphabet. This is, of course, just what map() does. Procedures to implement a simple monoaphabetic cipher might look like this:

```
procedure encipher(plain, in, out)
  return map(pt, in, out)
end
procedure decipher(crypto, out, in)
  return map(crypto, out, in)
end
```

where in and out are the keys.

It is commonly assumed that in is globally known and the key is just out. In this case the procedures might be cast as

```
procedure encipher(plain, out)
  return map(pt, in, out)
end
procedure decipher(crypto, out)
  return map(crypto, out, in)
end
```

The easiest way to create a simple monoalphabetic substitution cipher is to use an output alphabet that is a rearrangement of the input al-

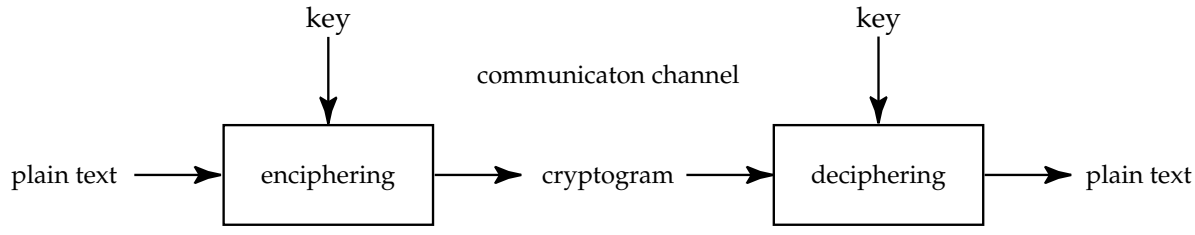

Figure 1. Enciphering and Deciphering

phabet. Reversal is commonly used to illustrate this:

input alphabet: "abc … xyz"
output alphabet: "zyx … cba"

That is, all as in the plain text are replaced by zs, all bs by ys, and so on.

In the case where the output alphabet is a rearrangement of the input alphabet, the key can be the rearrangement method, which usually is simpler and shorter than the resulting output alphabet. Procedures might look like this:

```
procedure encipher(plain, p)
  return map(pt, in, p(in))
end
procedure decipher(crypto, p)
  return map(crypto, p(in), in)
end
```

where p() is a procedure applied to the (known) input alphabet to get the output alphabet. For example,

```
crypto := encipher(plain, reverse)
```

enciphers plain using the reversal of the input alphabet as the output alphabet.

For some such ciphers, arguments to the procedure for forming the output alphabet may be needed. In this case our model can be extended as follows:

```
procedure encipher(plain, p, args[])
  return map(pt, in, p ! args)
end
procedure decipher(crypto, p, args[])
  return map(crypto, p ! args, in)
end
```

For example,

```
crypto := encipher(plain, rotate, 3)
```

uses the input alphabet circularly rotated by three characters as the output alphabet. This is known as Caeser's cipher because it was used by Julius Caesar.

The procedure and its arguments can be encapsulated in a single key as follows:

```
procedure encipher(plain, key[])
  local p
  p := get(key)
  push(key, in)
  return map(pt, in, p ! key)
end
procedure decipher(crypto, key[])
  local p
  p := get(key)
  push(key, in)
  return map(crypto, p ! key, in)
end
```

One can imagine all kinds of ways of constructing simple monoalphabetic substitution ciphers. They are easily broken, however, by using tables of known letter frequencies for material written in the input alphabet.

Next Time

The next more sophisticated approach is to use more than one output alphabet — so-called polyalphabetic substitution ciphers.

We'll start with this topic in the next article on classical cryptography and then move on to transposition ciphers.

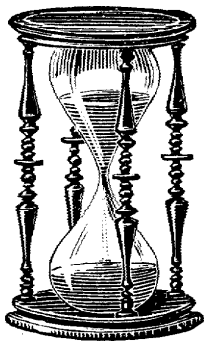
Subscription Renewal

For many of you, your present subscription to the Analyst expires with the next issue. If so, you'll find a renewal form in the center of this issue.



Renew now so that you won't miss an issue.

Your prompt renewal helps us by reducing the number of follow-up notices we have to send. Knowing where we stand on subscriptions also lets us plan our budget for the next fiscal year.

Weavable Color Patterns (continued)

In the first article on this subject [1], we showed examples of small colored patterns that cannot be created by the interlacement of colored threads. We also showed a "forcing" pattern that provides a sufficient basis for the solution of larger patterns in which it is embedded. The forcing pattern is shown again for reference in Figure 1.

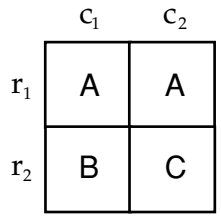


Figure 1. The Forcing Pattern

In Figure 1, c_1, c_2, and r_2 are not constrained but r_1 is completely determined and must be A for the entire pattern in which this subpattern is embedded.

In this article, we'll list the program and describe its more important components.

Data Structures

Columns and rows are treated alike as vectors, for which the record declaration is:

```
record vector(
   index,        # index of this row/column (1–based)
   label,        # row/column label: "rnnn" or "cnnn"
   mchar,        # character used in mapping
   cells,        # colors in row/column cells
   live,         # colors in active row/column cells
   fam,          # color family
   ignored       # non–null if solved or redundant
   )
```

Another record is used to represent the set of vectors that must be the same color:

```
record family
   vset,         # set of vectors
   color         # assigned color (null if not yet set)
   )
```

Two global variables, rows and columns, contain lists of the respective vectors. Each row and column is identified by a unique "mapping" character.

The pattern is represented using the c1 palette with its keys identifying the colors.

Program Organization

The program starts by reading in the pattern, which may be an image file or an image string, and then initializing the data structures.

Next, duplicate rows and columns, as well as solid-colored vectors, are "removed" by marking them "ignored". This may reduce the problem size significantly.

The main loop in the program then iterates over the pattern, developing constraints and setting colors determined by instances of the forcing pattern.

If at any time the pattern can be completely solved by arbitrarily assigning any remaining unspecified colors, the problem is solved. Otherwise, all 2×2 subpatterns are examined for instances of the forcing pattern. If a forcing pattern is found, the colors it forces are set and the loop continues.

If at any point there are no more instances of the forcing pattern, an attempt is made to assign colors to the remaining vectors arbitrarily. If this succeeds, the pattern is solved. If it fails, the pattern cannot be solved.

Procedures

Here's an overview of the procedures in the program:

- active() generates the active vectors in a list.
- addvector() adds a vector.
- chkforce() checks forced colorings.
- dupls() checks for duplicate vectors.
- quad() finds forcing patterns.
- samecolor() links two vectors that must be the same color.
- setcolor() sets a vector to a color and checks the consequences.
- setmaps() resets mapping strings for active vectors.
- setpattern() initializes the data structures.
- solids() checks for families of vectors that are all one color.
- success() reports a successful solution.
- trivial() determines if the pattern can be solved by arbitrary color assignment.

- vectmap() concatenates the mapping characters of active vectors.

Figure 1 shows a procedure call graph for the program.

Program Listing

Here's a somewhat abbreviated listing of the program. Initialization, diagnostics, information logging, and code to display the output have been omitted. The complete program is available on the Web site for this issue of the Analyst.

   s := ""
   every v := active(vlist) do
      s ||:= v.mchar
   return s

end
```

Output

On completion, the program writes a line indicating whether or not the pattern could be solved. An enlarged version of the pattern then is displayed in a window with row and column color assignments along the top, bottom, and sides. If the pattern could not be solved, the colors just reflect the program state at termination. Figure 3 shows a solved color pattern. This image is much better viewed in color; see the Web site for this issue of the Analyst.

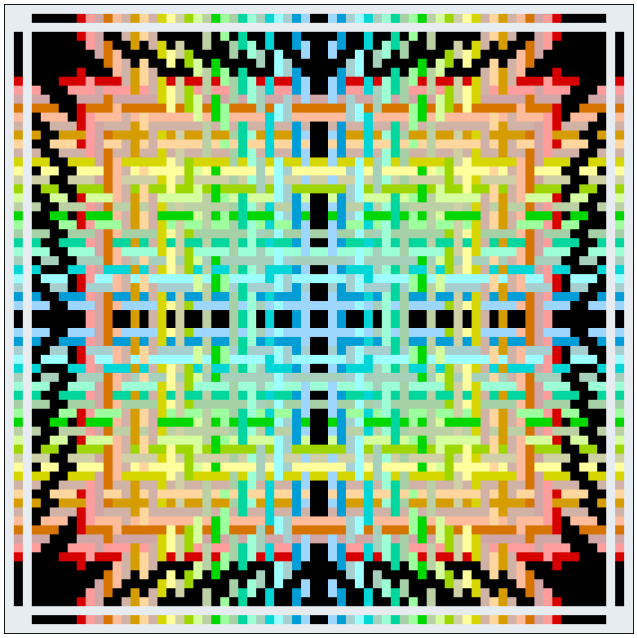

Figure 3. Solution

Command-Line Options

The program supports several command-line options that are not shown in the listing above:

- –b Run in batch mode (no window for results).
- –d Show details of solution on standard error output.
- –n No shortcuts; retain solid and duplicate vectors.
- –r Raw output to standard output of columns, rows, and grid data.
- –t Provide timing information.
- –v Write verbose commentary to standard output.

Comments About the Program

The c1 palette is used because it is the largest palette all of whose keys are "printable". This simplified program development and debugging as well as the representation of colors in the program output. Because of the use of the c1 palette, at most 90 colors in a pattern can be discriminated. In practice, weaves rarely have many colors, so this is not a problem for patterns that might actually be woven. However, the colors shown in the result may be slightly different than the original colors, or worse, different colors may be mapped into the same color (yarns used in weaves sometimes differ only subtly in color).

The maximum number of colors could be increased to 256 by using the c6 palette. This would make some of the keys used "unprintable" unless they were written with escapes.

The problem with color discrimination could be removed by using a custom palette [2].

Because characters are used to identify rows and columns, the maximum size of an image the program can handle is 256×256. This limit is a result of the coding techniques used but not of the method.

If you looked closely at the code, you may have wondered about the line

```
shuffle(wlist)
```

at the beginning of quad(). This deliberately disorganizes the vectors on the theory that adjacent vectors are more likely to be similar than randomly chosen ones, so that if one is unproductive, it's likely the next one is. (Recall that quad() returns after finding the first forcing pattern.) This heuristic has not been tested.

An alternative would be to sort the vectors by the number of colors they contain on the theory that vectors with more colors are more likely to have forcing patterns.

The program only determines if a color pattern can be woven and, if so, assigns colors. It does not consider floats, which can render the pattern "unweavable" from the standpoint of fabric integrity. See the article **Floats** that starts on page 1.

In most cases, if there is one solution, there are many different solutions. However, even if a program were structured to provide all solutions, there usually would be so many that it would be impractical to find one with the shortest floats. Finding a solution with the shortest floats (or with other constraints) is a much harder problem than determining color weavability.

A related problem is determining the minimum changes that would be needed to render an unweavable pattern weavable.

Timings

As mentioned in the first article on weavable color patterns [1], the combinatorial nature of the problem makes the efficiency of a solution method of paramount importance.

We have three solution methods to compare: the brute-force, try-all-possibilities method, a 2SAT algorithmic solution, and the heuristic solution described here.

We have a general idea of the relative efficiency of the different methods from trying many cases, but we have not conducted systematic timing tests. To give at least one representative example, we used all three methods on a 64×64 pattern (the heuristic method is so fast on smaller problems that it's not possible to get meaningful comparisons with the other methods). Here are the results in CPU seconds on a 400 MHz Linux PC:

heuristic	0.21
2SAT	3.51
brute force	> 1696560.

We don't know how long it would have taken for the brute-force program to complete; we had to terminate the job because of an equipment upgrade. 1,696,560 seconds is about 19.6 *days* — and that's CPU time.

What Remains

The programs give color assignments for weavable color patterns. In order to actually weave a pattern, it's necessary to have a draft — threading and treadling sequences and a tie-up.

We'll show how to convert color thread assignments to a draft in the next article in this series.

Acknowledgment

Will Evans wrote the 2SAT version of the solution.

Understanding Icon's Linker

The Icon compiler produces *ucode*, which consists of instructions for a virtual machine [1]. Ucode files need not comprise a complete program. For example, a module consisting of one or more procedures can be converted to ucode for use in various programs.

Icon's linker combines ucode files and produces executable *icode* files.

Scope Resoluton

The linker performs several tasks, one of the most important of which is resolving the scope of undeclared variables.

If there is a global declaration for a variable in any of the ucode files the linker combines, undeclared variables by that name become global; otherwise they become local.

There are three kinds of global declarations: global, procedure, and record. Except for global, only one global declaration is allowed for a variable.

Elimination of Unreferenced Code

Another function Icon's linker performs is the elimination of global declarations for variables that do not appear explicitly in a program. For example, in the program

```
procedure main()
   while write(*read())
end
procedure uc(s)
   return map(s, &lcase, &ucase)
end
```

the variable uc does not appear in the code and the procedure uc() is eliminated by the linker; the code is unreachable.

The elimination of unreferenced code allows the use of modules in which some procedures are needed without adding the excess baggage for those that are not.

The reduction in the size of icode files can be substantial, especially in programs that use graphics. For example, the simple program

```
link graphics
procedure main(args)
   WOpen("image=" || args[1])
   Event()
end
```

produces a 762-byte icode file. If unreferenced code is not deleted, the icode file is 509,811 bytes! Of course, for more complicated programs that use more of the graphics facilities, the savings are less.

The difficulty with eliminating code that is not explicitly referenced is that it is not necessarily unreachable. String invocation [2] allows any procedure to be referenced by the string name of a variable as opposed to a variable itself. Here's a program contrived to illustrate this:

```
procedure main()
   while write("uc"(read()))
end
procedure uc(s)
   return map(s, &lcase, &ucase)
end
```

In this program there is no occurrence of the variable uc; instead the procedure uc() is called using the string "uc". The linker, on the other hand, eliminates the procedure uc(). The program terminates with a run-time error because there is no code for uc() in the icode file.

The program above is silly, but this program, which applies a procedure name given on the command line, is not:

```
procedure main(args)
   while write(args[1](read()))
end
procedure uc(s)
   return map(s, &lcase, &ucase)
end
```

What happens when this program is executed depends on what's given on the command line. For example, if the program is named xform,

```
xform trim
```

works properly and trims the input file. But

```
xform uc
```

results in a run-time error.

Unfortunately, the symptoms of this problem are mysterious. Looking at the program, uc() is there. Icon novices (and sometimes, in more complicated situations, experienced Icon programmers) search in vain for the cause of such an error. Students learning Icon typically jump to the conclusion that there's a bug in Icon.

About all the advice we can give on this problem is to file it on a list of things to check when a program mysteriously malfunctions because a an expected procedure is not present.

When implicit references to procedures are known to occur, the problem can be avoided by using the invocable declaration. The easiest and safest way is to include

```
invocable all
```

in the program. This prevents Icon's linker from eliminating code. The invocable declaration also can be used with a list of procedures that may be invoked implicitly, as in

```
invocable "uc", "lc"
```

Note the quotation marks.

Listing the procedures that are invocable is, of course, prone to error, especially in large programs that are developed over time.

An alternative, which we prefer, is to add explicit references that do nothing but prevent the linker from removing needed code. For the example given above, an expression consisting of just the variable uc can be added to the main procedure:

```
procedure main(args)
   uc
   while write(args[1](read()))
end
procedure uc(s)
   return map(s, &lcase, &ucase)
end
```

The variable uc, standing alone, has no effect on program function.

Linking Information

Icon's linker can provide information about what it does. The command-line option –v*n* controls the "verbosity" of its standard error output as follows:

–v0: no advisory output; equivalent to –s

–v1: default output

–v2: show space allocation in icode file

–v3: also list discarded globals

Typical –v2 output, with space in bytes, is:

```
bootstrap      176
header         108
procedures    3344
records          4
fields           0
globals        208
statics          0
linenums       920
strings        380
total         5140
```

The list of discarded globals shown by –v3 can be quite long. Here's part of the results from linking the small graphics program shown earlier:

```
discarding procedure    args
discarding record       bev_record
discarding global       bev_table
discarding procedure    BevelTriangle
        …     [435 similar lines omitted]
discarding procedure    XPMImage
discarding procedure    XPM_Key
discarding procedure    XPM_RdStr
discarding procedure    XPM_Nth
```

Recurrence Relations

A recurrence relation gives the terms of a sequence as a function of previous terms. For example, the Fibonacci sequence is given by the recurrence

$$a_n = a_{n-1} + a_{n-2}$$

with the initial terms $a_1 = a_2 = 1$ to get the sequence started. Different initial terms produce different but related sequences.

The number of initial terms required is determined by how far back in the sequence terms are specified — called the *order* of the recurrence relation. For example,

$$a_n = a_{n-1} + 2a_{n-3}$$

is a recurrence relation of order 3 and requires three initial terms, a_1, a_2, and a_3, to specify the sequence it produces.

The examples given above are linear recurrence relations with constant coefficients — LRRCs for short — and are instances of the general form

$$a_n = c_1 a_{n-1} + c_2 a_{n-2} + \ldots + c_k a_{n-k} \qquad (1)$$

where only the first powers of previous terms are used and the coefficients are constant.

There are other kinds of recurrence relations. For example,

$$a_n = a^2_{n-1} + a^2_{n-2} + a_{n-4}$$

is a quadratic recurrence of order 4, while

$$a_n = a_{n-1} + na_{n-2}$$

is a linear recurrence of order 2 but with a non-constant coefficient.

LRRCs are important in subjects including pseudo-random number generation, circuit design, and cryptography, and they have been studied extensively. LRRCs also have periodic residue sequences [1], which is the main reason for our interest in them. Despite the importance of LRRCs and the work done on them, much about them remains unknown. Very little of a general nature is known about nonlinear recurrence relations. We'll focus mainly on LRRCs.

LRRCs

LRRC Canonical Form

Equation 1 above shows the canonical form for LRRCs. This form does not provide for a constant term, as in

$$a_n = a_{n-1} + 1$$

The reason for not having a constant term in the canonical form has to do with manipulations of LRRCs in which a constant term would require special handling.

A linear recurrence of order k with a constant term can be converted to a linear recurrence of order $k+1$ in canonical form. Consider the example above:

$$a_n = a_{n-1} + 1 \qquad (2)$$

From this it follows that

$$a_{n-1} = a_{n-2} + 1 \qquad (3)$$

Subtracting Equation 3 from Equation 2, we get

$$a_n - a_{n-1} = a_{n-1} + 1 - a_{n-2} - 1$$

and hence

$$a_n = 2a_{n-1} - a_{n-2}$$

which is in the required canonical form.

Problems Related to LRRCs

There are many interesting problems related to LRRCs. In the article on residue sequences, we touched on the properties of their residue sequences. Other problems of interest are:

- computing the sequence for an LRRC
- determining if a sequence can be represented by an LRRC and, if so, finding it
- solving an LRRC to produce an explicit formula for its nth term

An LRRC Generator

An LRRC can be completely characterized by two lists: one containing its coefficients and another containing its initial terms. For an LRRC of order k, both lists are of length k. For example, the recurrence relation

$$a_n = a_{n-1} + 2a_{n-3}$$

has the coefficient list [1, 0, 2]; the initials list, as always, determines the actual sequence. For example, the initials list [1,1,0] produces the sequence

1, 1, 0, 2, 4, 4, 8, 16, 24, 40, 72, 120, …

Following the model for the Fibonacci sequence given in the article on residue sequences [1], here's a general-purpose generator for LRRCs:

```
procedure lrrcseq(terms, coeffs)
  local i, term

  suspend !terms

  repeat {
    term := 0
    every i := 1 to *coeffs do
      term +:= terms[i] * coeffs[-i]
    suspend term
    get(terms)
    put(terms, term)
    }

end
```

Finding LRRCs

Many sequences can be represented by LRRCs, even if the recurrences are not obvious.

The *difference method* often works and it can be done by hand or with a simple program [2]. This method starts with a row containing the terms of the original sequence. The second row consists of the differences of successive terms in the first row, and so on. The rows are labeled Δ^0, Δ^1, Δ^2, … . Here's an example:

Δ^0	1	7	18	34	55	81	112	148	189	…
Δ^1		6	11	16	21	26	31	36	41	…
Δ^2			5	5	5	5	5	5	5	…
Δ^3				0	0	0	0	0	0	…

If a constant row appears, as it does in this example, the process is complete, there is an LRRC, and it can be obtained by using Equation 4 below, which is a consequence of the way the differences are computed:

$$\Delta^k a_n = \sum_{i=0}^{k} (-1)^i \binom{k}{i} a_{n+k-i} \qquad (4)$$

where $\binom{k}{i}$ is the binomial coefficient

$$\binom{k}{i} = \frac{k!}{(k-i)!\,i!}$$

To get an LRRC in canonical form, it is necessary to go to a row of zeroes; Δ^3 in this case. Therefore, by Equation 4

$$\Delta^3 a_n = \sum_{i=0}^{3} (-1)^i \binom{3}{i} a_{n+3-i} = 0$$

Expanding this, we get

$$\binom{3}{0} a_{n+3} - \binom{3}{1} a_{n+2} + \binom{3}{2} a_{n+1} - \binom{3}{3} a_n = 0$$

and hence

$$a_{n+3} - 3a_{n+2} + 3a_{n+1} - a_n = 0$$

from which we get the LRRC

$$a_n = 3a_{n-1} - 3a_{n-2} + a_{n-3}$$

The initial terms are, of course, the first three in Δ^0.

Here's a program to produce LRRCs by the method described above. The sequence is read from standard input.

```
link lists
link math

procedure main()
  local sequence, order, sol, i, original, initials, c

  original := [ ]

  while put(original, integer(read()))

  sequence := copy(original)

  order := 0

  until c := constant(sequence) do {
    sequence := delta(sequence)
    order +:= 1
    if *sequence = 0 then
      stop("No recurrence relation found")
    }

  if c > 0 then order +:= 1

  initials := original[1+:order]

  sol := [ ]

  every i := 1 to order do
    put(sol, (-1 ^ (i + 1)) * binocoef(order, i))

  write("recurrence of order ", order)
  write("coefficients: ", limage(sol))
  write("initial values: ", limage(initials))

end

procedure delta(seq)
  local deltaseq, i

  deltaseq := [ ]

  every i := 2 to *seq do
    put(deltaseq, seq[i] - seq[i - 1])

  return deltaseq

end

procedure constant(seq)
  local c

  c := seq[1]
```

```
   if !seq ~= c then fail
   else return c
end
```

The output for the sequence given earlier is

```
recurrence of order 3
coefficients: [3,–3,1]
initial values: [1,7,18]
```

Any recurrence derived from a finite number of terms is, of course, conjectural.

Explicit Formulas for LRRC Terms

Any sequence that leads to a 0 Δ sequence can be represented by a polynomial in n. Conversely, all polynomials in n can be represented by a single LRRC; the coefficients of the polynomial only affect the initial terms for the LRRC.

This follows from another equation that results from the method of differences:

$$a_{n+m} = \sum_{k=0}^{n} \binom{n}{k} \Delta^k a_m \qquad (5)$$

From this, we can obtain an explicit formula for the nth term of the corresponding LRRC. Setting m to 1 in Equation 5 gives

$$a_{n+1} = 1\binom{n}{0} + 6\binom{n}{1} + 5\binom{n}{2} + 0\binom{n}{3}$$

(1, 6, 5, and 0 are the leading terms in Δ^0, Δ^1, Δ^2, and Δ^3.) This evaluates to

$$a_{n+1} = 1 + \frac{7}{2}n + \frac{5}{2}n^2$$

Implementing this is similar to finding LRRCs by the difference method. We're out of space, so we'll leave it as an exercise.

What's Coming Up

In the next issue of the Analyst, we plan to have another article on tie-ups, an article on creating drafts for weavable color patterns, and a second article on classical cryptography.

Continuing the series related to periodic sequences, we plan an article on continued fractions, and in particular those for quadratic irrationals.

For the **Graphics Corner**, we expect to have an article on an interactive application for constructing custom palettes.

Shaft Arithmetic

Editors' Note: This article was adapted from one designed as a tutorial for weavers without a technical background. We have added program material only near the end.

Shafts and treadles of looms are numbered for identification [1]. The numbers of the shafts through which successive warp threads pass form a sequence, as do the numbers of the treadles for successive picks. Consider the draft shown in Figure 1, in which the arrows indicate the orientation:

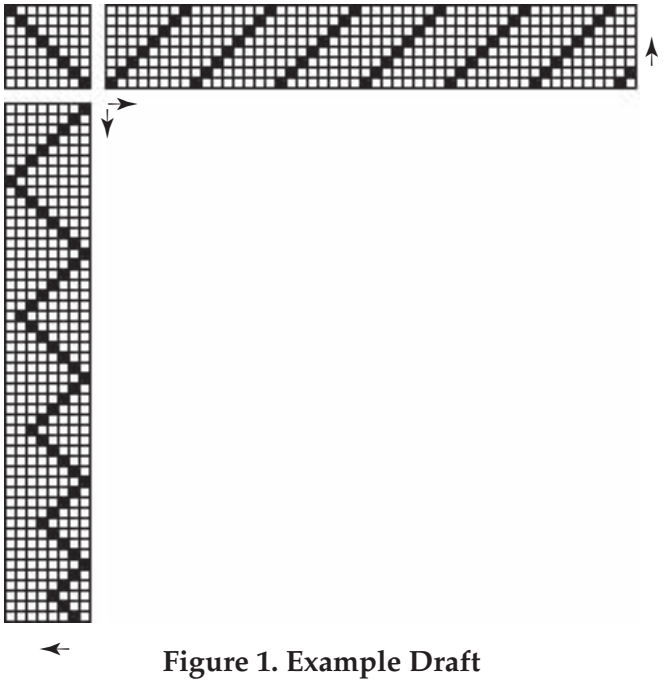

Figure 1. Example Draft

The threading is an upward straight draw. The sequence is:

1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5,
6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, 1, 2,
3, 4, 5, 6, 7, 8, 1, 2

The treadling sequence is more complicated:

1, 2, 3, 4, 5, 6, 7, 8, 7, 6, 5, 4, 3, 2, 1, 2, 3, 4, 5, 6, 7,
6, 5, 4, 3, 2, 1, 2, 3, 4, 5, 6, 5, 4, 3, 2, 1, 2, 3, 4, 5, 4,
3, 2, 1, 2, 3, 4, 3, 2

These two sequences, in combination with the tie-up, define the structure of the weave.

Threading and treadling sequences often have distinctive patterns, as in the repeat for the threading sequence above. In the case of a repeat, it's only necessary to know the basic unit, which we'll indicate by an overbar:

$$\overline{1,2,3,4,5,6,7,8}$$

Modular Arithmetic

Since looms have a fixed number of shafts and treadles, the sequences are most easily understood

in terms of modular arithmetic, sometimes called clock or wheel arithmetic, in which numbers go around a circle clockwise, starting with 0. If there are 8 shafts, there are 8 equally spaced points on the circle 0 to 7, as shown in Figure 2:

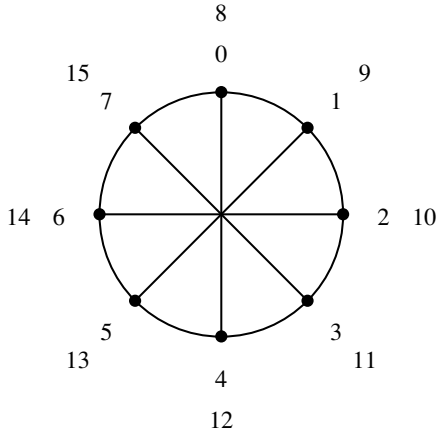

Figure 2. Arithmetic Modulo 8

The numbers on the inner circle are those that exist in the modular arithmetic. If we continue beyond 7, as shown in the outer ring, the numbers wrap around the wheel. Numbers on the same spoke are equivalent. For example, 0 and 8 are equivalent, 1 and 9 are equivalent, 2 and 10 are equivalent, and so on. Another way to look at it is that when 9 is introduced into modular arithmetic with 8 shafts, it *becomes* 1, and so on.

Shaft Arithmetic

Although modular arithmetic uses the number 0 as a starting point, most persons count from 1. Shafts and treadles are numbered this way. This 1-based numbering system is easily accommodated by rotating the wheel counterclockwise by one position, as shown in Figure 3:

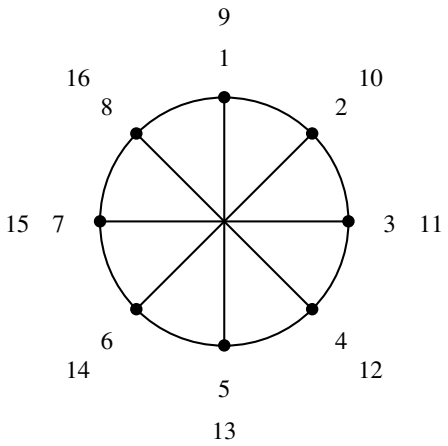

Figure 3. Shaft Arithmetic Modulo 8

Notice that 1 and 9 are still equivalent, as are 2 and 10, and so on. 0 has gone away, but it will be back.

For sequences, shafts and treadles are handled the same way, so we'll call this *shaft arithmetic*, with the understanding that it applies to treadles also. Of course, most facts about shaft arithmetic hold for ordinary modular arithmetic.

In shaft arithmetic, an upward straight draw for 8 shafts is described by the positive integers in sequence:

1, 2, 3, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, …

and wrapped around the shaft circle to produce

1, 2, 3, 4, 5, 6, 7, 8, 1, 2, 3, 4, 5, 6, 7, 8, …

The point is that an upward straight draw comes from the most fundamental of all integer sequences, the positive integers in increasing order. (We'll discuss downward straight draws later.)

Drafting with Sequences

The idea behind drafting with sequences is that many sequences have interesting patterns, which often become more interesting in shaft arithmetic. In fact, many sequences show repeats when cast in shaft arithmetic. For example, the shaft sequence for an upward straight draw for 8 and 10 shafts are represented by

$$\overline{1,2,3,4,5,6,7,8}$$

and

$$\overline{1,2,3,4,5,6,7,8,9,10}$$

respectively.

Patterns in Sequences

Sequences may produce interesting woven patterns when they are used for threading and treadling.

There are a great many well-documented integer sequences. The Fibonacci sequence, which has many connections in nature, design, and mathematics, is one of the best known and most thoroughly studied of all integer sequences. The Fibonacci sequence starts with 1 and 1. Then each successive number (*term*) is the sum of the preceding two:

1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, …

As the sequence continues, the numbers get

very large. For example, the 50th term in the Fibonacci sequence is more than 12 billion. Shaft arithmetic brings this sequence under control. For 8 shafts, the result is

1, 1, 2, 3, 5, 8, 5, 5, 2, 7, 1, 8, 1, 1, 2, 3, 5, 8, 5, 5, 2,
7, 1, 8, 1, 1, 2, 3, 5, 8, 5, 5, 2, 7, 1, 8, …

As you can see, there is a repeat, so the entire sequence can be represented by

$$\overline{1,1,2,3,5,8,5,5,2,7,1,8}$$

Patterns in sequences are more easily seen if they are plotted, as in the grids used in weaving drafts. For 8 and 12 shafts, the Fibonacci sequence are shown in Figures 4 and 5:

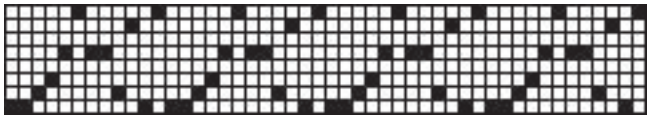

Figure 4. Fibonacci Sequence for 8 Shafts

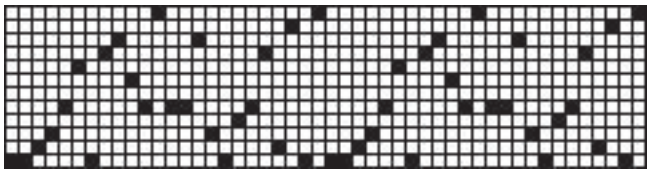

Figure 5. Fibonacci Sequence for 12 Shafts

Here are some other simple sequences and what they look like for various numbers of shafts.

Figure 6. The Squares for 5 Shafts

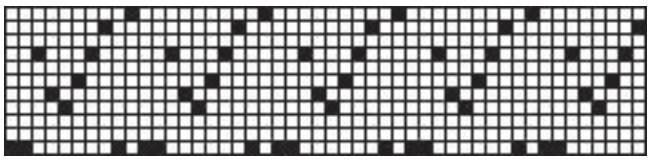

Figure 7. Fibonacci Cubes for 11 Shafts

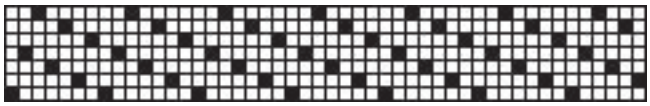

Figure 8. Every Third Positive Integer for 7 Shafts

The patterns such sequences produce in weaves depend on many factors. To keep things simple to begin with, we'll use direct tie-ups and treadling as drawn in (that is, the same sequence for the threading and the treadling) [2]. Even in this very limited framework, interesting woven patterns abound.

Figure 9 shows a drawdown for a few repeats of the Fibonacci sequence for 4 shafts:

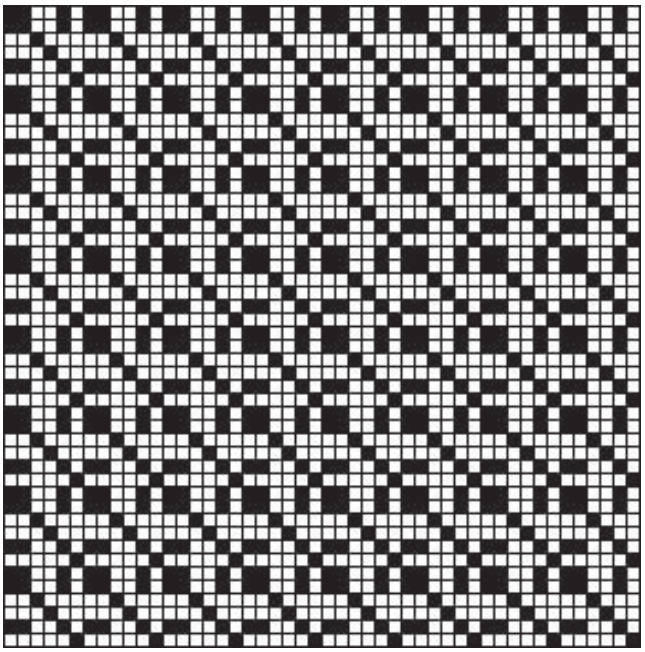

Figure 9. Fibonacci Drawdown for 4 Shafts

The pattern is noticeably different for 8 shafts, as shown in Figure 10. If you compare the two, however, you'll see commonalities:

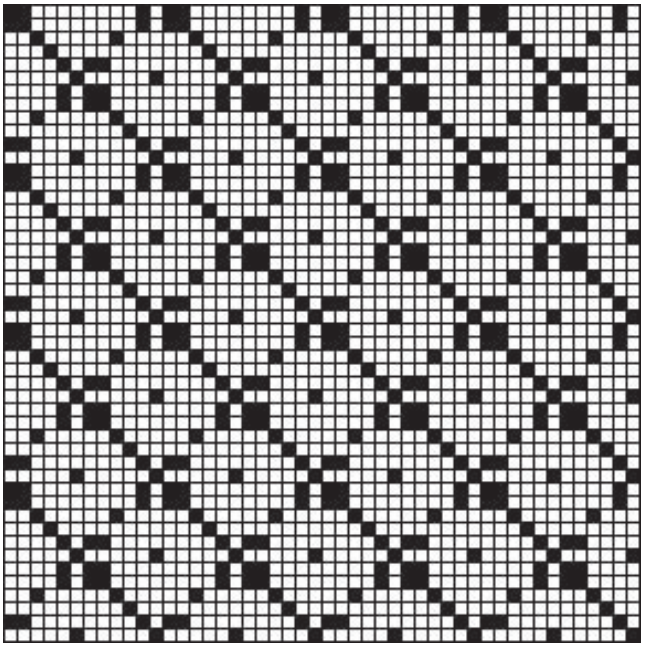

Figure 10. Fibonacci Drawdown for 8 Shafts

A simple sequence that produces interesting patterns is the "multi" sequence, which starts with a single 1 and is followed by 2 copies of 2, 3 copies of 3, and so on:

1, 2, 2, 3, 3, 3, 4, 4, 4, 4, 5, 5, 5, 5, 5, 6, 6, 6, 6, 6, 6, …

Note that there are no repeats in shaft arithmetic for this sequence, since the "width" of the repeated integer blocks constantly increases.

The drawdown for the multi sequence for 4 shafts is shown in Figure 11.

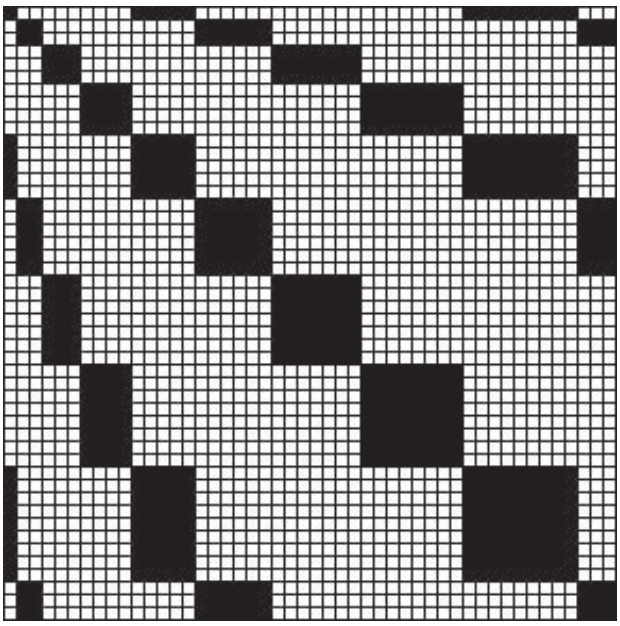

Figure 11. 4-Shaft Multi Sequence Drawdown

One way to produce interesting sequences is to combine other sequences, such as interleaving the terms of two sequences. For example, interleaving the positive integers and the Fibonacci sequence produces

1, 1, 2, 1, 3, 2, 4, 3, 5, 5, 6, 8, 7, 5, 8, 5, 1, 2, 2, 7, 3,
1, 4, 8, 5, 1, 6, 1, 7, 2, 8, 3, 1, 5, 2, 8, 3, 5, 4, 5, 5, 2,
6, 7, 7, 1, 8, 8 …

A drawdown for 8 shafts is shown in Figure 12.

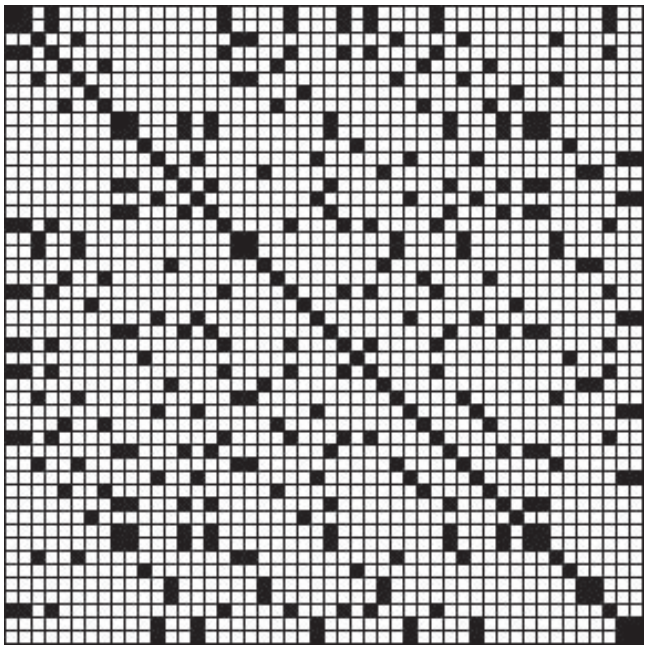

Figure 12. Interleaved Integer and Fibonacci Sequences for 8 Shafts

Other tie-ups, as well as threading sequences and treadling sequences that are different, produce all kinds of interesting results.

Zero and Negative Integers

There's one more matter to be dealt with — zero and negative numbers. Weavers drafting on the basis of sequence usually just drop such numbers or take the absolute values of negative numbers. The proper way to deal with these is indicated by looking at what happens when you have negative integers in increasing sequence as they cross over to the positive integers:

…, –7, –6, –5, –4, –3, –2, –1, 0, 1, 2, 3, 4, 5, 6, 7, 8, …

Now think of the modular wheel and what happens if you wrap this sequence of numbers around it. See in Figure 13.

Supplementary Material

Supplementary material for this issue of the Analyst, including program material, images, and Web links, is available on the Web. The URL is

http://www.cs.arizona.edu/icon/analyst/iasub/ia57/

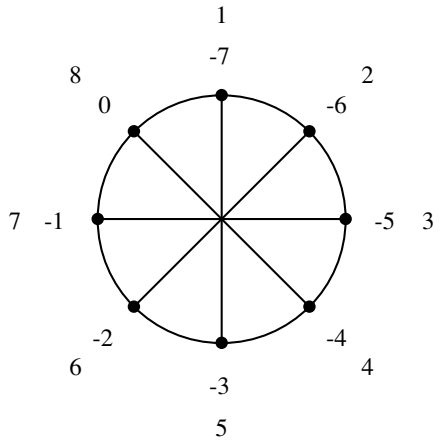

Figure 13. Negative Shaft Arithmetic Modulo 8

In other words, –1 becomes 7, –2 becomes 6, and so on. Note that 0, which we've been hiding, becomes 8.

Perhaps you now see the integer sequence that produces a downward straight draw:

0, –1, –2, –3, –4, –5, –6, –7, –8, –9, –10, …

All that's needed to convert a non-positive remainder to a shaft number is to add it to the number of shafts. For –1, for example,

8 + (–1) = 7

The Programming View

Icon's remaindering operation, i % j, produces the remainder of i divided by j. The sign of the result is the sign of i. Therefore, –7 / 3 produces –1. But the *common residue* (usually just residue) [3] in modular arithmetic is defined to be the remainder of i divided by j but given between 0 and j – 1. This is what the wheel shows.

A procedure to produce the residue is

```
procedure residue(i, j)
   i := i % j
   if i < 0 then i := j + i
   return i
end
```

This procedure can be modified to give results with indexing based on a number other than 0:

```
procedure residue(i, j, k)
   /k := 0
   i := i % j
   if i < k then i := j + i
   return i
end
```

Since k defaults to 0, if the third argument is omitted the usual residue is produced, but if k is 1, we get the *shaft residue*.

Incidentally, the underlying sequence for an upward straight draw is given by seq(1), while the sequence for a downward straight draw is given by –seq(0).

Periodic Sequences

A periodic sequence is an infinite sequence in which a finite subsequence repeats indefinitely. The digits of the mantissa (see the side-bar on the next page) of the decimal expansion of 1/7 provide an example:

1, 4, 2, 8, 5, 7, 1, 4, 2, 8, 5, 7, …

A periodic sequence may have a pre-periodic part before the repeat, as in the digits of the decimal expansion of 1/12:

0, 8, 3, 3, 3, 3 …

Sequences with pre-periodic parts are called *quasi-periodic*; those without pre-periodic parts are call *strictly periodic*.

There are many mathematical sources of periodic sequences. The main ones are:

- residues of terms of non-periodic sequences
- decimal (and other base) expansions of fractions
- denominators of continued fractions for quadratic irrationals
- samples of periodic functions like sin(*x*)

There probably are others we haven't thought of, and there's always the miscellaneous category.

Mantissa

If you look in a dictionary, the definition you'll most likely find for mantissa is that it's the decimal part of a logarithm.

In mathematics, the term has a more general meaning as the fractional part of a real number [1]:

$$\text{mantissa}(x) = x - \lfloor x \rfloor$$

where $\lfloor x \rfloor$ is the floor of x, the largest integer less than or equal to x.

The first use of the term mantissa in this way is attributed to Gauss.

A procedure to produce the mantissa of a real (floating-point) number would be trivial except for the possibility that the string representation may be in scientific notation, such as "2.45e–2".

This is just a messy detail of the kind that infests programming. Here's a procedure:

```
link numbers

procedure mantissa(r)
   local fpart

   r := real(r)

   fpart := r – floor(r)       # from numbers module

   fpart ?:= {
      tab(upto('.') + 1)
      tab(0)
      }

   fpart ? {
      if fpart := tab(upto('Ee')) then {
         move(1)
         if = "+" then fpart := "0"
         else {
            move(1)
            fpart := repl("0", tab(0) – 1) || fpart
            }
         }
      }

   return "." || fpart

end
```

There are many things of interest about periodic sequences: their periods, the values they contain, the patterns of values, and so on. But before we explore these areas, we need to discuss notation and the representation of periodic sequences in data and programs.

Notation and Representation

Sequences usually are written with terms separated by commas as shown in preceding examples. Sometimes other separators, such as blanks, are used, but commas make the separation of terms easier to see and we'll use commas here.

For periodic sequences, it's conventional to use a bar over the repeat, as in

$$\overline{1,4,2,8,5,7}$$

and

$$0,8,\overline{3}$$

Like many forms of mathematical notation, bars over text are typographically difficult. Word processors and page layout systems generally do not support them, since they cannot be composed from characters, unlike underscores, which come with font families. (Recall that we used underscores to indicate repeated digit patterns in versum numbers [1].) We've had to go to a program specifically designed for laying out mathematical expressions to provide the examples here.

When representing sequences as strings for processing by programs, neither overbars nor underscores are available. The string representation we chose is to enclose repeats in brackets, as in

```
"[1,4,2,8,5,7]"
```

and

```
"0,8,[3]"
```

Strings are awkward and inefficient to process in a program. For finite sequences we usually use lists, which are sequences by definition and might have been so named. Since the repeat in a periodic sequence is finite, we can represent periodic sequences by a pair of lists: a pre-periodic part (possibly empty) and repeat. A record brings these together in a single (defined) type:

```
record perseq(pre, rep)
```

Examples are

```
one_seventh := perseq([], [1, 4, 2, 8, 5, 7])
```

and

```
one_twelveth := perseq([0, 8], [3])
```

Note that a finite sequence can be represented in this way also by using an empty repeat, as in

```
one_eighth := perseq([1, 2, 5], [])
```

It's worth mentioning that for sequences consisting of single digits, strings could be used in place of lists, as in

```
one_twelveth_s := perseq("01", "3")
```

Several operations apply to both strings and lists. For example,

```
!one_twelveth
```

and

```
!one_twelveth_s
```

generate equivalent results, although the first produces integers and the latter one-character strings, which in numerical contexts are converted to integers automatically.

Although strings require less memory than lists, there are potential pitfalls and we'll generally avoid this "shortcut".

There is another possibility for representing the periodic part of a sequence — as a list whose last element points to the list itself. Thus,

```
one_seventh_p := [1, 4, 2, 8, 5, 7]
put(one_seventh_p, one_seventh_p)
```

can be visualized as shown in Figure 1.

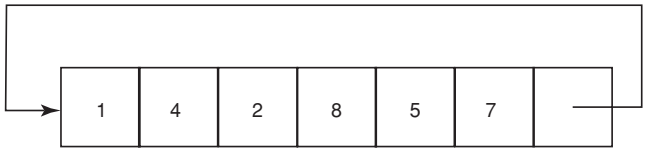

Figure 1. A Looping Structure

Programs that process such a representation need to take it into account, as in this procedure, which generates the elements of a repeat:

```
procedure genelem(rep)
   local x

   repeat {
      every x := !rep do {
         if type(x) == "list" then {
            rep := x
            break next                  # go to repeat loop
            }
         else suspend x
      break                             # exit if finite
      }
end
```

There is no need for this extra complexity in our consideration of periodic sequences, but the representation is useful in more general contexts, which we'll discuss in a later article on "packet sequences".

Next Time

In the next article on periodic sequences, we'll explore the role of modular arithmetic in the creation of periodic sequences. See the article **Shaft Arithmetic**, which begins on page 1, for a hint of what's in store.

1. "Versum Factors", Icon Analyst 40, p. 9-14.

Finding Repeats

Given a finite portion of a sequence that is known to be periodic or that might be, how do you find the repeat?

In the first place, the problem is not well defined. For example, given the terms

0, 1, 2, 3, 4, 5, 6, 7

it might seem obvious that the next term is 8. However, if this sequence is the initial portion of the nonnegative integers mod 8, the next term is 0. The next term could, of course, be anything.

Even though the problem is not well defined, it's still possible to make useful guesses.

The method for finding a possible repeat is not conceptually difficult. You just try initial subsequences until one, when repeated, matches the rest of the sequence. If there is none, you remove the initial term and add it to a sequence for a pre-periodic part (initially empty) and start over. Eventually this process terminates, either with a possible repeat or with all the terms in the pre-periodic part. Here's a procedure:

```
link lists

record perseq(pre, rep)

procedure repeater(seq, ratio, limit)
   local init, i, prefix, results, segment, span

   /ratio := 2
```

```
    /limit := 0.75

    results := copy(seq)

    prefix := []

    repeat {
       span := *results / ratio
       every i := 1 to span do {
          segment := results[1+:i] | next
        if lequiv(lextend(segment, *results), results) then
             return perseq(prefix, segment)
          }
       put(prefix, get(results)) |    # first term to prefix
          return perseq(prefix, results)
      if *prefix > limit * *seq then return perseq(seq, [ ])
       }

end
```

The argument sequence is copied, so that it is not modified. The list prefix holds the potential pre-periodic part.

The variable ratio determines how long the repeat can be as a fraction of the length of the sequence and is designed to allow a reasonable determination of a repeat. The default, 2, ensures that the original sequence has at least two full repeats.

The variable limit prevents a very long a pre-periodic part with a short repeat at the end, which usually is erroneous.

In the repeat loop, initial subsequences from 1 to the allowed maximum are tried. For each, the subsequence is extended by repeating to the length of the sequence using lextend() from the lists module of the Icon program library.

If the two lists are equivalent, using lequiv(), also from the lists module, a possible repeat has been found and the procedure return with a record containing the pre-periodic part and the repeat.

If the two lists are not equal, the initial term of the current sequence is removed, appended to the pre-periodic part, and the loop is repeated. If the sequence is exhausted without finding a repeat, the procedure returns a record with all of the original sequence in the pre-periodic part and an empty repeat.

The procedure lextend() is a list version of the weaving procedure Extend() [1]:

```
procedure lextend(L, i)
   local result

   result := copy(L)

   until *result >= i do
      result |||:= L

   result := result[1+:i]

   return result

end
```

We'll come back to lequiv() later.

Figure 1 shows output from an instrumented version of repeater().

```
pre-periodic part:  []

```

Figure 1 (concluded). Finding a Repeat

As we mentioned earlier, the problem of finding a repeat is not well defined. The procedure may fail to find a repeat because there are not enough terms. More serious, perhaps, is a "false positive" in which a potential repeat is found but it is not a repeat in a longer portion of the entire sequence.

Neither of these problems can be avoided altogether, so it is well to treat the results with reservations.

Performance Issues

A brute-force approach like this can be very slow, especially for long sequences in which no repeat is found. As mentioned earlier, this may occur even when there is a repeat if the sequence given does not have enough terms. This is a caution

to the user to provide an adequate numbers of terms. The downside of this is that if there is no repeat, the procedure takes even longer.

If you look at Figure 1, you no doubt will see ways to improve the performance of the procedure. Suggestions are welcome. Send e-mail to

icon-analyst@cs.arizona.edu

Hidden in the library code is a source of inefficiency that has nothing to do with repeater(). The procedure lequiv() is designed to handle lists in their most general form, in which list elements can be of any type, included structures:

```
procedure lequiv(x,y)
   local i

   if x === y then return y
   if type(x) == type(y) == "list" then {
      if *x ~= *y then fail
      every i := 1 to *x do
         if not lequiv(x[i], y[i]) then fail
      return y
     }
end
```

For lists of numbers, this generality is not needed and the following somewhat faster procedure will do:

```
procedure seqequiv(seq1, seq2)
   local i

      every i := 1 to *seq1 do
         if seq1[i] ~= seq2[i] then fail

      return seq2

end
```

This improvement is, of course, minor compared to the combinatorial nature of the problem.

Name Drafting

Many handweavers simply weave from the large number of drafts that are available in books and magazines about weaving. These weavers may make minor modifications, but the designs they weave are the creations of others.

The measure of "real" handweavers is the desire and ability to create their own designs.

Weavers who have woven only from the drafts of others often come to the point where they want to design their own drafts — to become "real" handweavers. But how to start?

A type of weaving known as *name drafting* often is recommended for this situation. (Name drafting also is known as name code drafting, code drafting, commemorative drafting, and personalized design.)

Although name drafting is naive in concept, as you'll see, it does provide an easy bridge between copying the work of others and creating new designs.

Mapping Strings into Draft Sequences

The basic idea is simple: A string — a word, or more often, a phrase or sentence — is coded to make shaft and treadling sequences. Such drafts usually are treadled as draw in, with the same sequence used for both the threading and treadling, so we'll just refer to threading sequences here.

The coding assigns a shaft number to each character of the selected string. Although any method of associating shafts with characters could be used, only a few appear in the literature [1-6] and weavers generally are instructed to use one of these. Three codings that commonly are used for four shafts are:

ABCDEFG	shaft 1
HIJKLMN	shaft 2
OPQRSTU	shaft 3
VWXYZ	shaft 4
ABCDEF	shaft 1
GHIJKL	shaft 2
MNOPQR	shaft 3
STUVWXYZ	shaft 4
AEIMQUY	shaft 1
BFJNRVZ	shaft 2
CGKOSW	shaft 3
DHLPTX	shaft 4

Using a specified coding formula is an example of the dominating role of rote among unsophisticated weavers. It also is telling that only letters are considered and that upper- and lowercase letters always are taken to be equivalent. This is akin to the problem of a person who is not familiar with computing and has trouble with the fact that a blank is just a much character as X. Surprisingly, to this day this problem exists with beginning computer science students.

One problem in choosing a mapping between characters and shaft numbers is whether some shafts will be underutilized or not used at all. There are strong statistical patterns in the frequency in which characters appear in written text (usually considered only in terms of letters). Average frequencies vary with the subject and the language. It's well known that in English, e is the most commonly used letter and q and z are the least.

Letter frequency is an important aspect of some kinds of cryptography and we'll discuss it in more detail in that context in an upcoming article.

The mapping can be chosen to try to balance shaft usage, but any predefined mapping can be defeated by a particular string — not to mention the fact that the string chosen may not contain as many different characters as there are shafts to be used. In practice, strings are chosen to work around such problems.

Modifying Sequences for Weaving

Name drafts usually employ a kind of weaving called *overshot* [7-8] in which a pattern is woven over a background texture. A technical requirement of overshot is that the shaft numbers alternate between odd and even. This problem is solved by adding "incidentals" where necessary to break odd and even pairs that arise from the coding.

The result usually is better if this is done in a systematic way. OddEvenPDCO{} in Icon Analyst 55 [9] works nicely (and corresponds to what name drafters usually do, although the directions for doing it are often are given on a case-by-case basis and fail to reveal a general method). The idea is simple: When a prohibited pair occurs, insert a shaft number one greater than the first member of the pair, wrapping around where necessary using shaft arithmetic (see the article that starts on page 1).

Thus, for four shafts, the sequence

1, 1, 2, 3, 4, 4, 3, 3, 1

becomes

1, 2, 1, 2, 3, 4, 1, 4, 3, 4, 3, 4 1

In practice, weavers often make other modifications to produce more attractive weaves after small trial weaves (called samples). We won't get into that here, since there is no system to it.

Implementing Name Drafting

To implement name drafting, we generalized the conventional interpretation of characters to

include all characters, not just letters. Making upper- and lowercase letters equivalent or disregarding some characters is done by applying an appropriate function to the chosen string. For example,

```
string := map(string)
```

maps uppercase letters to lowercase ones, leaving all other characters unchanged. There are many other relevant uses of map(), including transpositions [10].

Other functions may be useful, such as

```
string := cset(string)
```

which removes duplicate characters and puts the results in lexical order.

The Icon program library module strings contains several procedures that may be useful in this context:

compress(s, c) compresses runs of characters in c that occur in s to a single character.

csort(s) sorts the characters of s but does not remove duplicates.

deletec(s, c) deletes characters in c from s.

fchars(s) orders the characters in s according to decreasing frequency of occurrence.

ochars(s) places the unique characters of s in the order in which they first occur.

Procedures can be written to produce various other effects, including adapting the mapping to the string chosen to balance shaft usage.

The next step is to assign a positive integer to each distinct character of the string. Here's a procedure. Note that it assigns integers in the order in which characters occur.

```
procedure shaftmap(s)
   local j, map_table

   map_table := table()

   j := 0

   every /map_table[!s] := (j +:= 1)

   return map_table

end
```

The table returned then can be used for the actual mapping. Notice that at this point, the result is independent of the number of shafts. When the draft is created, shaft arithmetic is applied to bring the values in range.

The mapping table then can be applied to any string. This procedure generates the shaft numbers:

```
procedure genshafts(s, tbl)

   suspend tbl[!s]

end
```

The two processes can be combined:

```
procedure genmapshafts(s1, s2)

   suspend genshafts(s1, shaftmap(s2))

end
```

Other Aspects of Name Drafting

Name drafts usually are reflected about their centers to add symmetry and increase the visual appeal of the resulting weaves.

As mentioned earlier, name drafting usually is done using an overshot weave. In overshot weaves, the tie-up usually is a twill, which, in its simplest form, produces a diagonal surface effect as shown in Figure 1.

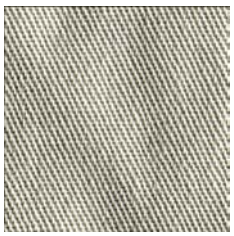

Figure 1. A Twill

The particular twill tie-up used may have a dramatic effect on a weave produced by a name draft. We don't have space here to explore twills, but we'll get to them in a later article.

Name Drafting in Perspective

Certainly name drafting is an *ad hoc* mechanism for producing threading and treadling sequences. Other mechanisms are easy to imagine. In fact, one of the main subjects we'll treat in upcoming issues of the Analyst is drafting based on integer sequences. Name drafting is just one way of getting an integer sequence. See the article **Shaft Arithmetic** that begins on page 1 for examples.

To weavers, however, name drafting can serve a real purpose, which is indicated by the alternative term "commemorative drafting". The string chosen may have a meaning that is personal to the weaver, resulting in a weave embodying this mean-

ing. This aspect of name drafting is sometimes forgotten, however. A recent article on name drafting [6] described the author's attempts to find a phrase that produced an attractive weave, finally settling on "The Random House Dictionary" as the result of glancing at a nearby bookshelf. An attractive weave, yes. A special meaning? Hardly (even according to the author).

Next Time

As mentioned above, we'll explore twills in the future issue of the Analyst. In the meantime, we'll leave you with the name-drafted images in Figure 2. Don't try to figure out the strings used. To have any hope of deciphering a name draft, you need to know the tie-up used. We'll "reveal all" in the next article.

Variations on Versum Sequences

There have been 18 Analyst articles on versum sequences, those sequences that result from repeatedly adding the reversal of a number to itself [1-18]. It's been a year since the last article, not because we lack material but because we had other things to cover and thought a respite from versum sequences was in order.

This article doesn't include anything from our older unpublished versum material but rather introduces some variations on the reverse-addition process.

One variation is characterized by "reverse, add, and then add *j*" where *j* is a fixed integer. For example, with the seed 196, adding 7 produces this sequence:

894	1279101088
1399	10080120816
11337	71882228824
84655	114764457648
140310	961518925066
153358	1622048740242
1006716	4042527142510
7182724	4194944394921
11455548	5489878889842
96010966	7979767679694
162912042	12949535359498
403131310	102444888954426
416262621	726904777398634
542525242	1163798554808268
785050494	9791883113781886
	…

The procedure versumseq(i) from the genrfncs module of the Icon program library was originally designed to generate the ordinary versum sequence. It can easily be generalized to take j as a second argument:

```
procedure versumseq(i, j)
   /i := 196
   /j := 0
   repeat {
      i +:= reverse(i) + j
      suspend i
      }
end
```

Note that i defaults to the infamous 196, while j defaults to 0, so that if the second argument in a call of versumseq() is omitted, the ordinary versum sequence is generated.

There are seveal questions we might ask about this generalization to versum sequences:

- How do such sequences depend on the value of *j*?
- What happens if *j* is negative?
- Do such sequences contain palindromes in the fashion of regular versum sequences?

One of the featured sequences in *The Encyclopedia of Integer Sequences* [19] <1> is characterized by "reverse, add, then sort" (RATS). For example, starting with the seed 1, the sequence is:

2	12333445
4	66666677
8	133333444
16	556667777
77	1233334444
145	5566667777
668	12333334444
1345	55666667777
6677	123333334444
13444	556666667777
55778	1233333334444
133345	5566666667777
666677	12333333334444
1333444	55666666667777
5567777	123333333334444
	…

A procedure to generate such sequences is simple:

```
procedure ratsseq(i)
   /i := 196
   repeat {
      i +:= reverse(i)
      i := integer(csort(i))
      suspend i
      }
end
```

The procedure csort(), from the strings module of the Icon program library, sorts the characters of a string.

RATS sequences raise all kinds of questions, such as:

- Do they ever contain repdigit terms (terms consisting entirely of one digit)?
- Are terms ever pandigital (containing at least one of every digit except, in this case, 0)?

This procedure can be generalized to allow an optional unary operation to be specified:

```
procedure versumopseq(i, p)

   /i := 196

   /p := csort

   repeat {
      i +:= reverse(i)
      i := integer(p(i))
      suspend i
      }

end
```

A further generalization allows for operations with more than one argument:

```
procedure versumopseq(i, p, args[])

   /i := 196

   /p := ochars

   push(args)            # make room for first argument

   repeat {
      i +:= reverse(i)
      args[1] := args    # make i first argument
      i := integer(p ! args)
      suspend i
      }

end
```

For example, versumopseq(1, rotate, 1) rotates the reversal left one digit and produces the following sequence:

2	219991
4	199034
8	300256
61	522599
77	5178241
541	6069566
866	27291721
5341	109934
7766	498355
44431	522491
78755	167167
345421	289289
699644	2722711
1466401	8949833
5130422	23393311
3707377	47326433
14444501	7888078
49889422	65969651
23883167	16666078
37327391	…

Reduction in the numbers of digits occurs when zeros are shifted into leading positions.

Here we might ask if there is a limit to the size of terms.

Incidentally, procedure versumopseq() subsumes ratsseq(), since versumopseq(i, csort) peforms the required operation.

Note that versumopseq(), as written, does not check that p is a valid operation.

There are many other possible variations on the reverse-addition process, such as adding the number of digits to the result or adding the term number to the result.

But what is the point of all this? There are infinitely many variations. Ordinary versum sequences are of interest because of palindromes. What about the others?

If you look at recent Analyst articles on weaving, you'll see the emergence of sequences as an important tool in drafting interesting weaves. Do versum sequences produce interesting weaves? Do variations on versum sequences produce interesting weaves? In a related question, do the residues of versum sequences yield periodic sequences?

We'll address these question in future articles. For now, we'll leave you with some weaves based on versum sequences, both ordinary and with variations, as shown in Figure 1.

Answers to Quiz on Pointer Semantics

See Icon Analyst 56, page 17, for the questions.

1.

(a)

```
L :=[]
put(L, L)
```

(b)

```
L1 := []
put(L1, L1)
L2 := [L1]
```

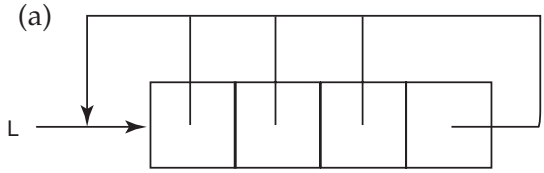
(c) Same as (b) — just drawn differently

(d)

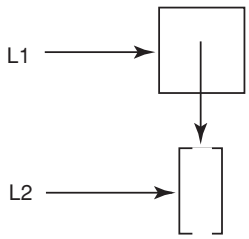
```
L2 := []
L1 := [L2]
put(L2, L2, L1)
```

2.

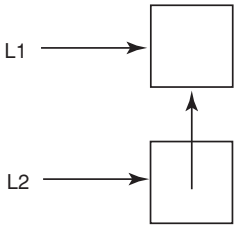
(a)

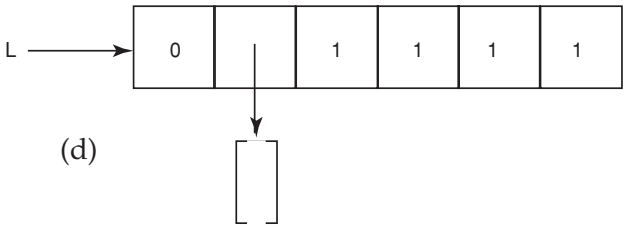


(b)



(c)





(d)

In these diagrams, [ ] indicates an empty list.

It's very easy to make mistakes when working with pointers, especially when the structures involve loops.

There's a very useful procedure in the Icon program library for situations like this: ximage(). We described it in detail in an early **From the Library** article [1]. Here's a program that shows the successive structures in question 2(d):

```
link ximage

procedure main()

   L1 := list(5, 1)
   write(ximage(L1))
   write()
   push(L1, [], L1)
   write(ximage(L1))
   write()
   L1[1] := 0
   write(ximage(L1))
   write()
   pull(L1)
   write(ximage(L1))

end
```

The output of this program is:

```
L1 := list(5,1)

L1 := list(7,1)
   L1[1] := L1
   L1[2] := L5 := list(0)

L1 := list(7,1)
   L1[1] := 0
   L1[2] := L5 := list(0)

L1 := list(6,1)
   L1[1] := 0
   L1[2] := L5 := list(0)
```

Note that the output of ximage() is in the form of executable expressions that can be used to build the structures.

From the Library — Rational Arithmetic

A rational number is just a fraction, the ratio of two integers, p/q, where p and q are integers and $q \neq 0$.

Many numerical computations can be done using floating-point approximations to rational numbers. For example, the value of

```
46368.0 / 75025.0
```

is approximately 0.6180339887, which is quite close to 46368/75025 numerically.

However, you cannot recover 46368/75025 with any certainty from the floating-point value shown above. Several other fractions, such as 121393/196418, give the same floating point value.

For exact computations involving fractions, the Icon program library provides the module rational.

Data Representation

As in all cases like this, it is necessary to provide a standard representation of rational numbers as strings — if only for input and output. The form used for rational numbers consists of two integers separated by slashes and surrounded by parentheses, as in "(46368/75025)". The parentheses isolate rationals in strings from any surrounding string context in which they may be placed. The integers may be signed, as in "(–46368/75025)".

For computation in programs, rational numbers are represented as records:

```
record rational(numer, demon, sign)
```

The sign is 1 or –1 depending on whether the rational number as a whole is positive or negative. Using 1 and –1 allows sign computation by multiplication.

Records for rationals produced by the procedures in rational always are in a canonical form in which the numerator and denominator are positive and reduced to lowest terms (that is, with no common divisor grater than 1). For example, "(6/–14)" is converted to

```
rational(3, 7, –1)
```

The module rational contains the following procedures for converting between types:

rat2str(r)	convert rational to string
str2rat(s)	convert string to rational
rat2real(r)	convert rational to real (floating-point)
real2rat(x)	convert real (floating-point) to rational

There are five procedures for performing rational arithmetic:

addrat(r1, r2)	add rationals
divrat(r1, r2)	divide rationals
mpyrat(r1, r2)	multiply rationals
negrat(r)	form negative of rational
reciprat(r)	form reciprocal of rational

In addition, ratred(r) performs error checking and reduces a rational to its lowest terms.

Problems with Zero

Zero is not allowed as a denominator in rational numbers since division by zero is undefined. A zero denominator may come about from conversion of a string or by division (and, equivalently, forming a reciprocal). If a zero appears for a denominator, a user-defined run-time error occurs.

Zero is allowed as a numerator, but $0/n$ has the same value for all $n \neq 0$. Consequently, if a zero appears for a numerator, rational(0, 1, 1) is produced.

Problems with User-Supplied Rationals

Although the procedures in the module rational always produce values in canonical form, there

is nothing to prevent a user from creating a rational record that is not in canonical form or is erroneous. Possible examples are

```
rational(5, 50, 1)
rational(–5, –2, –1)
rational(0, 0, 1)
rational(2.5, 3.2, 1)
rational(3, 7)
rational("10x", 5, 1)
```

Handling all possible cases is messy. The details are relegated to ratred(), which is called by other procedures in rational to make sure their arguments are legal and in proper form.

Example Procedures

Typical procedures are:

```
procedure addrat(r1, r2)
   local denom, numer, div, sign

   r1 := ratred(r1)
   r2 := ratred(r2)

   denom := r1.denom * r2.denom
   numer := r1.sign * r1.numer * r2.denom +
      r2.sign * r2.numer * r1.denom

   if numer = 0 then return rational(0, 1, 1)

   if numer * demon >= 0 then sign := 1
      else sign := –1

   numer := abs(numer)
   denom := abs(denom)

   div := gcd(numer, denom)

   return rational(numer / div, denom / div, sign)
end

procedure str2rat(s)
   local div, numer, denom, sign

   s ? {
      ="(" &
      numer := integer(tab(upto('/'))) &
      move(1) &
      denom := integer(tab(upto(')'))) &
      pos(–1)
      } | fail

   if denom = 0 then runerr(510, 0))
   if numer = 0 then return rational(0, 1, 1)

   if numer * denom >= 0 then sign := 1
      else sign := –1

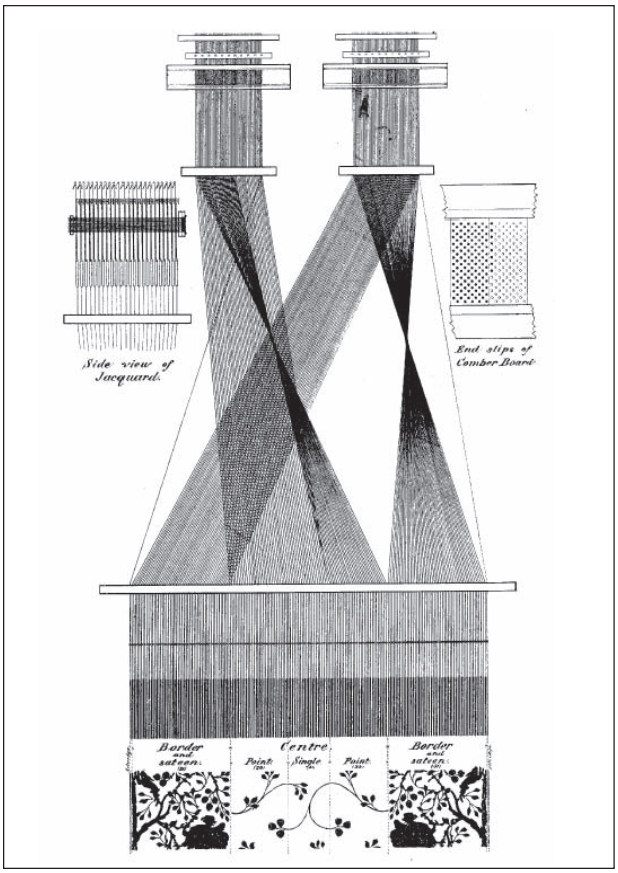
   numer := abs(numer)
   denom := abs(denom)

   div := gcd(numer, denom)

   return rational(numer / div, denom / div, sign)
end
```

New Version of rational.icn

As often happens, writing articles about programs results in their revision. The current version of the module rational is on the Web site for this issue of the Analyst.



What's Coming Up

We had expected to have an article on weavable color patterns for this issue of the Analyst, but we ran out of space and time. This article has high priority for the next issue.

We'll continue the series on periodic sequences with ones that result from modular arithmetic.

We've been planning a series of articles on "classical" cryptography for some time. That's on the table for the next issue.

In **From the Library**, we'll continue the survey of the basic modules in the Icon program library.

Weave Draft Representation

Pattern-Form Drafts Revisited

We designed pattern-form drafts (PFDs) so that patterns in threading and treadling sequences could be preserved [1]. The file format we chose was designed to be compact and to be processed by programs. Each line contains one component of the draft as shown in Figure 1. Notice that the number of shafts and number of treadles are encoded in the tie-up.

Since information is positional and not self-identifying, it is not well suited for manual editing, although that's possible: It's ASCII text with few enough lines that individual components can be identified.

Pattern-form drafts have been central to our work on weave structure. It's important that PFDs can represent all the information we need and do that in a convenient way.

The original format did not handle all aspects of weave structures that we subsequently found to be important, such as liftplans.

As we mentioned in the article about Dobby looms and liftplans [2], liftplans often are large compared to tie-ups. Although using a bit-string representation for liftplans is possible, it's awkward and impractical. And while we once hoped to deal with patterns in tie-ups in a way similar to the what we did with threading and treadling sequences, the kinds of patterns they have require a different approach. This freed us from an immediate need to represent them in drafts in a manner that made their structure evident.

Both liftplans and tie-ups are binary matrices. We therefore decided to us Icon's bi-level pattern format for conciseness (see the **Graphics Corner** article that starts on page 4). An important consideration in making this choice was the existence of several programs and procedures in the Icon program library for creating and manipulation bi-level patterns. The interactive pattern manipulator is described in *Graphics Programming in Icon* [3] is particularly useful.

```
aquadesign                                                                  name
[[1>8]*5][[7<1]8*4]765432[[1>8]*5][[7<1]8*4][7<1]                           threading
[[1>8]*10]                                                                  treadling
[G*20][H*39][G*20][G*19][H*39][G*20]                                        warp colors
[0–>80]                                                                     weft colors
c1                                                                          palette
8;8;1001001111000001111000000111000000111001100101000100101000100101      tie-up
```

Figure 1. A Pattern-Form Draft

It's worth noting that bi-level pattern strings, while compact, are not easy to decipher without the aid of a program. For example, consider the tie-up grid diagram in Figure 2.

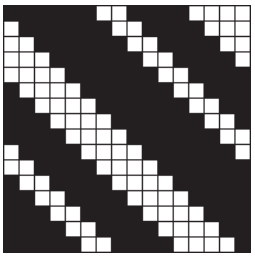

Figure 2. A Tie-Up Grid

The corresponding bi-level pattern is

```
16,#0f3f1e7e3cfc79f8f3f0e7e1cfc39f873f0f7
e1efc3cf879f0f3e1e7c3cf879f
```

This string is 68 characters long compared to the 262 characters the bit-string representation would require.

While we were revamping the PFD format, we decided that we needed more generality in dealing with warp and weft color sequences. Originally they were strings of palette keys. In the new PFD format, they are strings of characters that index a string of palette keys (the character encoding for indexes that are greater than 9 is the same as used in the threading and treadling sequences).

The new PFD format has 11 lines:

name	text
threading	pattern form
treadling	pattern form
warp colors	pattern form
weft colors	pattern form
palette	palette name
keys	palette keys
tie-up	bi-level pattern
shafts	integer
treadles	integer
liftplan	bi-level pattern

The lines for the number of shafts and treadles are included so that it's not necessary to extract them from the tie-up.

The liftplan may be empty. If it is present, the tie-up and treadling may be empty, although in WIFs [1] they usually are included in addition to a liftplan so the draft can be used on a loom without a dobby device.

Problems with Pattern-Form Drafts

Pattern-form drafts have several limitations. The number of shafts and treadles is limited to the number of characters that are available for encoding integers. Although this is not a problem for real looms, some computer weaving programs are capable of dealing with 256 shafts and/or treadles.

The use of palettes instead of actual color values is more limiting than it might seem. Most drafts do not have a large number of colors (although some do). But built-in palettes provide no way for representing, say, 32 equally spaced shades of blue. A more serious practical problem is that some drafts specify combinations of subtly different hues. For these, no Icon color palette may be able to separate them and they may come out to be the same using PaletteKey().

Internal Representation of Drafts

PFD is a file format. In order to manipulate a draft in a program in a reasonable way, it's necessary to convert it to an internal format that typically involves lists and arrays (lists of lists) [4].

It would be useful to be able to save an internal draft as-is and to be able to use it later, perhaps in a different program. The procedures xencode() and xdecode() in the Icon program library module xcode [5], make this easy to do.

In order to encode an entire internal draft structure as a single file, it's necessary to have all the components in one structure — a top-level structure that includes the rest. A record is the natural choice for this.

A record declaration for an internal structure draft (ISD) has 12 fields:

```
record isd(
   name,
   threading,
   treadling,
   warp_colors,
   weft_colors,
```

```
    color_list,
    shafts,
    treadles,
    width,
    height,
    tieup,
    liftplan
    )
```

The name field contains a string. The shafts, treadles, width, and height fields contain integers. The width and height fields are included so that the dimensions of the weave can be specified independently of the lengths of the threading and treadling lists. The sequences can be truncated or extended as needed [6].

The tieup and liftplan fields contain binary matrices. The other fields contain lists. The color list is a list of color values, which can be in any form that Icon supports (except mutable colors). The remaining lists are composed of numbers (not character codes representing numbers).

Given an ISD, it can be saved to a file by

```
xencode(draft, file)
```

and restored from a file by

```
xdecode(file)
```

The big disadvantage of ISDs is that they have no way of representing patterns (but we're working on that …). A minor disadvantage compared to PFDs is that they are larger — typically by a factor of 3 or 4, but ISDs are smaller than corresponding WIFs. In return for the increased size, ISDs provide ready-made internal structures, the capability for representing any number of shafts and treadles, and the capability for handling any color value that Icon can handle.

From the Library — Programmer-Defined Control Operations

> *A book ought to be like a man or a woman, with some individual character in it, though eccentric, yet its own; with some blood in its veins and speculation in its eyes and a way and a will of its own.* – John Mitchel

The collection of programmer-defined control operations in the Icon program library has grown quite large. Since the on-line version of the library is updated only infrequently, we've put the current version of this module, pdco.icn, on the Web site for this issue of the Analyst.

Some of the PDCOs in this module illustrate how various control structures can be modeled. Examples are:

AltPDCO{*e1*, *e2*}	*e1* | *e2*
EveryPDCO{*e1*, *e2*}	every *e1* do *e2*
GaltPDCO{*e1*, *e2*, … }	*e1* | *e2* | ...
GconjPDCO{*e1*, *e2*, … }	*e1* & *e2* & …
LimitPDCO{*e1*, *e2*}	*e1* \ *e2*
RepaltPDCO{*e*}	|*e*
ResumePDCO{*e1*, *e2*, *e3*}	every *e2* \ *e2* do *e3*

The main value of these PDCOs is pedagogical. By studying them, you can learn the details of Icon's control structures.

Other PDCOs of main interest in the library follow. The code for some is given in Reference 1.

BinopPDCO{*e1*, *e2*, *e3*} applies the binary operations from *e1* to values from *e2* and *e3*.

ComparePDCO{*e1*, *e2*} compares the sequences *e1* and *e2*. It succeeds if the sequences are the same but fails otherwise.

ComplintPDCO{*e*} produces the integers starting at 0 that are not in *e*. The sequence produced by *e* must be non-decreasing.

DeltaPDCO{*e*} produces the differences of successive integer values from *e*.

IncreasingPDCO{*e*} removes values from *e* as necessary to produce an increasing sequence.

IndexPDCO{*e1*, *e2*} selects values of *e1* in the positions produced by *e2*. The sequence produced by *e2* must be non-decreasing.

InterPDCO{*e1*, *e2*, …} interleaves values from *e1*, *e1*, … . *Note:* This procedure was named InterleavePDCO{} in Reference 1.

LengthPDCO{*e*} produces the length of (number of terms) in *e*.

OddEvenPDCO{*e*} inserts values into *e* to make odd-even sequence.

PalinPDCO{*e*} produces a palindrome sequence.

PatternPalinPDCO{*e*} produces a pattern palindrome sequence [2].

RandomPDCO{*e1*, *e2*, …} produces values from *e1*, *e2*, … selected at random.

ReducePDCO{*e1*, *e2*} "reduces" *e2* by applying the binary operation given by *e1* to the values from *e2*.

ReplPDCO{*e1*, *e2*} replicates each value from *e1* *e2* times.

ReversePDCO{*e*} produces the reversal of *e*.

RotatePDCO{*e*, *i*} rotates *e* by *i* terms. Positive *i* rotates to the left, negative *i* to the right.

SeqlistPDCO{*e*, *i*} returns the first *i* values of *e* in a list.

SkipPDCO{*e1*, *e2*} produces *e1*, skipping the number of terms given by *e2*.

TrinopPDCO{*e1*, *e2*, *e3*, *e4*} applies the trinary operations from *e1* to the values produced by *e2*, *e3*, and *e4*.

UniquePDCO{*e*} filters out duplicate values from *e*.

UnopPDCO{*e1*, *e2*} applies the unary operations from *e1* to *e2*.

See also the answers to the quiz on PDCOs on page 11.

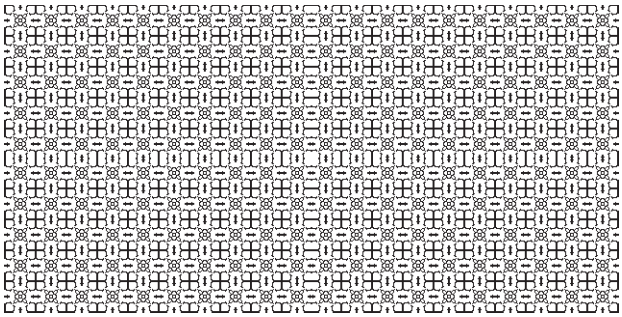


Graphics Corner—Bi-Level Patterns

We have discussed image strings in previous articles [1,2]. Such image strings are based on palettes and have a palette character (key) for every pixel in the image.

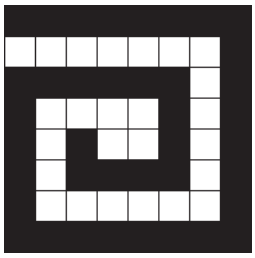
For bi-level (two-color) images, Icon supports a more compact representation. A bi-level image string is drawn in the current foreground and background colors. By default, these are black and white, respectively, but they can be any colors. Hence bi-level image strings are not equivalent to palette-based image strings with the g2 palette.

Data Format

A bi-level image string, also called a pattern, has the form *width*,#*data*. Note that the # distinguishes bi-level image strings from palette-based image strings. The *data* portion contains a sequence of hexadecimal digits that specify rows from top to bottom. Each row is specified by *width* / 4 digits with fractional values rounded up.

The digits of each row are interpreted as hexa-

decimal numbers. Each bit of a hexadecimal digit corresponds to a pixel: 0 for background, 1 for foreground. The bits that form a hexadecimal digit are read from right to left. Figure 1 shows an example:



```
1111 1111   f f
0000 0001   8 0
1111 1101   b f
1000 0101   a 1
1010 0101   a 5
1011 1101   b d
1000 0001   8 1
1111 1111   f f
```

8,#ff80bfa1a5bd81ff

Figure 1. A Bi-Level Pattern

This ordering is confusing, but it's rarely necessary to construct or interpret a bi-level image string by hand: There are library programs for this [3].

Built-In Patterns

A few patterns of a general nature are built into the Icon repertoire. These are shown in Figure 2.

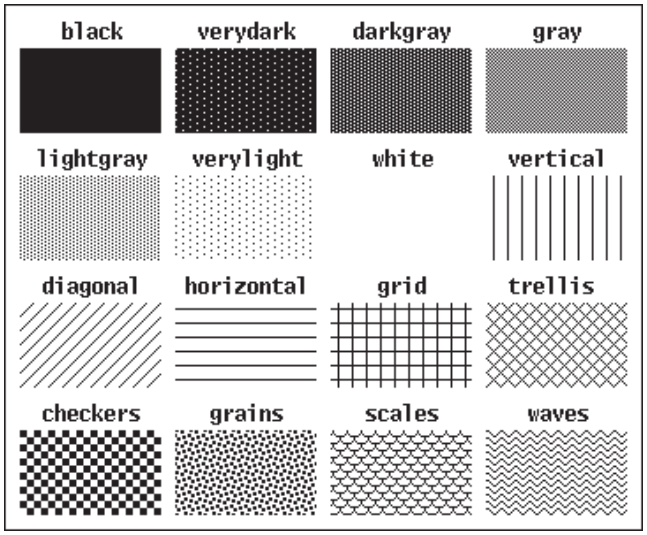


Figure 2. Built-In Patterns

Using Patterns

A pattern is specified by the pattern attribute. This attribute can be set in several ways. For example, both

```
Pattern("8,#ff80bfa1a5bd81ff")
```

and

```
WAttrib("pattern=8,#ff80bfa1a5bd81ff")
```

set the pattern to the example given earlier. The pattern attribute also can be given in WOpen(), as in

```
WOpen("pattern=8,#ff80bfa1a5bd81ff", …)
```

The built-in patterns are specified by their string names, as in

```
Pattern("checkers")
```

The pattern is used for all drawing operations, with the details depending on the fill style. With "fillstyle=solid", the default, the pattern has no effect on drawing. With "fillstyle=textured", drawing is done with the foreground and background as specified by the pattern. With "fillstyle=masked", drawing is done with the foreground as specified by the pattern, but background pixels are left unchanged.

Patterns are aligned with the upper-left corner of the window and tile across it. You can imagine drawing with a fill style of "textured" or "masked" as exposing an underlying pattern.

The following program illustrates these features of patterns:

```
link graphics

procedure main()

   WOpen("size=600,300", "pattern=trellis") |
      stop("*** cannot open window")

   WAttrib("fillstyle=solid")        # (the default)

   FillRectangle()

   WriteImage("figure_3.gif")

   Pattern("trellis")

   WAttrib("fillstyle=textured")

   FillCircle(210, 150, 100)
   FillCircle(390, 150, 100)

   WriteImage("figure_4.gif")

   WAttrib("fillstyle=masked")

   Pattern("vertical")

   FillCircle(210, 150, 100)
   FillCircle(390, 150, 100)

   WriteImage("figure_5.gif")
```

```
    WAttrib("fillstyle=textured")

    FillCircle(210, 150, 100)
    FillCircle(390, 150, 100)

    WriteImage("figure_5.gif")

end
```

Here are the images produced by this program:

Figure 3. Filled Rectangle with Solid Fill Style

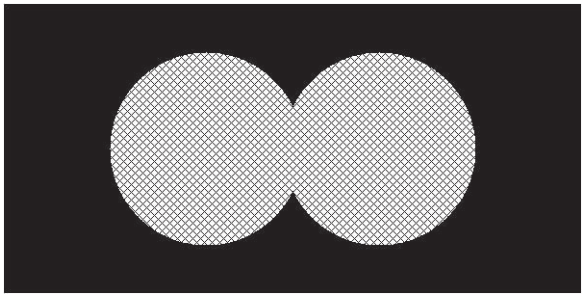

Figure 4. Filled Circles with Textured Fill Style

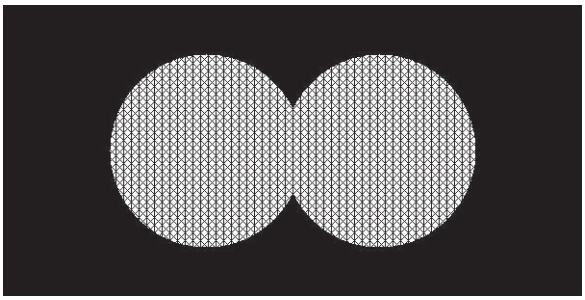

Figure 5. Filled Circles with Masked Fill Style

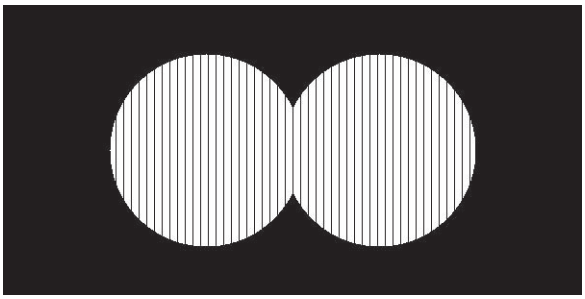

Figure 6. Filled Circles with Textured Fill Style

Figure 3 is solid black because the pattern has no effect with the solid fill style. Figure 4 shows the results of "punching out" two filled circles with the trellis pattern and textured fill style. Notice that the overlapping area tiles seamlessly.

In Figure 5, the filled circles are drawn again with the vertical pattern and masked fill style. Note that the background pixels left over from the trellis pattern are unchanged.

Finally, in Figure 6 the circles are filled with the vertical pattern again, but with the textured fill style. This wipes out the remains of the trellis pattern.

Conclusion

Patterns, like many aspects of computer graphics invite unusual and creative uses. You'll find some examples in Reference 4.

Exploring Sequences Interactively

Using Icon's built-in repertoire of generators and the procedures in the Icon program library, it's possible to produce an endless number of sequences of great variety.

These can be explored by writing individual programs, but that is tedious and time consuming.

The article describes an application that allows the user to enter and edit expressions that produce sequences and see the result quickly (or at least as quickly as the sequences can be computed).

The Application

The interface for this application is shown in Figure 1.

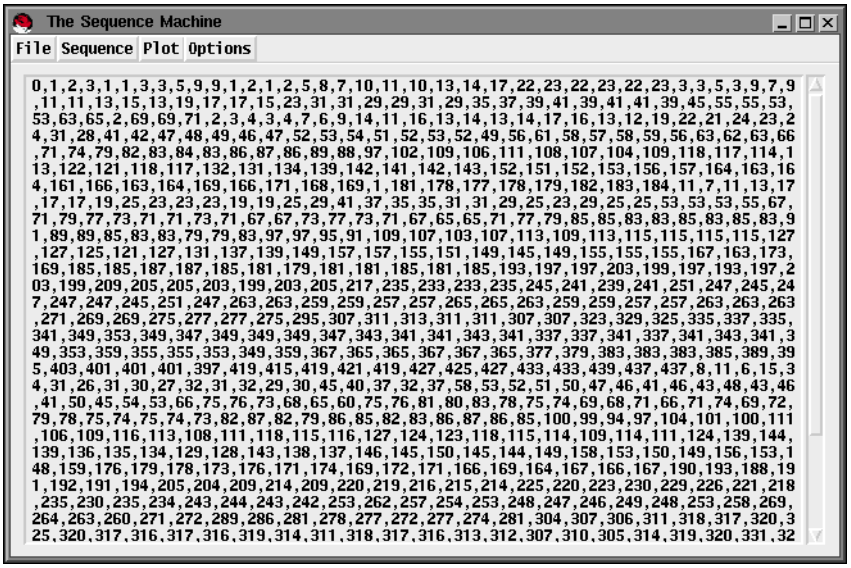

Figure 1. The Application Interface

The current sequence is shown in a scrolling text list that occupies most of the window.

Expressions are entered and edited in a dialog, which is shown in Figure 2.

Figure 2. The Edit Dialog

The File menu provides the usual items for saving the current expression and sequence, as well as for quitting the application.

The Sequence menu provides items for calling up the edit dialog and generating the sequence for the current expression.

The Options menu has items for limiting the number of terms produced and for specifying the separator between them.

The Plot menu provides items for presenting the current sequence visually. At present, only grid plots and point plots are supported. A grid plot is shown in Figure 3.

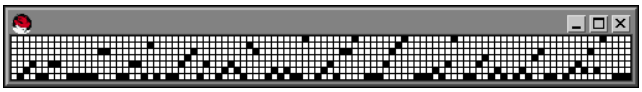

Figure 3. A Grid Plot

Since sequences may have very large values and many terms, grid plots and point plots have limited usefulness, and it's often not possible to show them visually in conventional ways.

We'll consider this problem and explore possible ways of visualizing sequences using unconventional techniques in a subsequent article.

The Implementation

The implementation of this application is largely straightforward and uses techniques described in previous Analyst articles. We'll only describe a few procedures here.

The global variables used by these procedures are:

```
global current_exp      # current expression
global display          # text–list vidget
global limit            # limit on number of terms
global results          # list of current results
global separator        # separator for terms
```

The expression given in the edit dialog is incorporated in a program, which is written to a file and compiled using the system() function. The program is then run as a pipe so that the results can be read into a list. Note that error output is redirected to a file in the /tmp directory. This allows the cause of a problem to be displayed in case there is an error in compilation or execution.

```
procedure run()
   local input, output, k, signal, result
```

```
    static call

    initial
      call := "icont –s –u expr_.icn 2>/tmp/sequent.err"

    output := open("expr_.icn", "w") | {
      Notice("Cannot open file for expression.")
      fail
      }

    write(output, "link seqfncs")
    write(output)
    write(output, "procedure main()")
    write(output)
    write(output, "every write(", current_exp, ") \\", limit)
    write(output)
    write(output, "end")

    close(output)

    WAttrib("pointer=watch")

    if system(call) ~= 0 then {     # didn't compile
      remove("expr_.icn")
      WAttrib("pointer=arrow")
      show_error()
      fail
      }

    input := open("expr_ 2>/tmp/sequent.err", "p")

    results := []

    while result := read(input) do {
      result := numeric(result)
      put(results, result)
      }

    signal :=  close(input)

    remove("expr_.icn")             # remove debris
    remove("expr_")

    WAttrib("pointer=arrow")

    if signal ~= 0 then {           # run-time error
      show_error()
      fail
      }

    display_results()               # display results

    return

  end
```

Displaying the results takes a little work in order to ensure that lines are broken so that they will fit in the width of the text list.

```
  procedure display_results()
    local result_list, term, disp_list, line
    static line_width

    initial line_width := (display.aw – Fudge) /
      WAttrib("fwidth")             # save a little room

    result_list := []

    every put(result_list, image(!results) || separator)

    line := ""
    disp_list := []

    while term := get(result_list) do {
      if *line + *term > line_width then {
        if *line = 0 then {
          put(disp_list, term[1+:line_width])
```

The Encyclopedia of Integer Sequences

The encyclopedia of integer sequences [1] contains a vast collection of integer sequences from a wide range of disciplines.

In it you can find all kinds of things, including sequences related to primes, Mersenne numbers, versum sequences, "self-organizing" sequences, sequences related to chess problems, continued fractions, and strange (to us) sequences like "Remoteness Numbers for Tribulations", and specialized mathematical sequences like "Unique Attractors for the Sliding Möbius Transform".

The book is well worth owning if you are interested in recreational mathematics, but there's a more accessible and extensive source on the Web <1>. With it you can look up sequences, give the terms of a sequence and find out if it's in the database, and submit new sequences.

You also can download the entire database <2>, which at this writing has 49 sections containing nearly 50,000 sequences.

To get an idea of the developing database, at the present time about 10,000 new sequences are being added each year.

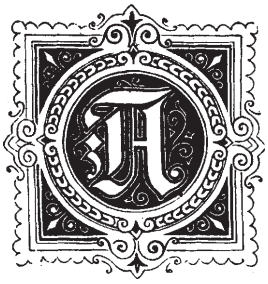
```
            line := term[line_width:0]
            }
          else {
            put(disp_list, line)
            line := term
            }
          }
        else line ||:= term
        }
    if *line > 0 then put(disp_list, line)
    VSetItems(display, disp_list)   # display sequence
    return
end
```

The complete program is on the Web site for this issue of the Analyst. Be aware, though, that the program still is under development and probably will have more features than shown here.



Answers to Quiz on Programmer-Defined Control Operations

See Icon Analyst 55, page 16, for the questions.

1.

(a)

```
procedure ExchangePDCO(L)
   local i
   while i := @L[1] do
      suspend @L[1] | i
end
```

(b)

```
procedure CumulativePDCO(L)
   local i
   i := 0
   while i +:= @L[1] do
      suspend i
end
```

Note: This operation can be done by

```
ReducePDCO{"+", expr}
```

See page 4.

(c)

```
procedure IntegerPDCO(L)
   local x
   while x := @L[1] do
      if type(x) == "integer" then suspend x
end
```

Note: The problem was poorly phrased. A procedure that filters *out* non-integer values should be named IntegerPDCO{} as above, not NonintegerPDCO{}. Notice that the version given above only passes through values of type integer and does not attempt to convert values of other types. The code for the latter interpretation is

```
   while x := @L[1] do
      suspend integer(x)
```

(d)

```
procedure ModnPDCO(L)
   local i, j
   every i := seq() do {
      j :=  @L[1]  | fail
      suspend j % i
      }
end
```

Note: This operation can be done by

```
BinopPDCO{"%", e, seq()}
```

See page 3.

None of these PDCOs has a problem with infinite sequences, *per se*. However, IntegerPDCO{} stops producing values but doesn't terminate if an infinite sequence stops producing integer values.

2.

(a) Term-wise sum of the integers and the Fibonacci numbers: 2, 3, 5, 7, 10, 14, 20, 29, 43, 65, 100, 156, 246, 391, 625, 1003, …

(b) Alternating sums and differences of the primes and Fibonacci numbers: 3, 2, 7, 4, 16, 5, 30, -2, 57, -26, 120, -107, 274, -334, 657, -934, 1656, -2523, 4248, -6694, 11019, -17632, …

(c) The integers *i* repeated *i* times: 1, 2, 2, 3, 3, 3, 4, 4, 4, 4, 5, 5, 5, 5, 5, 6, 6, 6, 6, 6, 6, 7, 7, 7, 7, 7, 7, 7, …

(d) Differences of successive primes: 1, 2, 2, 4, 2, 4, 2, 4, 6, 2, 6, 4, 2, 4, 6, 6, 2, 6, 4, 2, 6, 4, 6, 8, 4,

2, 4, 2, 4, 14, 4, 6, 2, 10, …

(e) The Fibonacci numbers with insertions, where necessary, to make terms alternate between odd and even. The inserted terms (every fourth term in this case) are underscored: 1, 2, 1, 2, 3, 4, 5, 8, 13, 14, 21, 34, 55, 56, 89, 144, 233, 234, 377, 610, 987, 988, 1597, 2584, 4181, 4182, 6765, 10946, 17711, 17712, …

(f) The Fibonacci numbers and the primes interleaved and then reduced modulo 8: 1, 2, 1, 3, 2, 5, 3, 7, 5, 3, 0, 5, 5, 1, 5, 3, 2, 7, 7, 5, 1, 7, 0, 5, 1, 1, 1, 3, 2, 7, …

(g) The Fibonacci numbers interleaved with the primes taken mod 8: 1, 2, 1, 3, 2, 5, 3, 7, 5, 3, 8, 5, 13, 1, 21, 3, 34, 7, 55, 5, 89, 7, 144, 5, 233, 1, 377, 3, 610, 7, …

(h) The sizes (numbers of digits) of the Fibonacci numbers: 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 3, 3, 3, 3, 3, 4, 4, 4, 4, 5, 5, 5, 5, 5, 6, 6, 6, 6, 6, 7, 7, 7, 7, 7, 8, 8, 8, 8, 9, 9, 9, 9, 9, 10, 10, 10, 10, 10, 11, 11, 11, 11, 11, 12, 12, 12, 12, 12, 13, 13, 13, 13, …

(i) The individual digits of the Fibonacci numbers (since ! is a generator, each application runs through all the characters (digits) of the term to which it is applied): 1, 1, 2, 3, 5, 8, 1, 3, 2, 1, 3, 4, 5, 5, 8, 9, 1, 4, 4, 2, 3, 3, 3, 7, 7, 6, 1, 0, 9, 8, 7, 1, 5, 9, 7, 2, 5, 8, 4, 4, 1, 8, 1, 6, 7, 6, 5, 1, 0, 9, 4, 6, 1, 7, 7, 1, 1, 2, 8, 6, 5, 7, 4, 6, 3, 6, …

3.

(a) The integers *i* repeated *p* times by the corresponding primes *p*:

```
ReplPDCO{seq(), primeseq()}
```

(b) The integers *i* repeated by *i* repeated *i* times (as in solution 2(c)):

```
ReplPDCO{seq(), ReplPDCO{seq(), seq()}}
```

(c) The primes interleaved with the primes plus 3:

```
InterPDCO{primeseq(), primeseq() + 3}
```

(d) The primes made into an odd-even sequence:

```
OddEven{primeseq()}
```

4.

(a) Puzzle1PDCO{*e1*, *e2*, …, *en*} produces results from its argument expressions selected at random.

(b) Puzzle2PDCO{*e1*, *e2*} skips the number of terms in *e1* given by *e2*. For example,

```
Puzzle2PDCO{seq(), primeseq()}
```

produces

1, 4, 8, 14, 22, 34, 48, 66, 86, 110, 140, 172, 210, 252, 296, 344, 398, 458, 520, 588, 660, 734, 814, 898, 988, 1086, 1188, 1292, 1400, 1510, 1624, 1752, 1884, 2022, 2162, …

(c) Puzzle3PDCO{*e*} fills in *e* with runs of consecutive integers as necessary. For example,

```
Puzzle3PDCO{
  InterleavePDCO{primeseq(), seq()}
  }
```

produces

2, 1, 2, 3, 2, 3, 4, 5, 4, 3, 4, 5, 6, 7, 6, 5, 4, 5, 6, 7, 8, 9, 10, 11, 10, 9, 8, 7, 6, 5, 6, 7, 8, 9, 10, 11, 12, 13, 12, 11, 10, 9, 8, 7, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 16, 15, 14, 13, 12, 11, 10, 9, 8, 7, …

Woven Images

Producing images from weaving drafts is not particularly difficult, but it's well worth thinking about how to do it efficiently.

The naive approach is to examine each point of interlacing to determine whether the warp thread or the weft thread is on top and drawing the intersection in the appropriate color. We'll just draw a point, so that the threads are one-pixel in width.

The Naive Approach

Using ISDs (see pages 2 and 3), the naive approach is:

```
every x := 1 to *draft.threading do {
  every y := 1 to *draft.treadling do {
    if draft.tieup[x, y] = 1 then
      Fg(draft.color_list[draft.warp_colors[x]])
    else
      Fg(draft.color_list[draft.weft_colors[y]])
    DrawPoint(x – 1, y – 1)
    }
  }
```

This method, requiring a separate computation for every pixel, is painfully slow because the complexity is $n \times m$ for an $n \times m$ image. For example, for a small image of 100×100 threads, there are 10^4 iterations of the inner loop.

Insight

One way to speed the process is to draw in all the warp threads as vertical stripes and then overlay the weft threads in those places where they are on top:

```
every x := 1 to *draft.threading do {
    Fg(draft.color_list[draft.warp_colors[x]])
    DrawLine(x – 1, 0, x – 1, *draft.treadling – 1)
    }

every x := 1 to *draft.threading do {
  every y := 1 to *draft.treadling do {
    if draft.tieup[x, y] = 0 then
      Fg(win, draft.color_list[draft.weft_colors[y]])
    DrawPoint(x – 1, y – 1)
    }
  }
```

Figure 1 shows what a typical woven image looks like after the warp background is drawn.

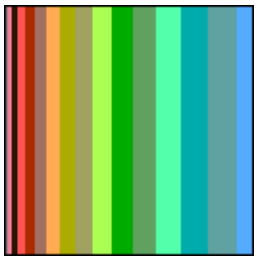


Figure 1. Warp Background

Drawing the warp background first saves a DrawPoint() for those intersections where the warp thread is on top, but the number of loop iterations is slightly larger — $10^4 + 100$ for a 100×100 image. There is a noticeable gain in speed, but the basic problem remains.

Incidentally, we could draw a weft background of horizontal stripes and overlay the warp. We chose to follow the order used in actual weaving, where the warp is set up in advance and the weft threads added during the weaving process. In addition, the performance wouldn't change much for narrow weaves — the warp interlacements would be longer in that case.

More Insight

A significant improvement can be made by noting that there can be only as many different weft overlay patterns as there are treadles. These can be pre-computed and put in a list indexed by the treadle number. By representing the patterns as lists of points, all the weft pixels can be drawn in a single call of DrawPoint(). Here's code for the pre-computation of the treadle lists:

```
treadle_list := list(draft.treadles)

every !treadle_list := []

every i := 1 to draft.treadles do {
  every j := 1 to draft.shafts do {
    if draft.tieup[i, j] = 0 then {
      every k := 1 to *draft.threading do {
        if draft.threading[k] = j then
          put(treadle_list[i], k – 1, 0)
        }
      }
    }
  }
```

Note that the y coordinates are all set to 0; their actual values aren't known until the weft overlay is drawn. It's not necessary, however, to change them; the y coordinate can be set by using translation:

```
every y := 1 to *draft.treadling do {
  treadle := draft.treadling[y]
  Fg(draft.color_list[draft.weft_colors[y]])
  WAttrib("dy=" || (y – 1))
  DrawPoint ! treadle_list[treadle]
  }
```

This greatly improves the speed of drawing. Ignoring the pre-computation costs, which amount to an insignificant percentage of the total cost even for small images, the complexity drops from $n \times m$ to m — from 10^4 to 100 for our example.

We can further improve the performance by keeping track of the picks that use the same color. For each color, we can then set the foreground accordingly draw all the weft overlays for that color. Again, this adds to the complexity of the code:

```
                    …
treadle_colors := list(*draft.color_list)
every !treadle_colors := []

every i := 1 to *draft.threading do {
```

```
   j := draft.weft_colors[i]
   put(treadle_colors[j], i)
   }
every i := 1 to *treadle_colors do {
   Fg(win, draft.color_list[i]) | stop("bogob")
   every y := !treadle_colors[i] do {
      WAttrib(win, "dy=" || (y – 1))
      DrawPoint ! treadle_list[draft.threading[y]]
      }
   }
```

Special Cases

It's worth adding code for special cases that arise frequently: when the warp and/or weft threads are the same color. The notable example of this is in drawdowns in which the warp threads are all black and the weft threads are all white. If the warp threads are all the same color, the background can be filled in with FillRectangle(). If the weft threads are all the same color, the foreground need be set only once. Here's the code for handling the case where all the warp threads are the same color:

```
if *set(draft.warp_colors) = 1 then {
      Fg(draft.color_list[draft.warp_colors[1]])
      FillRectangle()
      }
else …                    # general case
```

Note how easy it is to check for this case.

Here's what's needed for the case the weft threads are all the same color:

```
if *set(draft.weft_colors) = 1 then {
   Fg(draft.color_list[draft.weft_colors[1]])
   every y := 1 to *draft.treadling do {
      treadle := draft.treadling[y]
      WAttrib("dy=" || (y – 1))
      DrawPoint ! treadle_list[treadle]
      }
else …                    # general case
```

Perhaps Too Much Cleverness

We toyed with the idea of drawing line segments for weft overlays so that several weft threads are that on top in succession could be done with one drawing operation. We decided the potential advantages were outweighed by the additional complexity that would be involved. In addition, most weaves have relatively few "floats" where a weft thread is on top of several warp threads in a row. We'll have more to say about floats in a future article.

There is another possibility for improving performance: Keep track of where the first weft overlay pattern is drawn in each weft color and when that pattern occurs again in the same color, use CopyArea() instead of DrawPoint() for that line.

Although CopyArea() is very fast, it's not clear that the gain would be enough to justify — or even offset — the extra testing that would be required (not to mention the more intricate code needed).

Drawdowns

As mentioned earlier, a drawdown is obtained by using black for all warp threads and white for all weft threads. Consequently, the same code can be used for drawdowns as for regular woven images.

Drawdowns, however usually are shown on grids with squares several pixels on a side for each intersection rather than the single pixel we've used here. This can be handled easily enough using the methods given here. It's probably best to use a separate procedure for drawdowns rather than to further complicate the code used for ordinary woven images.

Incidentally, magnified images are easily obtained by using Zoom() from the graphics module of the Icon program library.

Shadow-Weave Wallpaper

In an article on shadow weaves [1], we explored one of Painter's built-in drafts and showed the fascinating structure of its threading sequence, which is composed of a sequence of anchor points and palindromes connected by runs.

From there, we explored variations on the weave by making systematic modifications to the way the sequence was put together. We did not begin to explore all possible variations — the number of them is incomprehensibly vast. Yet some variations of a more radical nature produce interesting results. See Figure 1.

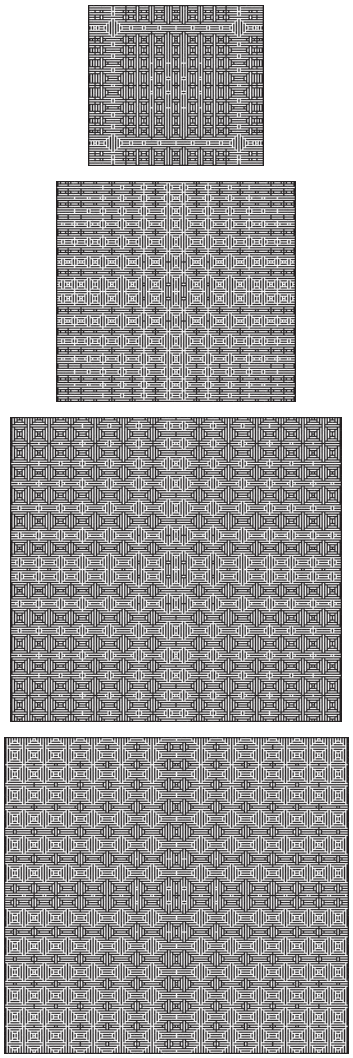

Figure 1. Variations on a Shadow Weave

One approach to further explorations would be to try to deduce the kinds of variations that might prove interesting. Another approach is to produce random changes in hopes of stumbling on interesting specimens.

We do not know enough to deduce interesting variations in a controlled fashion. And random variations are a lot easier to do.

Coincidental with our pondering this problem, a weaver who was interested in our work on shadow weaves asked if we could put up some shadow-weave "wallpaper" on the Web — a page with a shadow-weave background that changes periodically to show variations.

This was relatively easy to do. We created one Web page with two images, one of the original shadow weave and another with a variation that changes periodically. The image that changes periodically is linked to another page that is featureless except the image is used as a background.

Miniature versions of these pages are shown in Figures 2 and 3.

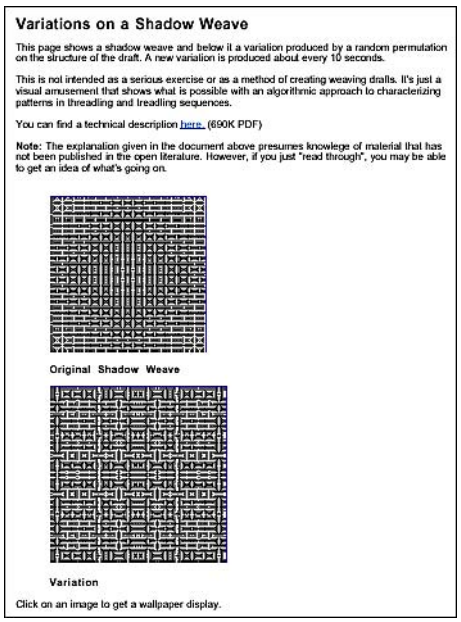

Figure 2. Shadow-Weave Page

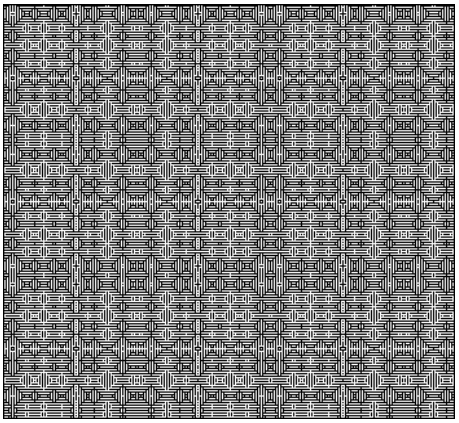

Figure 3. Shadow-Weave Wallpaper Page

The HTML for the wallpaper page is simplicity itself:

```
<HTML>
<HEAD>
<TITLE>Shadow Weave</TITLE>
</HEAD>
<BODY BACKGROUND="bandw.gif">
</BODY>
</HTML>
```

The program that produces the images uses ISDs instead of PFDs (see pages 1 through 3) and constructs the sequences explicitly rather than creating pattern forms that are expanded, as was done in the earlier version.

```

global palpat
global palindromes

procedure main(args)
   local tieup, palette, mutant, win1, win, colorways, i

   randomize( )

   anchors := [ ]
   every put(anchors, 1 to 7)

   palpat := [ ]
   every put(palpat, integer(!"8214365"))

   palindromes := list(*palpat)

   every i := 1 to *palpat do
      palindromes[i] := lreflect(palpat[1:i + 1], 2)

   mutant := isd()
   mutant.name := "shadowweave"
   mutant.shafts := 8
   mutant.treadles := 8
   mutant.color_list := ["black", "white"]
   mutant.tieup := pat2rows("8,#55aa956aa55aa956")

   repeat {
      palindromes := shuffle(copy(palindromes))
      anchors := shuffle(copy(anchors))
      mutant.threading := mutant.treadling :=
         sequence(anchors, palindromes)
      mutant.warp_colors :=
         lextend([1, 2], *mutant.threading)
      mutant.weft_colors :=
         lextend([2, 1], *mutant.treadling)
      win := weavegif(mutant)
      WriteImage(win, "bandw.gif")
      WDelay(win, 10000)
      WClose(win)
      }
end

procedure sequence(anchors, palindromes)
   local i, j, k, p, threading

   anchors := copy(anchors)
   palindromes := copy(palindromes)

   threading := []

   i := put(threading, get(anchors)) |
      stop("program malfunction")

   while p := copy(get(palindromes)) do {
      every put(threading, run(threading[–1], get(p)))
      every put(threading, !p)
      i := get(anchors) | break
      every put(threading, run(threading[–1], i))
      }

   threading := lreflect(threading, 2)

   return threading

end

procedure run(i, j)

   if i < j then suspend i + 1 to j
   else if i > j then suspend i – 1 to j by –1
   else fail

end
```

We ran into an unexpected problem. After some number of images were created, the program crashed for lack of memory, even though every window was closed before a new one was created: There was a memory leak. The leak probably is in Icon's storage management for window resources, although it conceivably could be in X.

The solution was to terminate the program after a safe number of images had been processed, while launching another copy of it before terminating — a kind of suicidal self-cloning.

The changed code is:

```
   every 1 to 100 do {
      palindromes := shuffle(copy(palindromes))
      anchors := shuffle(copy(anchors))
         …
      }

   system("wallpapr &")

   exit()
```

If you investigate the shadow-weave Web pages <1, 2>, you can see variations by reloading the pages at intervals.

Of course, there's the ever present danger that the server on which the program runs will crash. The server is quite stable and the program has been known to run for weeks at a time. There is, however, nothing to be done about a power outage, which happens on occasion, especially during our "monsoon" season when there is a lot of electrical activity. And then there was the raccoon who passed on brilliantly, most literally, by chewing through the insulation on a cable at a nearby power substation.

What's Left?

The program shown in this article makes only minor variations on the original shadow weave. There are all kinds of other, more radical variations.

In thinking about these, we've become interested in other kinds of sequences produced by patterns connected by runs. We're not quite ready to write an article about this yet, but expect to see something, perhaps in disguise, in an article a few issues down the line.

Animation — Making Movies

In the context of computer presentation, a "movie" is a packaged animation. Sound may be included, but that is beyond the scope of this article.

Movies are a very hot topic in computing at the present time and there are several commercial applications that provide a variety of facilities.

Several formats are in widespread use. The main ones are MPEG, QuickTime, and AVI (Windows only).

Animated GIFs

The simplest and most widely used format for packaged animations, especially for the Web, is GIF89a ("animated GIFs"). GIF89a allows a sequence of images to be stored in one file. Application software then can produce an animation by displaying successive images (frames).

Most programs that create animated GIFs do so from a collection of previously prepared single–image GIFs. These can be in GIF87a or GIF89a format. The GIF89a file format allows control information to be included so that the application that displays the images can determine how they are to be presented.

The following options are supported for controlling the display. They are specified in the application that builds the animated GIF.

interlaced
interframe delay
loop
transparent background
frame position
disposal method

When interlacing is specified, each frame is displayed progressively and gradually filled in to the final detail. Interlaced images do not display any faster than non–interlaced ones, but they give the user something to look at while a large image is being downloaded. Animated GIFs usually are not interlaced, because this interferes with the visual transition between successive frames.

The interframe delay is the amount of time between drawing frames. It can be set to 0, but that may cause the animation to run too fast on some platforms.

If the looping value is greater than 0, the animation repeats the specified number of times and then stops. Not all programs support specific values — if you want an animation to display more than once, it's safer to use the "forever" option, which causes the animation to loop until it is interrupted.

Transparent backgrounds serve the same purpose that they do in GIFs that are not animated [1].

Frames can be shifted from the origin by arbitrary amounts. This can be useful for specialized animations.

Frame disposal refers to what is done with the currently displayed frame when the next frame is

drawn. "Do not dispose" is recommended for opaque animations and "Revert to Background" for transparent animations.

Some applications that create animated GIFs allow the frame–related options to be set separately for each frame. Others only apply the specified options to all frames.

Some also provide optional optimization, which crops all frames but the first to the part that is different from the preceding frame. In some kind of animations, this can considerably reduce the file size and increase the speed with which animations can be downloaded and displayed.

Creating Individual GIFs

Many applications can create the individual GIFs that go into an animation. For example, to create an animation of the Icon kaleidoscope program, a series of GIF images can be written as a program executes and can be packaged later.

All this requires is placing calls to WriteImage() at appropriate places — wherever the display is changed.

For the kaleidoscope application [2, 3], there is only one place that images need to be written:

```
procedure outcircle(off1, off2, radius, color)
   Fg(pane, color)
   draw_proc(pane, off1, off2, radius)
   draw_proc(pane, off1, –off2, radius)
   draw_proc(pane, –off1, off2, radius)
   draw_proc(pane, –off1,–off2, radius)
   draw_proc(pane, off2, off1, radius)
   draw_proc(pane, off2, –off1, radius)
   draw_proc(pane, –off2, off1, radius)
   draw_proc(pane, –off2,–off1, radius)
   WriteFrame()                    # write frame
   return
end
procedure WriteFrame()
   static count
   initial count := 1
   WriteImage(pane, "kaleido" ||
      right(count, 4, "0") || ".gif", –half, –half, size, size)
   write(&errout, count)
   count +:= 1
   return
end
```

The procedure WriteFrame() is used to isolate the necessary code, and it is particularly useful if images need to be written at several places in a program.

The images are numbered serially. This makes creating an animation from them easier, since many applications for composing animated GIFs order the individual images by the sorting order of their names. Writing the count to standard error output helps the person creating the frames keep track of how many have been written.

For the kaleidoscope, it is not necessary or desirable to write a frame for each of the eight symmetric drawings. Unless the animation is very fast, it would look peculiar, and it would increase the size of the animation by a factor of about eight.

Another place a frame might be written in the kaleidoscope program is when the diplay is cleared. This would clearly show the transitions between different parameter sets.

Creating Animated GIFs

There are freeware, shareware, and commercial applications that can package existing GIF images.

For UNIX, there is a freeware application, gifmerge <1>, that runs from the command line. For the Macintosh, there is a very capable freeware program, GifBuilder <2>, that runs interactively and supports "drag and drop". GifBuilder also can extract individual images from a packaged animation as well as convert between other movie formats. For Windows, there is a shareware program, GIF Construction Set <3>. As far as we know, there is no freeware GIF animation builder for Windows at the present time.

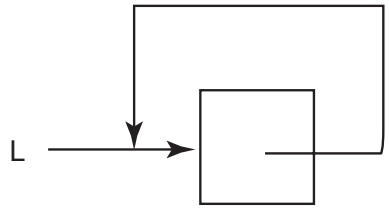
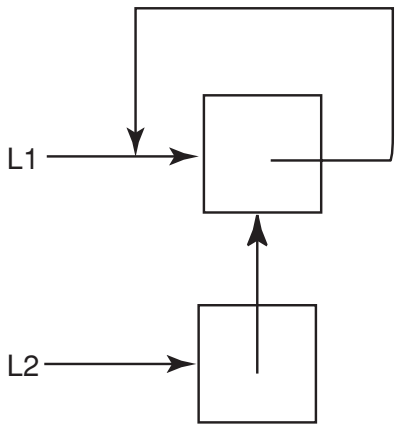
Quiz — Pointer Semantics

1. Write code segments that produce the following list structures. Each box represents a list element.

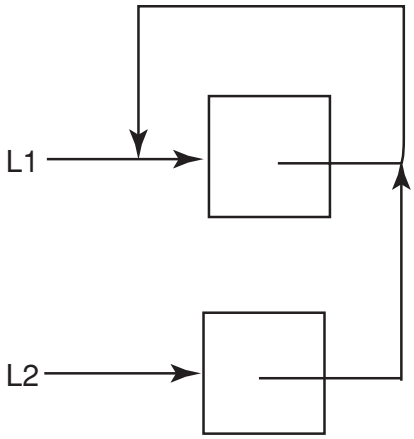
(a)



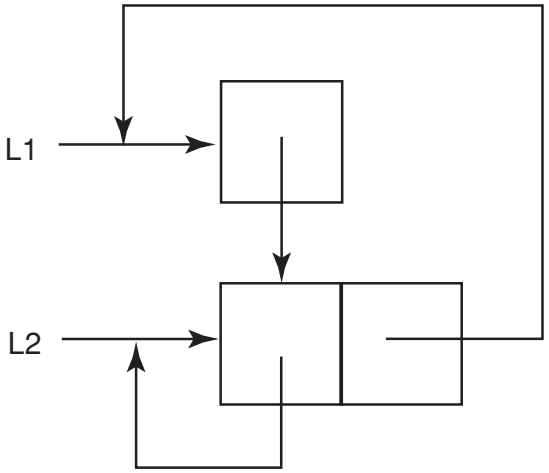
(b)



(c)



(d)



2. Diagram the list structures produced by the following code segments.

(a)

```
L := []
push(L, L, L, L)
```

(b)

```
L1 := []
L2 := copy(L1)
put(L1, L2)
```

(c)

```
L1 := []
L2 := copy(L1)
push(L2, L1)
```

(d)

```
L1 := list(5, 1)
push(L1, [], L1)
L1[1] := 0
pull(L1)
```

Drawups

The language of weaving is not easy to understand nor to write. Most of the weaving words we use are part of our non-weaving vocabulary: pattern, unit, block, simple, shadow, fancy, satin, plain, tie, profile, halftone, turned. You may not recognize the very specific ways these words are used in a sentence about weaving. — Madelyn van der Hoogt [1]

The Problem

A drawup is, in a sense, the opposite of a drawdown — a draft created from a drawdown, which is a representation of the interlacement of a weave [2].

Early in our explorations of weaving we recall encountering a well-known book that shows only drawdowns with no corresponding drafts that would show how to weave them [3]. Figure 1 is an example scanned from the book and Figure 2 is a drawdown obtained from this image by a program we'll describe in a later article.

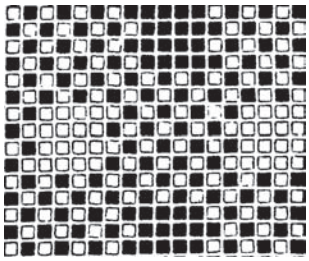


Figure 1. A Scanned Drawdown

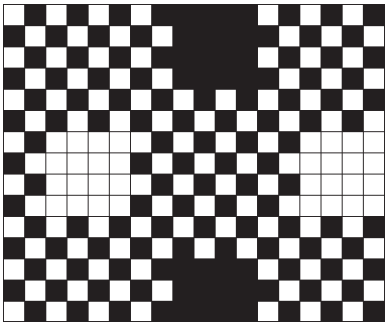

Figure 2. A Drawdown Grid

We were puzzled how a weaver could use drawdowns as a basis for weaving. We later were told by an experienced weaver "that's left as an exercise".

It wasn't at all obvious to us how to create a draft from a drawdown (and most weavers don't know how), so we set out to (what else?) write a program to do it. A primary objective was to produce a drawup with the fewest number of shafts and treadles. (The problem is trivial if a different treadle is used for every row and a different shaft is used for every column — but that's not helpful for actual weaving.)

The key observations are that if a drawdown contains duplicate rows, these rows can be produced by the same treadle, and if there are duplicate columns, they can be produced by the same shaft. Conversely, the draft must have at least as many shafts as there are different columns, and similarly for the treadles and rows. If there are no duplicates, then the number of treadles required is the number of rows in the drawup and the number of shafts required is the number of columns in the drawup.

It's then just a matter of identifying the duplicate rows and columns and creating a tie-up that connects them in a way that produces the desired result.

The Program

The following program works with a drawdown represented by a bi-level pattern (see pages 4 through 6) and produces an ISD (see pages 2 and 3).

```
link options
link patutils          # for pat2rows()
link patxform          # for protate()
link weavutil          # for isd declaration
link xcode

record analysis(rows, sequence, patterns)

procedure main(args)
   local threading, treadling, tie, pattern, i
   local symbols, symbol, drawdown, draft, opts

   opts := options(args, "n:")

   drawdown := pat2rows(read()) |
      stop("*** invalid input")

   treadling := analyze(drawdown)
   drawdown := protate(drawdown, "cw")
   threading := analyze(drawdown)

   symbols := table("")

   every pattern := !treadling.patterns do {
      symbol := treadling.rows[pattern]
      symbols[symbol] := repl("0", *threading.rows)
      pattern ? {
```

```
      every i := upto('1') do
       symbols[symbol][threading.sequence[i]] := "1"
      }
   }

symbols := sort(symbols, 3)
tie := ""

while get(symbols) do
   tie ||:= get(symbols)

draft := isd()
```

   draft.name := \opts["n"] | "drawup"
   draft.threading := threading.sequence
   draft.treadling := treadling.sequence
   draft.warp_colors := list(*threading.sequence, 1)
   draft.weft_colors := list(*treadling.sequence, 2)
   draft.color_list := ["black", "white"]
   draft.shafts := *threading.rows
   draft.treadles := *treadling.rows
   draft.tieup := tie2matrix(*threading.rows,
     *treadling.rows, tie)

   xencode(draft, &output)

end

procedure analyze(drawdown)
   local sequence, rows, row, count, patterns

   sequence := []
   patterns := []

   rows := table()

   count := 0

   every row := !drawdown do {
     if /rows[row] then {
       rows[row] := count +:= 1
       put(patterns, row)
       }
     put(sequence, rows[row])
     }

   return analysis(rows, sequence, patterns)

end

procedure tie2matrix(shafts, treadles, tieup)
   local matrix

   matrix := []

   tieup ? {
     every 1 to treadles do
       put(matrix, move(shafts))
         }

   return matrix

end
```

In order to manipulate the drawdown, it is converted from a bi-level pattern to a binary matrix: a list of strings composed of 0s and 1s.

The procedure analyze() goes through the rows of that matrix, using the table rows to hold the distinct rows, to which identifying numbers are assigned. At the same time, the list patterns is built to record the order in which the rows appear.

The procedure analyze() first is used on the rows of the drawdown and then, by rotating the

matrix using protate(), the columns.

All that remains is to create the tie-up. For every treadling pattern, its row is initialized with 0s, which indicate no tie. Then for every position in the row that is 1, the corresponding value is set to 1, indicating a tie.

Finally an ISD is assembled and output using xencode().

Figure 3 shows the drawup draft for the drawdown shown in Figure 2. Notice that it only requires six shafts and six treadles.

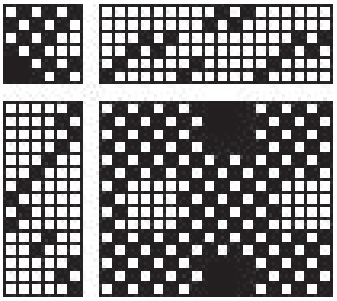

Figure 3. A Drawup Draft

Observation

The method described above can be used to create a draft for any two-color image. Although drawdowns usually are shown as grid diagrams with the squares large enough to see the interlacing easily, an image in which the interlacement is represented by single pixels contains the same information.

Be aware, though, that unless there are many duplicate rows and columns — or the image is tiny — the resulting draft will require more shafts and treadles than are available on treadle looms. There also is the important question of whether the fabric would hold together, a topic we'll cover in a subsequent article.

To Come

The next step beyond creating drafts from drawdowns and two-color images is to create them for multicolored "drawdowns" or, what is equivalent, multicolored images.

This is a much more difficult problem and, in general, there may be no solution. Figure 5 shows a three-color pattern for which there is no draft.

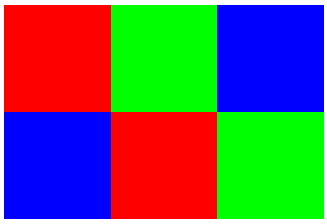

Figure 5. An Undraftable Color Pattern

Try to assign colors to the rows and columns of this pattern and you'll see the problem.

What's Coming Up

Everything should be built top-down, except the first time. — Alan Perlis

In the next issue of the Analyst, we plan to have an article on determining whether a color pattern can be drafted and woven, and, if so, how to create a draft. Continuing with weaving, we'll have an article on a weave design technique known as name drafting as well as an article on modular arithmetic as it applies to the numbering of shafts and treadles.

Versum sequences will reappear in a generalized form, and we may show a few versum weaves.

Our series on sequences will continue with an article on periodic sequences in which the same pattern of values repeats endlessly.

In **From the Library**, we plan to cover modules that support rational and complex arithmetic.

Algebraic Description of Coordination Sequences and Exact Topological Densities for Zeolites

R.W. Grosse-Kunstleve[1] & G.O. Brunner
Laboratory of Crystallography, ETH Zentrum, CH-8092 Zurich, Switzerland

N.J.A. Sloane
Mathematical Sciences Research Center, AT&T Research, Murray Hill, New Jersey 07974, USA

Abstract

Coordination sequences have been calculated for all approved zeolite topologies, all dense SiO_2 polymorphs and 16 selected non-tetrahedral structures, and the algebraic structure of these CS's has been analyzed. Two algebraic descriptions of coordination sequences are presented. One description uses periodic sets of quadratic equations and is already established in the literature. The second description employs generating functions which are well known in combinatorics, but are used here for the first time in connection with coordination sequences. The algebraic analysis based on generating functions turns out to be more powerful then the other approach. Based on the algebraic analyses, exact topological densities are derived and tabulated for all the structures investigated. In addition, "*n*-dimensional sodalite" is observed to have an especially simple *n*-dimensional graph.

Introduction

The notion of coordination sequence (CS) was formally introduced by Brunner & Laves (1971) in order to investigate the topological identity of frameworks and of atomic positions within a framework. The CS is a number sequence in which the *k*-th term is the number of atoms in "shell" *k* that are bonded to atoms in "shell" *k*-1. Shell 0 consists of a single atom, and the number of atoms in the first shell is the conventional coordination number.

The CS is now routinely used to characterize crystallographic structures (Meier & Möck, 1979, Atlas of Zeolite Structure Types, 1992 & 1996, Fischer 1973 & 1974) and even higher-dimensional sphere packings (Conway & Sloane, 1995, 1996). Other applications are to the determination of topological density, which can be obtained from the partial sums of terms in the CS. This density is correlated with other parameters such as lattice energy (Akporiaye & Price, 1989), the distribution of particular elements (Herrero, 1993), catalytic activity (Barthomeuf, 1993), and is useful for predicting of properties of synthetic zeolites (Brunner, 1979).

In an abstract sense, the CS describes the growth of a crystal, and was therefore initially called the "growth series" (Brunner & Laves, 1971). Previous investigations (Brunner, 1979, Herrero, 1994, Schumacher, 1994, O'Keeffe, 1991a) have shown that in some cases the terms in the CS increase quadratically with *k*, but up to now investigations were restricted to specific examples. In view of the increasing applications of the CS, up to 2000 terms have now been calculated for all approved zeolites topologies, as well as for all dense SiO_2 polymorphs and 16 selected non-tetrahedral structures, and the algebraic structure of these CS's has been analyzed.

The crystal structures investigated

The majority of the zeolite structures investigated in this work are listed in the Atlas of Zeolite Structure Types (1992 & 1996)[2]. All the zeolite topologies will be referred to by their three-letter codes. For example, Melanophlogite has code **MEP**. Coordination sequences for structures with more than one crystallographic site are referred to by the three-letter code followed by the site label of the atlas. For example, the zeolite Mazzite has two distinct sites (both tetrahedrally coordinated atoms) which are denoted by **MAZ T1** and **MAZ T2**.

The data for the twelve SiO_2 polymorphs were taken from the Inorganic Crystal Structure Database (ICSD, 1986-1995). Table 1 lists the mineral names together with the ICSD collection codes.

Mineral	ICSD collection code
Banalsite	4447
Coesite	18112
Cordierite	30947
Cristobalite	9327
Feldspar	100182
Keatite	34889
Milarite	71046
Moganite	67669
Paracelsian	24690
Quartz	31048
Scapolite	9502
Tridymite	29343

Table 1 : ICSD collection codes

For a comparison, 16 non-tetrahedral structure types having many chemical representatives have also been investigated. Table 2 gives the search codes for the corresponding entries in the Gmelin Handbook (TYPIX, 1994).

The coordination numbers of the zeolites and the dense SiO_2 polymorphs are always four, with the exception of the six interrupted zeolite frameworks (indicated by a dash preceding the three-letter code) which have a three- or twofold coordination for one of the sites. For the non-tetrahedral structures, Table 2 also gives the bond length limits and the resulting coordination numbers which were used in the calculations. For each of CaF_2, NiAs and W, two different parameters were considered, leading to two different coordination numbers.

Formula	TYPIX search code	Bond length limit (Å)	Coordination numbers
CaF_2 (2)	(225) cF12	2.5	4, 8
CaF_2 (1)	(225) cF12	3.5	8, 10
NaCl	(225) cF8	3.0	6
FeS_2-Marcasite	(58) oP6	2.7	4, 6
FeS_2-Pyrite	(205) cP12	2.7	4, 6
NiAs (2)	(194) hP4	2.5	6, 6
NiAs (1)	(194) hP4	2.7	6, 8
Cu	(225) cF4	2.7	12
Mg	(194) hP2	3.5	12
W (2)	(229) cI2	3.3	14
W (1)	(229) cI2	2.8	8
α-Nd	(194) hP4	4.0	12
Ni_2In	(194) hP6	3.3	11, 14
α-Mn	(217) cI58	3.5	12, 13, 16
Cr_3Si	(223) cP8	3.5	12, 14
σ-CrFe	(136) tP30	3.5	12, 14, 15
$MgZn_2$	(194) hP12	3.5	12, 16
$MgCu_2$	(227) cF24	3.5	12, 16

$MgNi_2$	(194) hP24	3.5	12, 16

Table 2 : TYPIX search codes

Primary determination of coordination sequence: A highly optimized node counting algorithm

In order to calculate the coordination sequence, the crystal structure, i.e. assembly of atoms, has to be abstracted to a mathematical topology (or graph) with nodes and certain bonds between nodes. In the case of zeolites and dense SiO_2 phases, the tetrahedral positions are taken to be the nodes, and the bridging framework oxygen atoms are replaced by bonds. For other classes of materials, e.g. metals or intermetallic phases, all atoms represent nodes, and bonds are created in an appropriate neighborhood of each atom (see for example Brunner & Laves, 1971).

The CS determination algorithm used here can be described as a *node counting* or *coordination shell algorithm*. The algorithm is started (with $k = 0$) by selecting an *initial node*. At the next step ($k = 1$), all nodes bonded to the initial node are determined. For $k \geq 2$, all characteristics of the algorithm become evident: those nodes, which are bonded to the "new nodes of the previous step (k-1)", but have not been counted before, are counted. This means that three sets of nodes for three topological distances (i.e. three coordination shells) have to be maintained: the *middle* (k-1) nodes, whose bonds are followed to determine the *next* (k) nodes, and the *previous* (k-2) nodes, to know which of the nodes bonded to the middle nodes have already been counted. The innermost shells with $k < k_{next}$-2 are not needed and can be deleted since the nodes counted before are fully surrounded by shell k-2. In this way, the memory required grows only quadratically with k, whereas other algorithms presented in the literature (Herrero, 1994) have a cubic growth rate.

Another important feature of the algorithm is that a "hashing" lookup technique was used to determine whether a newly generated node - a candidate for the next shell - was already in the middle or previous shell. This increased the speed of the program by about three orders of magnitude.

Both optimizations, with respect to memory and to speed, were necessary: without them it would not have been possible to compute the several hundred to several thousand CS terms that were required for the analysis. Computing times were a matter of hours on a high-speed workstation.

Algebraic description I: Quadratic equations defining the topological density

It was already shown in the literature (Brunner, 1979, Herrero, 1994, Schumacher, 1994, O'Keeffe,

1991a) that in many cases the k-th term of the coordination sequence, N_k, increases quadratically with k (just as the surface of a sphere increases quadratically with its radius). A very simple example is **SOD**, where $N_k = 2\,k^2 + 2$ holds for all k. Brunner (1979) gives also a more typical example: for diamond, "the equation $N_k = 2.5\,k^2 + 1.75$ renders values too high by 0.25 if k is odd and too low by 0.25 if k is even". An exact description for all k is achieved by introducing a periodic set of quadratic equations:

$N_k = 5/2\,k^2 + 3/2$ for $k = 2\,n + 1$, $n = 0,1,2,...$

$N_k = 5/2\,k^2 + 2$ for $k = 2\,n + 2$, $n = 0,1,2,...$

For **ABW**, the equations involve both k^2 and k:

$N_k = 19/9\,k^2 + 1/9\,k + 16/9$ for $k = 3\,n + 1$, $n = 0,1,2,...$

$N_k = 19/9\,k^2 - 1/9\,k + 16/9$ for $k = 3\,n + 2$, $n = 0,1,2,...$

$N_k = 19/9\,k^2 - 0\,k + 2$ for $k = 3\,n + 3$, $n = 0,1,2,...$

In general, all coordination sequences investigated in this study can be described exactly by a periodic set of quadratic equations of the form:

$$N_k = a_i k^2 + b_i k + c_i \quad \text{for} \quad k = M \cdot n + i, \quad \text{for} \quad n = 0, 1, 2, \ldots \text{ and } i = 1, 2, \ldots, M. \tag{1}$$

The number of equations, M, will be referred to as the *period length*. These equations hold for all k greater than or equal to some *starting point* k_0.

Following a definition of O'Keeffe (1991a), we define the "exact topological density" (TD) to be the mean of the a_i divided by the dimension N_D of the crystal space (which is 3 for all results presented here):

$$\mathrm{TD} = \frac{\langle a_i \rangle}{N_D} = \frac{1}{M \cdot N_D} \sum_{i=1}^{M} a_i \tag{2}$$

As k increases, the effect of the linear and constant coefficients b_i and c_i on the CS decreases, and the quadratic coefficient a_i dominates. The error in the approximation

$$N_k \approx N_D \cdot \mathrm{TD} \cdot k^2 \quad (3)$$

vanishes for

$k \to \infty$.

Algebraic description II: Generating functions

The generating function (GF) for a coordination sequence (cf. Sloane & Plouffe, 1994)

$$\mathrm{GF} = \sum_{k=0}^{\infty} N_k \cdot x^k \quad (4)$$

often provides a more concise description than the quadratic equations given in (1). The generating functions for the sequences considered in this study have the form:

$$\mathrm{GF} = \frac{\sum_{i=0}^{O(IT)-1} IT(i)x^i}{\prod_{i=0}^{O(PL)-1} (1 - x^{PL(i)})} \quad (5)$$

where IT is a set of order $O(IT)$ "initial terms" and PL is a set of (not necessarily distinct) $O(PL)$ "period lengths". The coefficients of the Taylor series expansion of the generating function then give the CS. For example, the GF for **ABW** is

$$\mathrm{GF}(\mathbf{ABW}) = \frac{1 + 3x + 6x^2 + 9x^3 + 9x^4 + 6x^5 + 3x^6 + x^7}{(1 - x^3)(1 - x^3)(1 - x)}$$

$$= 1 + 4x + 10x^2 + 21x^3 + 36x^4 + 54x^5 + \ldots$$

First, the GF's for some simple zeolites were obtained by using the Maple GFUN package (Waterloo Maple Software, 1994, Salvy & Zimmermann, 1994). However, more complex cases were beyond the capabilities of GFUN, and an alternative approach was used. Note that the Taylor series expansion of a generating function of the form (5) can be obtained by the simple *recursive reconstruction algorithm* shown in Fig. 1. This produces the coordination sequence from the sets *IT* and *PL*.

```
Copy initial terms to N0...NO(IT)-1
Set NO(IT)...Nk_max = 0
For each i = 0 to O(PL)-1
....For each k = PL(i) to kmax
........Nk = Nk + Nk-PL(i)
```

Figure 1 : Recursive reconstruction algorithm

Conversely, given the set *PL* and a *sufficient* number of CS terms, the set *IT* can be obtained by multiplying the GF by the denominator of (5). This is accomplished by the *recursive decomposition algorithm* shown in Fig. 2.

```
Copy the CS terms to N0...Nk_max
For each i = 0...O(PL)-1
....For each k = kmax-1...PL(i) step -1
........Nk = Nk - Nk-PL(i)
```

Figure 2 : Recursive decomposition algorithm

Properties (P) and manipulations (M) of generating functions and connection with quadratic equations

(P1) The individual members of the set *PL* can be arranged in any order. This follows immediately from Eq. (5). On the other hand, the order of the elements of the set *IT* is important.

(P2) Extra period lengths can be adjoined to the set *PL*, at the cost of enlarging the set *IT*. This corresponds to multiplying both the numerator and denominator of Eq. (5) by factors $1-x^n$.

(P3) In some cases it is possible to reduce the set *PL* by cancellation of factors. **APD T1** gives a simple example: with *PL* = { 21, 11, 8 } the set *IT* has 43 elements. However, with *PL* = { 11, 8, 7, 3 } the set *IT* has 32 elements. No further simplification is possible.

(M1) Reduction of set *IT* with enlargement of set *PL:*

Starting with initial sets *IT*/*PL*, two "compact" sets IT_c/PL_c are obtained with the algorithm shown in Fig. 3,

```
(a) Test if any element of PL can be omitted, by seeing if the
....corresponding term 1-xn divides the numerator of (5).
....If so, remove the element.
(b) Loop through the elements of PL.
....Call the current element the pivot element.
........Loop through all integer divisors of the pivot element
............Copy PL and divide the pivot element by the divisor
............Compute a large number of CS terms from the initial IT/
PL
............Apply the recursive decomposition algorithm and do a
................linear period search to recover a potentially
missing
................last period length
............Upon successful period search, restart with step (a)
```

Figure 3 : Reduction of set *IT* with enlargement of set *PL*

which is based on properties (P2) and (P3). This algorithm results in a set PL_c, of which no element can be omitted or further factorized. (However, this algorithm does not always produce the "most compact" GF.)

For IT_c/PL_c the following relations hold for all CS's investigated:

(P4) Let IT_c and PL_c be the sets obtained with manipulation technique (M1). The starting point for the periodic set of quadratic equations can be taken to be the difference between the degrees of the numerator and denominator of (5), or in other words

$$k_0 = O(IT_c) - \sum_{i=0}^{O(PL_c)-1} PL_c(i) \quad . \tag{6}$$

(P5) Let IT_c and PL_c be the sets obtained with manipulation technique (M1). The least common multiple

(LCM) of the elements of the set PL_c equals the period length of the set of quadratic equations:

$M = \mathrm{LCM}(PL_c)$.

For example, for **EUO T9** we have:

$O(IT_c) = 222$

$PL_c = \{ 36, 26, 24, 23, 22, 21, 17, 14, 10, 8, 5 \}$

$\Rightarrow k_0 = 222 - 206 = 16$

$M = 140900760$

(M2) Reversal of (M1) - Reduction of set *PL* with enlargement of set *IT*:

The number of elements of an initial set *PL* can be reduced with the algorithm shown in Fig. 4. Using this algorithm, it was possible to modify the generating functions for all the CS's investigated so that in every case exactly three *PL* elements were required.

```
(a) Test if any element of PL can be omitted.
....If so, remove the element.
(b) Loop through all pairs of elements of PL
........Copy PL, omitting the current pair of elements
........Compute a large number of CS terms from the initial IT/PL
........Apply the RD algorithm and do a linear period search to
............recover a potentially missing last period length
........Upon successful period search, restart with step (b)
(c) Repeat (a) and (b) until no change occurs
```

Figure 4 : Reduction of set *PL* with enlargement of set *IT*

(M3) Finding upper bounds on the sub-period lengths of the coefficients a_i, b_i, c_i of the set of quadratic equations:

Upper bounds on the sub-period lengths of the coefficients a_i, b_i, c_i can be established with a very simple algorithm. Based on IT_c/PL_c, about $3 \cdot \mathrm{LCM}(PL_c)$ CS terms are computed. Next, the recursive

decomposition algorithm is applied with PL = { LCM(PL_c), LCM(PL_c) }. With a linear period search in the resulting sequence, an upper bound pl_a on the sub-period length $O(a_i)$ is obtained. The process is repeated with PL = { LCM(PL_c), pl_a } to obtain pl_b, and finally with PL = { pl_a, pl_b } to obtain pl_c.

For all sequences but those of **GOO T3**, **JBW T1** & **T2**, **TON T1** & **T2**, the Fe position of FeS_2-Marcasite, and both position of CaF_2(2), the bounds pl_a, pl_b and pl_c are exactly equal to the sub-period lengths $O(a_i)$, $O(b_i)$ and $O(c_i)$, respectively. For the exceptional cases (and of course also in general), the relations $pl_a \geq O(a_i)$, $pl_b \geq O(b_i)$ and $pl_c \geq O(c_i)$ hold. Moreover, for all CS's the relation $pl_a \leq pl_b \leq pl_c$ holds, and $O(a_i) \leq O(b_i) \leq O(c_i)$ is valid for all CS except those of **GOO T3**, **JBW T1** & **T2**, the Fe position of FeS_2-Marcasite, and both positions of CaF_2(2).

By application of the manipulation techniques (M2) and (M3), it was always possible to obtain $O(PL)$ = 3 for all 390 three-dimensional CS's that were investigated. It is conjectured that this holds for any three-dimensional CS.

In simple cases, such as the f.c.c. or b.c.c. lattices, the elements of the set *IT* are positive integers. Indeed, it follows from the work of Stanley (1976 & 1980) that if certain conditions are satisfied (one of which is that the set of points in or on the *k*-th coordination shell is convex), then the *IT* are necessarily positive. In the present investigation, however, many examples with negative *IT* elements were encountered. For example, the As position of NiAs(1) has *IT* = { 1, 4, 12, 10, -5, 2 }, *PL* = {2, 1, 1 }.

Application of (M2) and (M3)

Since the computation of the CS terms with the recursive reconstruction algorithm requires the whole sequence to be held in memory, major difficulties arise for large period lengths. For example, the determination of the topological density for **EUO** requires about $3 \cdot M$ = 422702280 64-bit integers to be stored, a total of about 3.15 gigabytes. However, for the case *O(PL)* = 3, a special purpose algorithm for computing the CS terms with small memory was devised. This algorithm is several orders of magnitude slower than the simpler recursive reconstruction algorithm, but - in combination with the manipulation techniques (M2) and (M3) - enabled the determination of the topological density even for the largest cases.

Second differences of CS's

The second derivative of a quadratic polynomial is a constant. By analogy, the second differences between successive terms of the CS in a number of examples are constant, or have a constant period. For example, the CS of the SiO_2 polymorph tridymite (**tri**) and the corresponding first ($F_k = N_k - N_{k-1}$) and

second ($S_k = F_k - F_{k-1}$) differences are:

$$CS(\text{tri}) = \{4, 12, 25, 44, 67, 96, 130, 170, 214, 264, 319, 380, 445, 516, \ldots\}$$

$$1.Diff(CS(\text{tri})) = \{8, 13, 19, 23, 29, 34, 40, 44, 50, 55, 61, 65, 71, \ldots\}$$

$$2.Diff(CS(\text{tri})) = \{(5, 6, 4, 6), (5, 6, 4, 6), (5, 6, 4, 6), \ldots\}$$

The period length of the second differences is four, as indicated by the parentheses. [Although it is not needed here, it is worth mentioning that Herschel's "circulator" notation provides a convenient terminology for describing such periodic sequences (Comtet, 1974, p. 109).]

The occurrence of a constant period in the second differences implies $b_i = 0$ for the entire (periodic) set of quadratic equations. For example, for **ABW** some b_i are different from zero (see above) and the numerical values of the second differences are not constant. However, their plot (Fig. 5) clearly reveals a periodicity, which can be used to estimate one period length for the recursive decomposition. In this case the period length is three. And indeed, the set of period lengths for **ABW** is { 3, 3, 1 }.

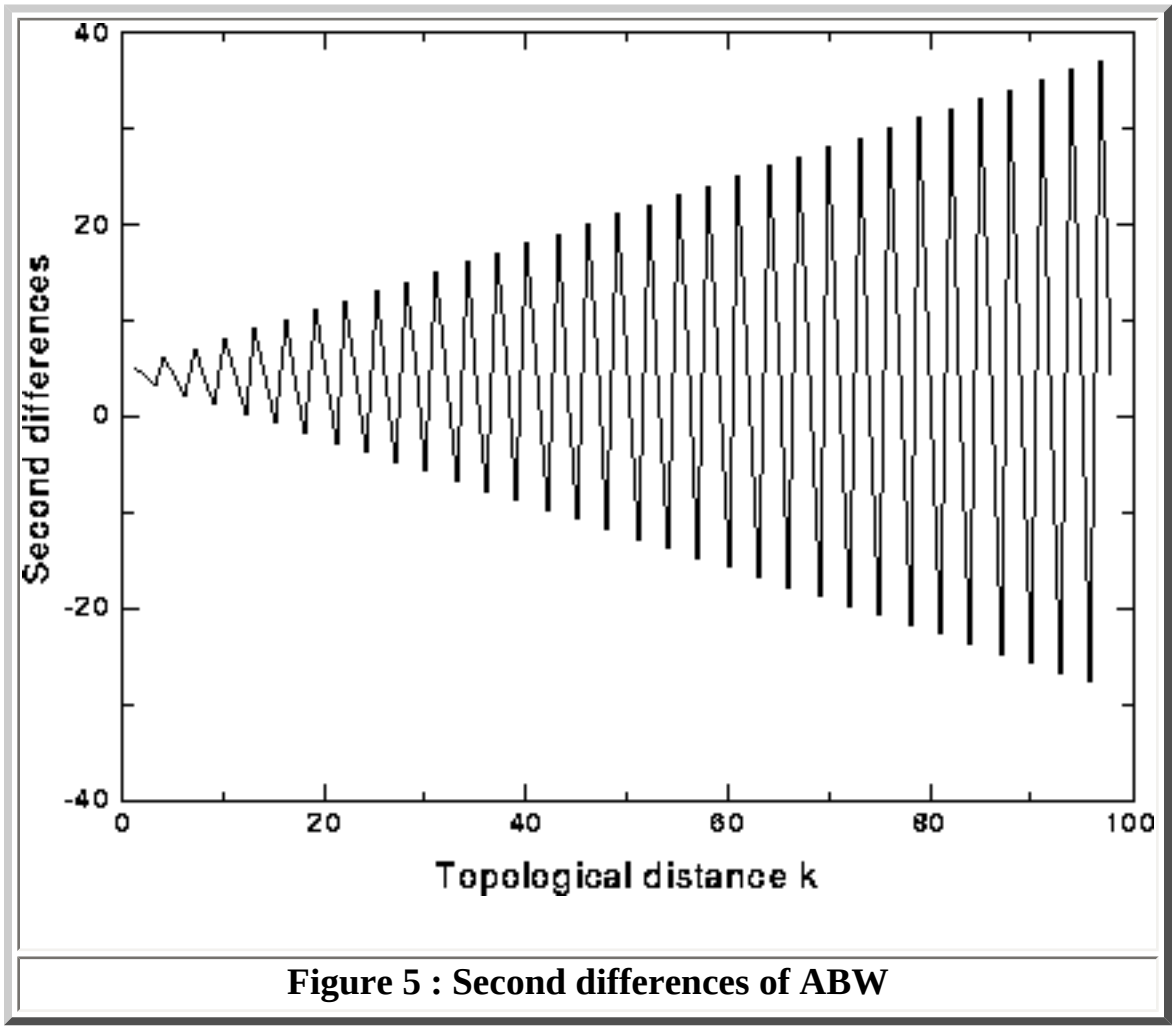

Figure 5 : Second differences of ABW

Strategy for the determination of the exact topological density

Typically, the determination of the exact topological density (TD) requires the following steps:

1. Computation from 100 to 2000 terms of the CS with the node-counting algorithm.
2. Investigation of the second differences: often this reveals one "period length" for the recursive decomposition.
3. Determination of the period lengths for the recursive decomposition.
4. Alternative 1: Computation of a few million terms of the CS, search for a periodic set of quadratic equations, and computation of TD from Eq. (2).
   Alternative 2: Computation of k_0 *via eq. (6)*, M = LCM(PL_c) and the corresponding $3 \cdot O(a_i)$ CS terms; computation of one sub-period of a_i; computation of TD from Eq. (2).

All but step (3) have been outlined above. For the determination of the period lengths for the recursive decomposition two techniques have been applied:

(a) A set of n maximum period lengths $PL_{max} = \{pl(0)_{max}, pl(1)_{max}, \ldots, pl(n\text{-}1)_{max}\}$ is prescribed, and the first position is tested from 1 to $pl(0)_{max}$. At each pass of the loop, the recursive decomposition algorithm is applied to the CS, followed by a check for a sufficiently large sequence of zeros at the end of the resulting sequence. Also, a linear period seeking algorithm tries to recover a possibly last missing period length. In case of no success, $pl(1)$ is also tested and a loop with two variables, but avoiding permutations, is executed. Unless a solution has been found, more and more loop positions are activated, until the entire set is depleted.

(b) A review of several known PL sets revealed that individual pl often occur in pairs. This observation and the exploitation of properties (P1) and (P2) led to the following strategy: Given a large number of CS terms, attempt to obtain a decomposition using $PL = \{ m, m, m\text{-}1, m\text{-}1, \ldots, 2, 2, 1, 1 \}$.

Upon success, the initial set PL is subjected to manipulation technique (M1), in order to obtain IT_c and PL_c, the compact form of description of the particular CS.

Example with decomposition technique (a)

For **EUO T9**, 1460 CS terms were calculated with the node counting algorithm. Investigation of the second differences suggested a pl of 15, which was then applied to the CS. The resulting sequence was processed with $PL_{max} = \{ 400, 300, 200, 100, 40, 40, 40 \}$ (of course there was no hope that this loop

would ever run to completion). At loop position *PL* = { 391, 286, 40 } the linear period seeking algorithm found a period with length 504. Using the combined set *PL* = { 504, 391, 286, 40, 15 }, the size of the set *IT* is 1252. By means of the manipulation technique (M1), the final solution PL_c = { 36, 26, 24, 23, 22, 21, 17, 14, 10, 8, 5 } was obtained, together with 222 IT_c elements.

Example with decomposition technique (b)

For **MAZ T2**, 999 CS terms were calculated with the node counting algorithm. Setting *PL* = { 15, 15, 14, 14, ... , 1, 1 } revealed a solution with 241 *IT* elements. Using manipulation technique (M1), the final solution PL_c = { 14, 11, 10, 8, 7 } with 51 IT_c elements was obtained.

Results of the algebraic analysis

For 127 crystal structures, a total of 402 coordination sequences were investigated, of which 390 are unique. For the zeolite structures there are eight sequences which occur in two or more crystallographically different environments:

ABW = **ATN**
LTA = **RHO**
CAN = **AFG T2** = **AFG T3** = **LIO T2** = **LIO T4** = **LOS T2**
GME = **AFX T1**
AFS T3 = **BPH T3**
EDI T1 = **THO T1**
ERI T1 = **OFF T1**
EAB T2 = **OFF T2**

Furthermore, the CS of one atom of α-Nd (the position at the origin) is equal to the CS of Mg, and one CS of NiAs(1) (again for the position at the origin) is equal to the CS of W(1).

Tables 3-5 list the results of the algebraic analysis. Column "*S*" gives the number of different CS's for the structure indicated in the first column. Except for **AFG** and **LIO**, which have two different sites with the same CS, this is also the number of crystallographically distinct positions. "*O(IT)*" and "*O(PL)*" designate the order of the set of initial terms and period lengths, respectively. For structures with more than one topologically distinct site, the range is given (e.g. **EUO**: 213-233 initial terms). However, if there are only two values, these are separated by a comma instead of a hyphen (e.g. for **EUO**, *O(PL)* is either 10 or 11 for all ten sequences), and in some cases all sets have an equal number of members and only one value is necessary. "*M*" is the number of quadratic equations which make up the periodic set. "TD", the exact topological density defined by Eq. (2), is given exactly, as a rational fraction multiplied by N_D = 3 (TD · N_D = $\langle a_i \rangle$) and, for better comparability, also as decimal number. "TD10" and "Δ%"

are defined by equations (7) and (8) below.

All the coordination sequences in this study have been added to the electronically accessible version of (Sloane & Plouffe, 1995) at the address sequences@research.att.com (Sloane, 1994). In this way, the CS can be used as a "fingerprint" to assist in the identification of a crystal structure.

Properties of the coefficients of the quadratic equations

For most of the zeolites with only one or two tetrahedral sites, and for the dense SiO_2 polymorphs, the structure of the coefficients of the quadratic equations was investigated. These structures all share one or more of the following characteristics: the parameter *a* is the same for all terms or shows a shorter period than *b* and *c*; the parameter *b* is zero or shows a shorter period than *c*; different periods appear for odd and for even values of *i*; some or all parameters are "palindromic". The following are some typical examples. The most "special" example is **SOD**. The CS is $N_k = 2k^2 + 2$: *4, 10, 18, 34, ,* thus *a = 2, b = 0, c = 2*; the period *M* is *1*. This type of equation also occurs for the structures of NaCl, W and Cu (P, I and F-lattice complexes) with *a = 4, 6* and *10*, respectively.

A somewhat less special example is **AFI**. The parameters are *a* = 21/10, *b* = 0 for all values of *k*, and *M* = 10. The parameter *c* is palindromic about *k* = *M*/2 = 5. This means that *c* is the same for *k* = 1 and *k* = 9; it is also the same for the pairs 2&8, 3&7, and 4&6, respectively. For *k* = 10, the parameter *c* is 2. Such palindromic behavior about *k* = *M*/2 is frequently observed. An example in which *M* is odd is **KFI** with *a* = 12/7, *b* = 0 for all *k*, *M* = 7, where *c* is palindromic about *k* = 3.5 (thus *c* is the same for the pairs *k* = 1&6, 2&5, and 3&4, respectively). For the last term of the period (*k* = 7), c is again 2. Another kind of palindromic behavior may appear if *b* is not zero: the magnitudes of *b* and of *c* are the same for pairs of *k* as in the previous examples, but the signs of *b* may differ for the two members of a pair. An example is **CAN**.

Very often, the parameters *a* and *b* are the same for all values of *k* or show a much shorter period than *c*. An example is **AFY: for site T1** *b* = 0 for all *k*, for atom **T2**, *b* has period 3 with the values 1/6, -1/6, 0 respectively, while *c* has a period of 30 if *k* is odd and 60 if *k* is even. In the examples mentioned so far, either *b* itself or the sum of the *b*'s over the period is zero. This is not the case for either atom of milarite: all values of *b* are negative.

TD as topological invariant

In those cases where the parameter *a* is not the same for all values of *k* but is periodic, $TD = \langle a_i \rangle / N_D$ (Eq. 2) is the same for all atoms in a framework. A check with two-dimensional nets showed that (after a certain number of spheres) it is even the same if any cluster is chosen as a "starting point". Therefore, for all structures considered in this work, the CS's have been computed and analyzed with all sites in the unit cell as starting cluster. In any case the resulting TD was equal to the TD when starting with only one

atom. Thus we conclude that TD is actually a topological invariant of a framework (in general, the parameters *a*, *b*, *c* and *M* (Eq. 1) are not), comparable to the cycle classes introduced by Beukemann & Klee (1994).

Correlation of TD and TD10

The Atlas of Zeolite Structure Types (1992 & 1996) lists a quantity called the "Topological Density" and denoted by TD10. This is defined to be the average number of nodes (atom sites) in a cluster of topological radius 10, weighted by the multiplicities m_j of the *s* sites:

$$TD10 = \left(\sum_{j=1}^{s} m_j \left(1 - \sum_{k=1}^{10} N_{kj} \right) \right) / \sum_{j=1}^{s} m_j \quad (7)$$

Using Eq. (3) (TD is the same for all sites of a structure) leads to

$$TD10 = \left(\sum_{j=1}^{s} m_j \left(1 - \sum_{k=1}^{10} (TD \cdot N_D)\, k^2 \right) \right) / \sum_{j=1}^{s} m_j = 1 - (TD \cdot N_D) \sum_{k=1}^{10} k^2 = 1 - 385\,(TD \cdot N_D)$$

hence

$$TD = \frac{TD10 - 1}{385 \cdot N_D} = TD10_{norm} \quad (8)$$

The rightmost column of Tables 3-5 (Δ%) lists the percentage deviations of $TD10_{norm}$ from the exact TD. Fig. 6 is a histogram of the distribution of the deviations. For the majority of the structures the deviation is well below 3%, but there are also some outliers. A deviation of more than five percent was found for **-CHI** and **-CLO**, two interrupted frameworks, for **FAU**, and for six of the non-tetrahedral structures. These three zeolites represent relatively open and/or complex structures and one might conclude that more than ten steps are necessary in such cases in order to achieve a satisfactory convergence, but on the other hand very complex structures like **PAU** and **MFI** show a very good correlation between the exact topological density and TD10. In view of this, the additional effort necessary to obtain the exact TD seems justified, and previous work based on approximations to the exact value should perhaps be reconsidered.

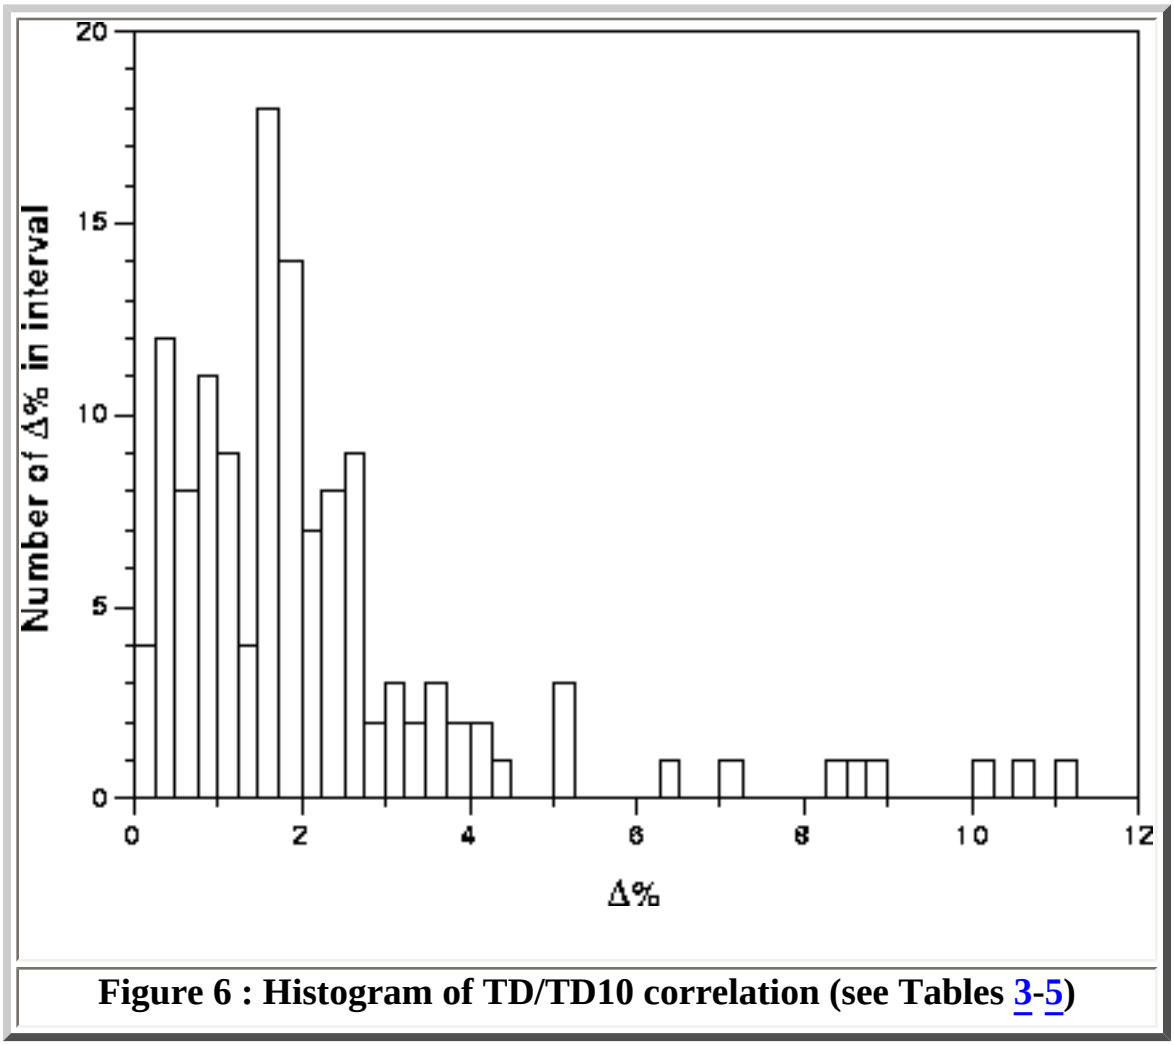

Figure 6 : Histogram of TD/TD10 correlation (see Tables 3-5)

Consequences for the definition of the coordination sphere

The choice of the bond length (Table 2) determines the network and is a constant matter of debate. The quantities TD and TD10, which reflect long range properties of the framework, may help in choosing a sensible specification for the local environment. As an example, the 8-coordinated network of tungsten (W(1) in Tables 2 and 5) leads to strange values for the densities, while the 14-connected network has densities which fit in the list of metallic structures. The 14-connected network admits the second-longest bonds, which are only 15% longer. A similar geometric situation exists in CaF_2, but now the second nearest (also 15% more distant) neighbors of fluorine should not be admitted. They would lead to a values for the densities which differ considerably from those of metals, whereas the lower coordination with only four neighbors brings CaF_2 (2) in the vicinity of NaCl, and again related structures stand together.

Some special n-dimensional periodic graphs

The coordination sequence of an *n*-dimensional graph or net (cf. Wells, 1977) necessarily has $O(PL) \geq n$.

In one dimension, the simplest periodic graph is a linear chain, for which the CS is 1, 2, 2, , with *IT* = { 1, 1 }, *PL* = { 1 }. In two dimensions, the hexagonal net 6^3 (which occurs for example in the mineral biotite) has the CS 1, 3, 6, 9, 12, 15, , with *IT* = { 1, 1, 1 }, *PL* = { 1, 1 }. In three dimensions, as already mentioned, sodalite has *IT* = { 1, 1, 1, 1 }, *PL* = { 1, 1, 1 }. In a sense, these are the simplest coordination sequences in dimensions 1, 2 and 3.

O'Keeffe (1991b) has generalized these three structures to higher dimensions, defining "*n*-dimensional sodalites" for all *n*. He also gives their coordination sequences for $n \leq 6$. The generating functions of these sequences have been analyzed, and were found to continue the pattern of the first three: the set *IT* consists of *n*+1 1's, and *PL* of *n* 1's. It is reasonable to conjecture that this holds in general. In a forth-coming paper (Conway & Sloane, submitted) it will be shown that this conjecture is equivalent to the assertion that the points in or on the *k*-th coordination shell of *n*-dimensional sodalite are in one-to-one correspondence with the *n*-dimensional "centered tetrahedral" numbers.

Conclusions

The main objectives of this work were to obtain (i) an exact definition and numerical values for topological densities, which can be used to investigate correlations with other properties of the crystal structures, and (ii) a better understanding of coordination sequences, since these are now frequently used to characterize structures (see for example the novel structure determination technique in Grosse-Kunstleve, 1996). Regarding this aim, we consider our work to be a full success. We have developed a recursive decomposition for the fast and efficient calculation of an arbitrary number of CS terms, and have computed exact numerical values for the topological density, which is an invariant of all the structures investigated.

However, the results are empirical, as there is no rigorous mathematical proof that a generating function of the form (5) must hold for the CS of a periodic structure. The applicability of Eq. (5) has been verified for certain one, two and three-dimensional periodic topologies. In the case of one and two dimensions, the justification is straightforward, but already in three dimensions there are difficulties. But this is a relatively minor point. Once the generating function has been discovered, watching its Taylor series expansion match the CS for hundreds or even thousands of terms carries complete conviction!

Another unresolved question concerns the conditions under which the special numerical properties of the quadratic equations hold.

Acknowledgment

The help of Uwe Hollerbach at Boston University in running the period search for the coordination sequences of **EUO** and **MFI** is very much appreciated.

Restricted 132-Involutions

Abstract. We study generating functions for the number of involutions of length *n* avoiding (or containing exactly once) 132 and avoiding (or containing exactly once) an arbitrary permutation *\tau* of length *k*. In several interesting cases these generating functions depend only on *k* and can be expressed via Chebyshev polynomials of the second kind. In particular, we show that involutions of length *n* avoiding both 132 and 12...k are equinumerous with involutions of length *n* avoiding both 132 and any *extended double-wedge pattern* of length *k*. We use combinatorial methods to prove several of our results.

Lattice paths, reflections, & dimension-changing bijections

(13 pages)

Abstract. We enumerate various families of planar lattice paths consisting of unit steps in directions N, S, E, or W, which do not cross the x-axis or both x- and y-axes. The proofs are purely combinatorial throughout, using either reflections or bijections between these NSEW-paths and linear NS-paths. We also consider other dimension-changing bijections.

Number theoretic aspects of a combinatorial function

Lorenz Halbeisen[1] and Norbert Hungerbühler

Abstract

We investigate number theoretic aspects of the integer sequence $\mathrm{seq}^{1\text{-}1}(n)$ with identification number A000522 in Sloane's On-Line Encyclopedia of Integer Sequences: $\mathrm{seq}^{1\text{-}1}(n)$ counts the number of sequences without repetition one can build with n distinct objects. By introducing the the notion of the "shadow" of an integer function, we examine divisibility properties of the combinatorial function $\mathrm{seq}^{1\text{-}1}(n)$: We show that $\mathrm{seq}^{1\text{-}1}(n)$ has the reduction property and its shadow d therefore is multiplicative. As a consequence, the shadow d of $\mathrm{seq}^{1\text{-}1}(n)$ is determined by its values at powers of primes. It turns out that there is a simple characterization of regular prime numbers, i.e. prime numbers p for which the shadow d of $\mathrm{seq}^{1\text{-}1}$ has the socket property $d(p^k) = d(p)$ for all integers k. Although a stochastic argument supports the conjecture that infinitely many irregular primes exist, there density is so thin that there is only one irregular prime number less than $2.5 \cdot 10^6$, namely 383.

1 Introduction

The sequence we are interested in has the ID number A000522 in Sloane's On-Line Encyclopedia of Integer Sequences (http://www.research.att.com/~njas/sequences). Former identification numbers of this sequence were M1497 in [SP] and N0589 in [Sl].

The sequence A000522 has many faces (see, e.g., [Ga], [Si] or [Ri]). The most accessible one is its combinatorial interpretation:

Definition 1 *For $n \in \mathbb{N} = \{0, 1, 2, \dots\}$ let $\mathrm{seq}^{1\text{-}1}(n)$ denote the number of one-to-one sequences – these are sequences without repetitions – we can build with n distinct objects.*

[1]The author would like to thank the *Swiss National Science Foundation* for supporting him.

2000 Mathematics Subject Classification: **11A51** 11B50 11B75 11A41

Notice that for $l \leqslant n$, each one-to-one function from $\{0, \ldots, l-1\}$ to $\{0, \ldots, n-1\}$ corresponds in a unique way to a sequence without repetitions of $\{0, \ldots, n-1\}$ of length l. For example, for two objects, say a_1 and a_2, we can build the following sequences:

$$\langle\ \rangle\ (= \text{the empty sequence}), \langle a_1\rangle, \langle a_2\rangle, \langle a_1, a_2\rangle, \langle a_2, a_1\rangle.$$

Hence, $\mathrm{seq}^{1\text{-}1}(2) = 5$. Of course, it is easy to find a general expression for $\mathrm{seq}^{1\text{-}1}(n)$. Since there are $\binom{k}{n}$ possible ways to choose k objects from a set of n (distinct) objects, and since k (distinct) objects give rise to $k!$ permutations, we get the following

Lemma 2 $\mathrm{seq}^{1\text{-}1}(n) = \displaystyle\sum_{k=0}^{n} \binom{n}{k} k! = \sum_{j=0}^{n} \frac{n!}{j!}$. ■

Also the next representation for $\mathrm{seq}^{1\text{-}1}(n)$ is elementary.

Lemma 3 *For all positive $n \in \mathbb{N}$ we have*

$$\mathrm{seq}^{1\text{-}1}(n) = \lfloor e\, n! \rfloor.$$

Remark: For $n = 0$ the formula does not hold, since $\mathrm{seq}^{1\text{-}1}(0) = 1 < 2 = \lfloor e\, 0! \rfloor$.

Proof of Lemma 3. According to Lemma 2 we have

$$\begin{aligned} en! &= \mathrm{seq}^{1\text{-}1}(n) + \sum_{j=n+1}^{\infty} \frac{n!}{j!} \\ &= \mathrm{seq}^{1\text{-}1}(n) + \\ &\quad + \underbrace{\frac{1}{n+1}\Big(1 + \frac{1}{n+2} + \frac{1}{(n+2)(n+3)} + \frac{1}{(n+2)(n+3)(n+4)} + \ldots\Big)}_{\leqslant \frac{1}{n+1}(e-1) < 1 \text{ for } n \geqslant 1}. \end{aligned}$$

■

The following recursive relation for $\mathrm{seq}^{1\text{-}1}(n)$ is an immediate consequence of the second formula in Lemma 2.

Lemma 4 *For all positive $n \in \mathbb{N}$ we have* $\mathrm{seq}^{1\text{-}1}(n) = n\,\mathrm{seq}^{1\text{-}1}(n-1) + 1$. ■

Using this formula, we finally get the following integral representation of $\mathrm{seq}^{1\text{-}1}(n)$.

Lemma 5 *For all $n \in \mathbb{N}$ we have*

$$\mathrm{seq}^{1\text{-}1}(n) = e \int_1^\infty t^n e^{-t} dt \,.$$

Proof. The formula is correct for $n = 0$. Moreover, by integration by parts, we have inductively

$$\begin{aligned} \mathrm{seq}^{1\text{-}1}(n) = e \int_1^\infty \underbrace{t^n}_{\downarrow} \underbrace{e^{-t}}_{\uparrow} dt &= e\left(-t^n e^{-t}\right)\Big|_1^\infty + e \int_1^\infty n t^{n-1} e^{-t} dt \\ &= 1 + n\,\mathrm{seq}^{1\text{-}1}(n-1) \end{aligned}$$

■

Just for the sake of completeness we like to mention that the exponential generating function $g(z)$ of $\mathrm{seq}^{1\text{-}1}(n)$ is given by $g(z) = \frac{e^z}{1-z}$. This is easily checked directly, or deduced, e.g. by Oberschelp's technique (see [Ob]).

In the sequel, to keep the formulas short, let $n^\star := \mathrm{seq}^{1\text{-}1}(n)$.

Notation: Throughout this text we adopt the standard notation $a|b$ to express that a divides b for $a, b \in \mathbb{N}$. Moreover, if $b \geqslant 1$ then $\mathrm{Mod}(a,b) := a - b\lfloor \frac{a}{b} \rfloor$ denotes the reminder of the division of a by b; and (a,b) denotes the greatest common divisor of a and b.

2 The divisibility of $n^\star$

We start our investigation on divisibility properties of $n^\star$ with a simple fact which has first been proved in [HS].

Lemma 6 *For natural numbers $n, k \in \mathbb{N}$, the following implication holds: If $2^k | n^\star$, then $2^k | (n+2^k)^\star$ and $2^k \nmid (n+t)^\star$ for any t with $0 < t < 2^k$.*

Proof. The implication $2^k | n^\star \implies 2^k | (n+2^k)^\star$ follows easily from the reduction property of the sequence $\mathrm{seq}^{1\text{-}1}(n)$ (see Lemma 9 below). So, we only have to prove here that if $2^k | n^\star$, then $2^k \nmid (n+t)^\star$ for any t with $0 < t < 2^k$.

For $k \leqslant 4$, an easy calculation modulo 2^k shows that for each n we have: If $2^k \mid n^\star$, then $2^k \nmid (n+t)^\star$ for $0 < t < 2^k$ (cf. also Lemma 9).

Assume there is a smallest k ($k \geqslant 4$) such that $2^{k+1} | n^\star$ and $2^{k+1} \mid (n+t)^\star$ for some t with $0 < t < 2^{k+1}$. Then, because $2^k | 2^{k+1}$, we have $2^k | n^\star$ and $2^k | (n+t)^\star$. Since k

is by definition the smallest such number, we know that t must be 2^k.

$$
\begin{array}{rcccccccccccl}
(n+2^k)^\star = \sum_{i=0}^{n+2^k} \frac{(n+2^k)!}{i!} = & & 1\cdot & 2\cdot & \ldots & \cdot 2^k\cdot & (2^k+1)\cdot & \ldots & \cdot(2^k+n) & & & & (1)\\
& + & & 2\cdot & \ldots & \cdot 2^k\cdot & & \ldots & \cdot(2^k+n) & & & & (2)\\
& & & & \ddots & & & & & & & & \vdots\\
& + & & & & 2^k\cdot & & \ldots & \cdot(2^k+n) & & & & (2^k)\\
& & & & & & & \ddots & & & & & \vdots\\
& + & & & & & & & (2^k+n) & & & & (2^k+n)\\
& + & & & & & & & & 1 & & & (2^k+n+1)
\end{array}
$$

It is easy to see that 2^{k+1} divides lines $(1) - (2^k)$ since $k \geqslant 2$ and $n \geqslant 2$.

If we expand the products in the lines $(2^k+1) - (2^k+n+1)$, we can collect all terms which are obviously divisible by 2^{k+1}. So, for a suitable natural number m we get

$$(n+2^k)^\star = 2^k \cdot \left(\sum_{j=0}^{n-1} \sum_{i>j}^{n} \frac{n!}{i \cdot j!} \right) + n^\star + 2^{k+1} \cdot m\,. \tag{1}$$

Remember that we have assumed $2^{k+1} | n^\star$, where $n \geqslant 3$ and $k \geqslant 4$. Thus, $n^\star$ is even and hence n has to be odd. If j is $n-1$, $n-2$ or $n-3$, then $\sum_{i>j}^{n} \frac{n!}{i \cdot j!}$ is odd. Moreover, if $0 \leqslant j \leqslant (n-4)$, then $\sum_{i>j}^{n} \frac{n!}{i \cdot j!}$ is even and therefore, $\sum_{j=0}^{n-1} \sum_{i>j}^{n} \frac{n!}{i \cdot j!}$ is odd. Hence, by (1) and $2^{k+1} | n^\star$ we get $2^{k+1} \nmid (n+2^k)^\star$, which is a contradiction. ■

Remark. The Lemma 6 is the crucial point in the proof – which does not make use of the axiom of choice – of the following fact (cf. [HS, Theorem 4]): For any infinite set M, there exists no bijection between the power-set of M and the set of all finite one-to-one sequences of M.

A natural question that arises in connection with Lemma 6 is whether for every $k \in \mathbb{N}$ there exists an $n \in \mathbb{N}$ such that $2^k \mid n^\star$. To answer this and related questions involving divisibility properties of integer sequences in general and of the sequence $\mathrm{seq}^{1\text{-}1}(n)$ in particular, we introduce the notion of the "shadow" of a sequence.

Definition 7 *If $\{f(n)\}_{n\in\mathbb{N}}$ is a sequence of natural numbers, we define its* **shadow** *to be the sequence $\{d(h)\}_{h\in\mathbb{N}}$ given by*

$$d(h) := |D(h)|,$$

where $D(h) := \big\{n \in \mathbb{N} : (n < h) \wedge (h \mid f(n))\big\}$ are the **shadow sets** *of the sequence f.*

The shadow $d(h)$ counts the sequence entries $f(0), f(1), \ldots, f(h-1)$ which are divisible by h. So, the shadow measures (to a certain extent) how "divisible" the entries of the sequence $f(n)$ are: For example, if only prime numbers occur in the sequence, then its shadow will reflect this fact by being small. If the entries of $f(n)$ have many divisors, the shadow will typically be large.

Remark. Lemma 6 implies that the shadow of $f(n) = \mathrm{seq}^{1\text{-}1}(n)$ has the following property: For all $k \in \mathbb{N}$, there holds $d(2^k) \leqslant 1$. Actually, as a consequence of Lemma 15, it will turn out that $d(2^k) = 1$ for all k.

Examples. If $f(n) = c \in \mathbb{N}$ is a constant function, then the shadow of f is

$$d(h) = \begin{cases} h & \text{if } h|c \text{ and } h > 1, \\ 0 & \text{otherwise.} \end{cases}$$

If $f(n)$ is an arithmetic sequence of first order, then its shadow is periodic, and for the shadow of Euler's φ-function we have $d(h) = 1$ for all $h \geqslant 1$. ◯

The shadow gives a certain amount of information on the divisibility of the entries of a sequence. Nevertheless, two different sequences can "cast" the same shadow as the following example shows.

Example. If for a function f there exists an $n_0 \in \mathbb{N}$ such that for all $h \geqslant n_0$ we have $d(h) = 0$, then for all $h \geqslant n_0$ we have $f(h) \leqslant h$. Vice versa, if $f(h) \leqslant h$ for all $h \in \mathbb{N}$, then $d(h)$ equals the number of zeros in $(f(0), f(1), \ldots, f(h-1))$. Hence, it is easy to construct different functions which have the same shadow:

n	0	1	2	3	4	5	6	7	...
$f_1(n)$	0	1	2	3	4	5	6	7	...
$f_2(n)$	0	1	1	2	3	4	5	6	...
$f_3(n)$	0	1	1	1	2	3	4	5	...
shadow	0	1	1	1	1	1	1	1	...

◯

Now, we want to investigate the shadow of $\mathrm{seq}^{1\text{-}1}(n)$. First, we show that this particular shadow is multiplicative and it turns out that the reason for this is the fact that $\mathrm{seq}^{1\text{-}1}$ has the reduction property:

Definition 8 *A sequence $\{f(n)\}_{n\in\mathbb{N}}$ is said to have the reduction property, if for all $n, q \in \mathbb{N}$, $q \geqslant 1$, we have*

$$\mathrm{Mod}(f(n), q) = \mathrm{Mod}(f(\mathrm{Mod}(n, q)), q).$$

Lemma 9 *The sequence $\{\mathrm{seq}^{1\text{-}1}(n)\}_{n\in\mathbb{N}}$ has the reduction property.*

Proof. For $q = 1$ or $q > n$, the statement is trivial. So, we may assume $1 < q \leqslant n$.

First we consider the case when $\mathrm{Mod}(n, q) = 0$. By Lemma 4 we have $\mathrm{seq}^{1\text{-}1}(n) = n \cdot \mathrm{seq}^{1\text{-}1}(n-1) + 1$ and hence by $\mathrm{Mod}(n, q) = 0$ we get $\mathrm{seq}^{1\text{-}1}(n) \equiv 1 \mod q$, which implies $\mathrm{Mod}(\mathrm{seq}^{1\text{-}1}(n), q) = \mathrm{Mod}(\mathrm{seq}^{1\text{-}1}(\mathrm{Mod}(n, q)), q)$, because $\mathrm{seq}^{1\text{-}1}(0) = 1$.

Now assume that $\mathrm{Mod}(n+1, q) \neq 0$ and that the statement holds for n. Again by Lemma 4 we have $\mathrm{seq}^{1\text{-}1}(n+1) = (n+1) \cdot \mathrm{seq}^{1\text{-}1}(n) + 1$ and by the assumption we get

$$\begin{aligned} \mathrm{seq}^{1\text{-}1}(n+1) &\equiv \mathrm{Mod}((n+1), q) \cdot \mathrm{seq}^{1\text{-}1}(\mathrm{Mod}(n, q)) + 1 \mod q \\ &\equiv \mathrm{seq}^{1\text{-}1}(\mathrm{Mod}(n+1, q)) \mod q. \end{aligned}$$

Therefore, $\mathrm{Mod}(\mathrm{seq}^{1\text{-}1}(n+1), q) = \mathrm{Mod}(\mathrm{seq}^{1\text{-}1}(\mathrm{Mod}(n+1, q)), q)$ is validated. ■

Lemma 10 *The shadow d of a sequence $f(n)$ which has the reduction property is multiplicative, i.e. if $(a, b) = 1$, then $d(ab) = d(a)d(b)$.*

Proof. Suppose $(a, b) = 1$, then we have by the reduction property

$$\begin{aligned} D(ab) &= \{n \in \mathbb{N} : n < ab \wedge ab | f(n)\} \\ &= \{n \in \mathbb{N} : n < ab \wedge a | f(n) \wedge b | f(n)\} \\ &= \{n \in \mathbb{N} : n < ab \wedge a | f(\mathrm{Mod}(n, a)) \wedge b | f(\mathrm{Mod}(n, b))\}. \end{aligned}$$

This means that a natural number n is an element of the shadow set $D(ab)$ if and only if it lies in the intersection of the two sets

$$A := \{i + ax : i \in D(a) \wedge x \in \{0, 1, \ldots, b-1\}\}$$

and

$$B := \{j + by : j \in D(b) \wedge y \in \{0, 1, \ldots, a-1\}\}.$$

In other words $D(ab) = A \cap B$.

Observe that since $(a, b) = 1$, we have that for all $\langle i, j\rangle \in \{0, 1, \ldots, a-1\} \times \{0, 1, \ldots, b-1\}$ there exists a unique $\langle x, y\rangle \in \{0, 1, \ldots, b-1\} \times \{0, 1, \ldots, a-1\}$ such that $i + ax = j + by$. This implies that $|A \cap B| = |D(a)|\,|D(b)|$ and hence,

$$d(ab) = |D(ab)| = |A \cap B| = |D(a)|\,|D(b)| = d(a)\,d(b).$$ ■

As an immediate consequence we get the following

Corollary 11 *If d is the shadow of* $\mathrm{seq}^{1\text{-}1}$ *and if $n = \prod_{i=1}^{k} p_i^{k_i}$ is the prime decomposition of n, then*

$$d(n) = \prod_{i=1}^{k} d(p_i^{k_i}).$$ ■

Therefore, the shadow d of $\mathrm{seq}^{1\text{-}1}$ is fully determined by its values on the powers of prime numbers. But what can we say about $d(p^k)$ for p prime? Let us start our discussion of this question by the following observation.

By the reduction property, all elements $m \in D(p^{k+1})$ must be of the form $m = n + l\,p^k$ for some $n \in D(p^k)$ and some $l \in \{0, 1, \ldots, p-1\}$. Hence, we get inductively that if $d(p) = 0$, then $d(p^k) = 0$ for all positive $k \in \mathbb{N}$.

Definition 12 *A prime number p with $d(p) = 0$ is called* **annihilating**.

Example. The sequence of annihilating primes is 3, 7, 11, 17, 47, 53, 61, 67, 73, 79, 89, 101, 139, 151, 157, 191, 199, ... ◯

From the observation above and the multiplicativity property, we have

Proposition 13 *If $n \in \mathbb{N}$ is divisible by an annihilating prime, then $d(n) = 0$.* ■

What can we say about primes that are not annihilating? For positive numbers $p, k, l, n \in \mathbb{N}$ we have the following:

$$\begin{aligned}
(n + l\,p^k)^\star &= \sum_{j=0}^{l\,p^k+n} \frac{(l\,p^k+n)!}{j!} \\
&= \frac{(l\,p^k+n)!}{0!} + \ldots + \frac{(l\,p^k+n)!}{(l\,p^k-1)!} + \frac{(l\,p^k+n)!}{(l\,p^k)!} + \ldots + \frac{(l\,p^k+n)!}{(l\,p^k+n)!} \\
&= \frac{(l\,p^k+n))!}{(l\,p^k-1)!}\,(l\,p^k-1)^\star + \sum_{j=l\,p^k}^{l\,p^k+n} \frac{(l\,p^k+n)!}{j!} \\
&= \Big((l\,p^k)\,(l\,p^k+1)\,\ldots\,(l\,p^k+n)\Big)\,(l\,p^k-1)^\star + \sum_{j=l\,p^k}^{l\,p^k+n} \frac{(l\,p^k+n)!}{j!} \\
&\equiv l\,p^k\,n!\,(l\,p^k-1)^\star + \sum_{j=l\,p^k}^{l\,p^k+n} \frac{(l\,p^k+n)!}{j!} \mod p^{k+1} \\
&\equiv l\,p^k\,n!\,(l\,p^k-1)^\star + l\,p^k \sum_{j=0}^{n-1}\sum_{i>j}^{n} \frac{n!}{j!\,i} + n^\star \mod p^{k+1} \\
&\equiv l\,p^k \left(n!\,(l\,p^k-1)^\star + \sum_{i=1}^{n}\sum_{j=0}^{i-1} \frac{n!}{j!\,i}\right) + n^\star \mod p^{k+1} \\
&\equiv l\,p^k \left(n!\,(l\,p^k-1)^\star + \sum_{j=0}^{n-1} \frac{n!}{(j+1)!}\,j^\star\right) + n^\star \mod p^{k+1} \\
&\equiv n^\star + l\,p^k \underbrace{\left(n!\,(p-1)^\star + \sum_{j=0}^{n-1} \frac{n!}{(j+1)!}\,j^\star\right)}_{=:s_{p,n}} \mod p^{k+1} \qquad (2)
\end{aligned}$$

From this calculation it is clear that the numbers $s_{p,n}$ defined in the previous line are crucial for a further investigation of the shadow of seq[1-1].

Definition 14 *The number*

$$X(p) := \prod_{n \in D(p)} \mathrm{Mod}(s_{p,n}, p)$$

is called the **excess** *of the prime p. A prime number p with $X(p) \neq 0$ is called* **regular** *and otherwise* **irregular**.

Example. Since the empty product is by definition equal to 1, all annihilating primes are regular. The smallest irregular prime number is 383, all other primes less than $2.5 \cdot 10^6$ are regular.

Lemma 15 *If p is a regular prime number, then the shadow d of* $\mathrm{seq}^{1\text{-}1}$ *has the socket property at powers of p, i.e. $d(p^k) = d(p)$ holds for all positive $k \in \mathbb{N}$.*

Before we prove Lemma 15, we state the following consequence.

Proposition 16 *If d is the shadow of* $\mathrm{seq}^{1\text{-}1}$ *and if $n = \prod_{i=1}^{k} p_i^{k_i}$ is the prime decomposition of n, then*

$$d(n) = \prod_{i=1}^{k} d(p_i)$$

provided each prime p_i is regular or one of the primes is annihilating. ■

To prepare the proof of Lemma 15, we need a property of $s_{p,n}$, which is given in the following

Lemma 17 *If p and n are natural numbers, then*

$$s_{p,n} \equiv s_{p,n+p} \mod p.$$

Proof. Let $r := \mathrm{Mod}(n, p)$, then $n = ap + r$ for some $a \in \mathbb{N}$. We first consider the case $n \geqslant p$, thus $a \neq 0$. Because $n \geqslant p$ we have $n! \equiv 0 \mod p$ and therefore $s_{p,n} \equiv \sum_{j=0}^{n-1} \frac{n!}{(j+1)!}\, j^\star \mod p$. Further we get

$$\begin{aligned}
\sum_{j=0}^{n-1} \frac{n!}{(j+1)!}\, j^\star &= \sum_{j=0}^{ap-2} \frac{n!}{(j+1)!}\, j^\star + \sum_{j=ap-1}^{n-1} \frac{n!}{(j+1)!}\, j^\star \\
&\equiv \sum_{j=ap-1}^{n-1} \frac{n!}{(j+1)!}\, j^\star \mod p \\
&\equiv \sum_{j=-1}^{r-1} \frac{r!}{(j+1)!}\, (p+j)^\star \mod p \\
&\equiv r!(p-1)^\star + \sum_{j=0}^{r-1} \frac{r!}{(j+1)!}\, j^\star \mod p\,.
\end{aligned}$$

If $n < p$, then $\mathrm{Mod}(n,p) = n$ and we get $r = n$. Hence, we have for all $p, n \in \mathbb{N}$ that

$$s_{p,n} \equiv r!(p-1)^\star + \sum_{j=0}^{r-1} \frac{r!}{(j+1)!}\, j^\star \mod p\,,$$

where $r := \mathrm{Mod}(n,p)$. ■

Proof of Lemma 15. Let p be a regular prime number. We proceed inductively: For $k = 1$ there is nothing to show. For exponents larger than 1 we recall that all elements $m \in D(p^{k+1})$ must be of the form $m = n + l\,p^k$ for some $n \in D(p^k)$ and some $l \in \{0, 1, \ldots, p-1\}$. By the calculation (2) above, we have

$$(n + l\,p^k)^\star \equiv n^\star + l\,p^k s_{p,n} \mod p^{k+1}.$$

Hence, it suffices to show, that

$$n \in D(p^k) \implies s_{p,n} \not\equiv 0 \mod p \tag{3}$$

In fact, since p is prime, if the conclusion of (3) holds, the congruence $n^\star + lp^k s_{p,n} \equiv 0 \mod p^{k+1}$ has a unique solution $l \in \{0, 1, \ldots, p-1\}$ and therefore, the sets $D(p^k)$ and $D(p^{k+1})$ have the same cardinality, which implies $d(p^k) = d(p^{k+1})$.

On the other hand, by Lemma 17, (3) holds for all k if it is true for $k = 1$. But this, by definition, is exactly the case for regular primes p. ■

3 How peculiar are irregular primes?

In this section we investigate the value of $d(p^k)$ for irregular primes p and $k \geqslant 1$, but first we recall some facts concerning regular primes.

For a regular prime p we have $d(p^k) = d(p)$ for any positive $k \in \mathbb{N}$. Further, by definition, a prime number p is annihilating if and only if $d(p) = 0$. Remember that all annihilating prime numbers are regular. Now, fix an irregular prime number p. What can we say for $k \geqslant 1$ about $d(p^k)$?

Example. If we consider the smallest irregular prime number $p = 383$, it turns out that $d(383) = 3$, but $d(383^k) = 2$ for all $k \geqslant 2$. The reason for this shall be explained below. ◯

First note that – because p is not annihilating – $d(p) > 0$. Because p is assumed to be irregular, there exists at least one $n \in D(p)$ such that $\mathrm{Mod}(s_{p,n}, p) = 0$ and therefore, by Lemma 17, we have $\mathrm{Mod}(s_{p,n+lp}, p) = 0$ for all $l \in \mathbb{N}$.

For $k \geqslant 1$ and any $n \in D(p^k)$ with $\mathrm{Mod}(s_{p,n}, p) = 0$ we have either the case $p^{k+1} \nmid n^\star$ or the case $p^{k+1} \mid n^\star$.

If $n \in D(p^k)$ with $\mathrm{Mod}(s_{p,n}, p) = 0$ – depending in which case we are – we have either $p^{k+1} \nmid (n + l\,p)^\star$ (for all $l \in \mathbb{N}$) or $p^{k+1} \mid (n + l\,p)^\star$ (for all $l \in \mathbb{N}$). To see this, remember that by (2), for any $n, l \in \mathbb{N}$ we have

$$(n + l\,p^k)^\star \equiv n^\star + l\,p^k \cdot s_{p,n} \mod p^{k+1}\,.$$

Therefore, if $p^{k+1} \mid n^\star$ (or $p^{k+1} \nmid n^\star$) and $p \mid s_{p,n}$, then we get $p^{k+1} \mid (n + l\,p^k)^\star$ (or $p^{k+1} \nmid (n + l\,p^k)^\star$, respectively) for any $l \in \mathbb{N}$.

Now let

$$\delta(p) := |\{n \in D(p) : \mathrm{Mod}(s_{p,n}, p) \neq 0\}|\,,$$

and for $k \geqslant 2$ let

$$\varepsilon(p^k) := |\{n \in D(p^{k-1}) : \mathrm{Mod}(s_{p,n}, p) = 0 \wedge p^k \mid n^\star\}|\,.$$

Notice that if $\varepsilon(p^{k_0}) = 0$ for some $k_0 \geqslant 2$, then $\varepsilon(p^k) = 0$ for any $k \geqslant k_0$. By the facts given above, it is not hard to verify that for $k \geqslant 2$ we have

$$d(p^k) = \delta(p) + p \cdot \varepsilon(p^k)\,.$$

Example. If we consider again the smallest irregular prime number $p = 383$, where $D(383) = \{296, 340, 353\}$ and therefore $d(383) = 3$, it turns out that $\delta(383) = 2$ and $\varepsilon(383^2) = 0$. This we get because $\mathrm{Mod}(s_{383,\,296}, 383) = 0$ and $383^2 \nmid 296^\star$. Thus, $d(383^k) = \delta(383) = 2$ for all $k \geqslant 2$. ◯

4 How rare are irregular primes?

We recall that a prime number p is irregular, if there exists an $n \in D(p)$ with $\mathrm{Mod}(s_{p,n}, p) = 0$. The function $n \mapsto \mathrm{Mod}(s_{p,n}, p)$ shows (for different primes p) a rather random-like behavior. The idea is now, to replace $n \mapsto \mathrm{Mod}(s_{p,n}, p)$ by equidistributed independent random variables $X_{p,n}$ which take values in $\{0, 1, \ldots, p-1\}$, i.e. the probability that $X_{p,n} = i$ is $\frac{1}{p}$ for each $i \in \{0, 1, \ldots, p-1\}$. From $X_{p,n}$ we construct a new random variable Y_p which takes, for each prime number p, the value 1 if $X_{p,n} = 0$ for some $n \in D(p)$ and zero otherwise. In other words, instead of looking whether $\mathrm{Mod}(s_{p,n}, p) = 0$ for $n \in D(p)$, we throw a dice with p faces $\{0, 1, \ldots, p-1\}$ for each $n \in D(p)$. Therefore, the values p for which $Y_p = 1$ are now called randomly irregular primes. The idea is, that randomly irregular primes

should have approximately the same distribution as the ordinary irregular prime numbers. The probability that p is randomly regular is

$$P(p \text{ is randomly regular}) = \left(1 - \frac{1}{p}\right)^{d(p)}.$$

Thus, we have

$$\begin{aligned} P(p_1, p_2, \ldots, p_k \text{ are all randomly regular}) &= \prod_{i=1}^{k} \left(1 - \frac{1}{p_i}\right)^{d(p_i)} \\ &= \exp \sum_{i=1}^{k} d(p_i) \log\left(1 - \frac{1}{p_i}\right). \end{aligned}$$

Observe, that $\log(1-x) \leqslant -x$ for $x \geqslant 0$ (and $|\log(1-x) + x| = O(x^2)$ for $x \to 0$). Thus, we can estimate

$$P(p_1, p_2, \ldots, p_k \text{ are all randomly regular}) \lesssim \exp\left(-\sum_{i=1}^{k} \frac{d(p_i)}{p_i}\right).$$

If we suppose for the moment – and experiments support this to some extent – that in average $d(p) \approx c > 0$ is approximately constant (with a numerical value of $c \approx 0.9$), then we have

$$P(p_1, p_2, \ldots, p_k \text{ are all randomly regular}) \lesssim \exp\left(-c \sum_{i=1}^{k} \frac{1}{p_i}\right). \tag{4}$$

Now, the sum of inverse primes is divergent, and hence,

$$P(p_1, p_2, \ldots, p_k \text{ are all randomly regular}) \to 0 \quad \text{for } k \to \infty.$$

In other words, the probability that after a certain prime number no other randomly irregular prime number occurs is – under the made hypothesis on $d(p)$ – zero. So, we should expect that infinitely many irregular prime numbers exist.

On the other hand, what can we say about the frequency of occurrence of (randomly) irregular primes? In order to answer this question, we close this discussion by calculating the distribution function of randomly irregular prime numbers. In other words we ask: How many randomly irregular primes may we expect in the set $\{p_1, p_2, \ldots, p_k\}$. This is simply

$$E\left[\sum_{i=1}^{k} \tilde{Y}_{p_i}\right] = \sum_{i=1}^{k} E[\tilde{Y}_{p_i}] = \sum_{i=1}^{k} \frac{d(p_i)}{p_i}.$$

Example. The expected number of randomly irregular prime numbers in the range $\{2, \ldots, 10^3\}$ is $1.99703\ldots$ (the actual number of irregular primes in this interval is 1). Further, the expected number of randomly irregular primes in the interval $\{2, \ldots, 10^6\}$ is about 2.67758, so still far below 3, and the expected number of randomaly irregular primes in the interval $\{385, \ldots, 2.5 \cdot 10^6\}$ is about 0.874123 (the actual number of irregular primes in this interval is 0). ◯

Again, under the assumption that $d(p)$ is in average a positive constant c, we can now state the following conjecture:

Conjecture 18 *There exist infinitely many irregular primes. Furthermore the distribution function of the irregular primes is asymptotically*

$$\big|\{p \leqslant n : p \text{ is an irregular prime number}\}\big| \sim c \sum_{\substack{p \leqslant n \\ p \text{ prime}}} \frac{1}{p}$$

for a positive constant c.

Remark. If we consider the random variable Z which takes the value p where p is the smallest randomly irregular prime, then a similar calculation as above shows that the expected value of Z is $E[Z] = \infty$.

As a final remark we should mention that similar arguments as above support the conjecture that there are infinitely many prime numbers p, such that

$$2^{p-1} \equiv 1 \mod p^2 \tag{5}$$

This conjecture is related to generalized Carmichael numbers (see [HH]). The prime numbers satisfying (5) seem to have a similar distribution as irregular primes, which makes them equally hard to find. In fact, at the moment, the only known prime numbers which satisfy (5) are 1093 and 3511.

Acknowledgment. We wish to thank Stephanie Halbeisen for writing all the C-programs, which built the touchstones for our conjectures.

1 Introduction

One of the central tools in enumerative combinatorics is that of generating functions. Generating functions can e.g., be used to find the asymptotic behaviour of the enumerating sequence (e.g., the Hardy-Ramanujan estimate for the partition function $P(n)$, see [3]) or even may yield an explicit formula for the solution (e.g., Rademacher's famous explicit formula for $P(n)$, see [6]).

Given a combinatorial problem, there are numerous ways to find the corresponding generating function. One possibility is to start with a recurrence relation, as, e.g., the recurrence for the Fibonacci numbers $(a_n)_{n\in\mathbb{N}_0} = (0, 1, 1, 2, 3, 5, 8, \ldots)$, which we write in the following form:

$$\begin{aligned} a_n &= a_{n-2} + a_{n-1} + \delta_{1,n} \qquad && \forall n \in \mathbb{Z}, \\ a_n &= 0 && \forall n < 0. \end{aligned} \tag{1}$$

($\delta_{k,n}$ denotes the Kronecker symbol.) The z-transformation method requires to multiply (1) by z^n and to sum over n. This yields an algebraic equation for the generating function $f(z) = \sum_{n=0}^{\infty} a_n z^n$, namely

$$f(z) = z^2 f(z) + z f(z) + z,$$

which is easily solved, giving $f(z) = \frac{z}{1-z-z^2}$. The Taylor expansion of this function yields

$$f(z) = \frac{z}{1-z-z^2} = \sum_{n=0}^{\infty} \left(\frac{z}{2}\right)^n \frac{(1+\sqrt{5})^n - (1-\sqrt{5})^n}{\sqrt{5}},$$

2000 Mathematics Subject Classification: 11B39, 05A15

i.e., we obtain the explicit Euler-Binet[1] formula for the Fibonacci numbers

$$a_n = \frac{1}{\sqrt{5}}\left(\left(\frac{1+\sqrt{5}}{2}\right)^n - \left(\frac{1-\sqrt{5}}{2}\right)^n\right).$$

A second way to find a generating function is to use Polya's index theorem. For example, let M be the set of all syntactic bracket figures with index n equal to the number of bracket pairs. For $n = 3$ we have the set M_3 of three bracket pairs:

$$M_3 = \{[\,][\,][\,], [[\,]]\,], [[\,][\,]], [[\,]][\,], [\,][[\,]]\}.$$

By

$$\begin{array}{rcl} M & \to & M_1 \times M \times M \cup M_0 \\ [a]b & \mapsto & ([\,], a, b) \\ \varnothing & \mapsto & \varnothing \end{array}$$

we have a bijection between the sets M and $M_1 \times M \times M \cup M_0$ which is additive, that is, $\mathrm{ind}([a]b) = 1 + \mathrm{ind}(a) + \mathrm{ind}(b)$. Then, by Polya's theorem, the relation between the sets translates directly into a relation for the generating function for the numbers $c_n = \mathrm{card}(M_n)$, namely,

$$f(z) = zf^2(z) + 1.$$

Taylor expansion of the solution $f(z) = \frac{1}{2z}(1 - \sqrt{1-4z}) = \sum_{n=0}^{\infty} c_n z^n$ yields the Catalan numbers

$$c_n = \frac{1}{n+1}\binom{2n}{n}.$$

A third way is to use methods from the theory of difference equations, which reach from continued fractions to Laplace transformation. As an example, we mention a recent theorem of Oberschelp (see [5]) that allows to transform a difference equation into a differential equation for the exponential generating function by a formal procedure. For example, the sequence Sloane-Plouffe sequence M1497 in [7], f_n, which counts the number of ways to build a sequence without repetition with n variables satisfies the recurrence $f_{n+1} = (n+1)f_n + 1$. Oberschelp's theorem requires the exchange

$$\tbinom{n}{k} f_{n+s-k} \quad \longleftrightarrow \quad \frac{z^k}{k!} f^{(s)},$$

i.e., to replace f_{n+1} by f', nf_n by zf', f_n by f, and 1 by e^z. This procedure yields the ordinary differential equation $(1-z)f' - f = e^z$ with the solution $f(z) = \frac{e^z}{1-z}$

[1]This formula was derived by Jacques P.M. Binet in 1843, although the result was known to Euler and to Daniel Bernoulli more than a century earlier.

determined by $f(0) = 1$. Since $f(z)$ is the exponential generating function, we get in fact $f_n = n!(1 + \frac{1}{1!} + \ldots + \frac{1}{n!})$.

Experience shows that the situation becomes considerably more delicate as soon as the problem requires to solve partial difference equations. In this article we want to describe methods which allow us to calculate the generating function from a recurrence relation. The idea is to link the Laplace transform directly to generating functions by interpreting the Fourier formula for the inverse Laplace transform as a residual integral. The reader who is not familiar with the Laplace or Fourier transformation might consult [1] or [8]. The idea is certainly not new; however, we would like to show that it applies also to more complicated (e.g., non-local) partial difference equations.

2 Auxiliary Results

2.1 Laplace transformation

Let $(a_n)_{n\in\mathbb{Z}}$, $a_n = 0$ for $n < 0$, be a sequence of real numbers with generating function $f(z) = \sum_{n\in\mathbb{Z}} a_n z^n$. We call

$$A(z) := \sum_{n\in\mathbb{Z}} a_n \chi_{[n,n+1[}(z)$$

the associated step-function. Here, χ_I denotes the characteristic function of the set I. Then the following theorem holds.

Theorem 1 *If the Laplace transform $\mathscr{L}[A]$ of the associated step-function A exists; it is related to the generating function f by*

$$\mathscr{L}[A](s) = \frac{1}{s}(1 - e^{-s}) f(e^{-s}).$$

Proof. Since we assume A to have at most exponential growth, we may transform term by term and get

$$\mathscr{L}[A](s) = \sum_{n=0}^{\infty} a_n \mathscr{L}[\chi_{[n,n+1[}].$$

Writing $\chi_{[n,n+1[} = H(\cdot - n) - H(\cdot - (n+1))$, where $H = \chi_{[0,\infty[}$ denotes the Heaviside function, and using that $\mathscr{L}[H](s) = \frac{1}{s}$, we obtain, by applying the basic rules for the Laplace transformation,

$$\mathscr{L}[A](s) = \sum_{n=0}^{\infty} a_n \frac{1}{s} e^{-ns}(1 - e^{-s}),$$

which is what we claimed. □

The following calculation provides a useful variant of Theorem 1: If $\frac{1}{z}g(e^{-z})$ is the Laplace transform of a piecewise smooth function G, we have by Fourier's formula for the inverse Laplace transformation that, for every point $x \in \mathbb{R}_+$ where G is continuous,

$$G(x) = \frac{1}{2\pi i}\,\mathrm{pv}\int_\Gamma \frac{1}{z}\,g(e^{-z})e^{xz}dz.$$

Here, Γ is the curve $\Gamma : \mathbb{R} \to \mathbb{C}, t \mapsto s+it$, with $s \in \mathbb{R}$ large enough, and "pv" denotes the principal value. If we denote $\Gamma_n : [0, 2\pi[\to \mathbb{C}, t \mapsto z := s + i(t + 2n\pi)$, we have

$$G(x) = \frac{1}{2\pi i}\,\mathrm{pv}\sum_{n\in\mathbb{Z}}\int_{\Gamma_n} \frac{1}{z}\,g(e^{-z})e^{xz}dz. \tag{2}$$

Observe that, by Fourier-series expansion, we have, for $x \notin \mathbb{Z}$,

$$\sum_{n\in\mathbb{Z}} \frac{1}{s+i(t+2n\pi)}e^{x(s+i(t+2n\pi))} = \frac{e^{\lceil x\rceil(s+it)}}{e^{s+it}-1},$$

where $\lceil\cdot\rceil$ denotes the ceiling function, i.e., $\lceil x\rceil$ is the smallest integer larger than or equal to x. Hence, by substituting $u = e^{-z}$, we obtain from (2) with $n = \lfloor x\rfloor$,

$$G(x) = \frac{1}{2\pi i}\int_\gamma \frac{g(u)}{1-u}\,\frac{du}{u^{n+1}} \tag{3}$$

where $\gamma : [0, 2\pi[\to \mathbb{C}, t \mapsto e^{-s}e^{it}$, and where $\lfloor\cdot\rfloor$ denotes the floor function, i.e., $\lfloor x\rfloor$ is the largest integer smaller than or equal to x. Thus, if g is analytic in a neighborhood of 0, we may interpret the integral in (3) as the Cauchy residue integral for the nth Taylor coefficient of the function $\frac{g(u)}{1-u}$. Thus, we have the following corollary.

Corollary 1 *Assume f and g_n are analytic functions in a neighborhood of 0 and a_n is given by*

$$a_n = \frac{1}{2\pi i}\,\mathrm{pv}\int_\Gamma \frac{1}{z}\,g_n(e^{-z})e^{xz}dz \tag{4}$$

for some (and hence any) $x \in]n, n+1[$ and Γ as above. If $\lim_{z\to 0}\frac{f(z)-g_n(z)}{z^n} = 0$ for all $n \in \mathbb{N}_0$, then $\frac{f(z)}{1-z}$ is the generating function of the sequence a_n.

Let us briefly mention some advantages that the use of the Laplace transformation provides: Suppose we are given a generating function $f(u)$. Only in simple cases it is possible to use direct Taylor expansion to obtain a formula for the coefficient a_n of u^n. Also, the Cauchy residue $a_n = \mathrm{Res}_{u=0}\frac{f(u)}{u^{n+1}}$ or (in case of a meromorphic function

$f)$ $a_n = -\sum \mathrm{Res}_{u\neq 0} \frac{f(u)}{u^{n+1}}$ is often difficult to calculate. In such a situation, it may be helpful to split the residues via the Laplace transformation (as in the calculation preceding Corollary 1) in order to obtain an expansion (or at least an asymptotic formula) for the a_n. To illustrate this, let us consider the example of the generating function of the Bernoulli numbers

$$f(u) = u\cot u = 1 + \sum_{n=1}^{\infty} \frac{(-1)^n 2^{2n} B_{2n}}{(2n)!} u^n.$$

According to Theorem 1, the Laplace transform of the associated step-function G is

$$g(s) = \frac{1-e^{-s}}{s} f(e^{-s})$$

and we may use the Fourier formula to invert g: $\mathscr{L}^{-1}[g](t) = \sum \mathrm{Res}\, g(s)e^{ts}$. The singularities of $g(s)e^{ts}$ are located at $s_{k,m} = m\pi i - \log(k\pi)$, $k \in \mathbb{N}$, $m \in \mathbb{Z}$. For $t \in \mathbb{Z}$ we have

$$\mathrm{Res}_{s_{k,m}}\, g(s)e^{ts} = \begin{cases} -\frac{1-k\pi}{s_{k,m}(k\pi)^t} & \text{if } m \text{ is even,} \\ -\frac{1+k\pi}{s_{k,m}(-k\pi)^t} & \text{if } m \text{ is odd.} \end{cases}$$

Combining residues for m and $-m$, we can easily sum the residues for fixed k over all m and obtain

$$\mathscr{L}^{-1}[g](t) = -\sum_{k=1}^{\infty} \frac{1}{(k\pi)^{2\lfloor t/2 \rfloor}}.$$

(Notice that one obtains a formula for $\sum_{m=1}^{\infty} \frac{1}{a^2+m^2}$ by expanding e^{ax} on $]-\pi,\pi[$ in a Fourier series.) Since $t \in \mathbb{Z}$ (G jumps in $\mathbb{Z}$), we finally get the zeta-function formula for the Bernoulli numbers:

$$B_{2n} = (-1)^{n+1} \frac{2(2n)!}{(2\pi)^{2n}} \sum_{k=1}^{\infty} \frac{1}{k^{2n}}.$$

A second benefit of the Laplace transformation are the various rules. For example, by the rule $\mathscr{L}[f'](s) = s\,\mathscr{L}[f](s) - f(0)$, we have, for $f_z(t) := t^z$, that

$$\mathscr{L}[f_z'](s) = s\,\mathscr{L}[f_z](s) = z\,\mathscr{L}[f_{z-1}](s).$$

Hence, for fixed s, the analytic function

$$h_s(z) := \mathscr{L}[f_z](s) = \int_0^{\infty} t^z e^{-st} dt$$

solves the difference equation $s\,h_s(z) = z\,h_s(z-1)$. In particular, for $s = 1$, we obtain Euler's integral representation of the Gamma-function. It is a particular feature of

the Laplace-transformation method that it can be used to determine the analytic continuation of a discrete function. The Laplace transformation also yields a functional connection between the exponential generating function $e(x)$ and the ordinary generating function $f(x)$ of a sequence a_n. In fact, we have

$$\mathscr{L}[e](s) = \mathscr{L}\left[\sum_{n=0}^{\infty} \frac{a_n}{n!} x^n\right](s) = \sum_{n=0}^{\infty} \frac{a_n}{n!} \underbrace{\mathscr{L}[x^n](s)}_{\frac{n!}{s^{n+1}}} = \tfrac{1}{s} f\left(\tfrac{1}{s}\right).$$

The translation-rule $\mathscr{L}[f(t-c)](s) = e^{-sc}\mathscr{L}[f(t)](s)$ for $c \geq 0$ allows us to transform a (linear) difference equation into an algebraic equation for the transformed function (this feature is similar to the z-transformation). In particular, it is possible to reduce a linear partial difference equation with n variables to an equation with $n-1$ variables. For an example see Section 3.4 or 3.5.

Another virtue of the Laplace transformation appears when one looks for an asymptotic expansion of a sequence or (which is a similar thing) when one treats difference equations which show oscillation and damping effects. If one is only interested in the stationary state, one can already, at the level of the transformed function, identify terms which lead to exponentially decaying terms in the solution and drop them for the rest of the calculation.

2.2 The dual of a linear difference equation

Many combinatorial problems lead to partial difference equations. As a prototype example, we investigate the two dimensional case.

Let $X \subset \mathbb{Z}^2$. For a map $p : X \to \mathbb{R}$, we consider the linear equation

$$p(z) = \sum_{\{\zeta \in X : \zeta \in \operatorname{spt} a_z\}} a_z(\zeta) p(\zeta) \qquad (*)$$

where we assume that the cardinality of the support of a_z ($\operatorname{spt} a_z \subset X$) is finite for all $z \in X$, i.e., that the sum in $(*)$ is always finite. A set $A \subset X$ is called *stable* if for all maps $f : A \to \mathbb{R}$ there exists a unique solution p of $(*)$ such that $p|_A = f$. A triple $(X, A, *)$ is called *triangular* if X can be written as $X = (x_i)_{i \in \mathbb{N}}$ in such a way that, for all $i \in \mathbb{N}$, there holds $\operatorname{spt} a_{x_i} \subset A \cup \{x_1, \ldots, x_{i-1}\}$, and for all $z \in A$: $\operatorname{spt} a_z = \{z\}$ and $a_z(z) = 1$. In particular we have that, for a triangular triple $(X, A, *)$, the set A is stable.

Now, let $(X, A, *)$ be triangular and $f : A \to \mathbb{R}$ be given. Then, for any fixed $x = x_i \in X$, the solution p of $(*)$ in x is a finite linear combination of the values of f on A, i.e.,

$$p(x) = \sum_{\zeta \in A} \alpha_x(\zeta) f(\zeta).$$

In order to determine the weights $\alpha_x(\zeta)$, we proceed as follows:

(i) Put a red mark on x.

(ii) Replace each red mark on $y \in X \setminus A$ by a blue one on y and by $a_y(\zeta)$ many red marks on ζ for all $\zeta \in \operatorname{spt} a_y$.

(iii) Iterate (ii) until no more red marks on $X \setminus A$ exist.

If n denotes the maximum of the set $\{i\colon$ there is a red mark on $x_i\}$, then, in each iteration step, n decreases at least by one due to the triangular structure. Hence, the iteration process terminates. If we denote by $\tilde{q}(\zeta)$ the number of red marks on ζ, the quantity

$$\sum_{\zeta \in X} \tilde{q}(\zeta) p(\zeta)$$

is invariant during the iteration. Hence, we obtain the result that after the iteration is completed the number of (red) marks on $\zeta \in A$, i.e., $\tilde{q}(\zeta)$, equals the weight $\alpha_x(\zeta)$.

If we denote by $q(\zeta)$ the final number of marks (blue or red) on ζ (i.e., after termination of the iteration), the iteration process described above translates into a partial difference equation for the function q:

$$q(z) = \sum_{\{\zeta \in A_x : z \in \operatorname{spt} a_\zeta\}} a_\zeta(z) q(\zeta) \qquad (**)$$

with $q(x) = 1$ and with $A_x := \operatorname{tr} x \setminus A$, where $\operatorname{tr} x$ is the equivalence class of x with respect to the transitive hull of the relation $u \sim v :\iff u \in \operatorname{spt} a_v, v \notin A$. Notice that $(A_x, \{x\}, **)$ is triangular and finite. Let us summarize this result in a theorem.

Theorem 2 *If $(X, A, *)$ is triangular with prescribed values f on A, then the weights α_x in the solution formula $p(x) = \sum_{\zeta \in A} \alpha_x(\zeta) f(\zeta)$ can be determined by the iteration scheme (i)–(iii) or, equivalently, by solving the dual linear recursion $(**)$ with initial value $q(x) = 1$.*

Many transformation problems (for example the boustrophedon transformation in [4]) can be described as follows: Let $(X, A, *)$ be triangular; then we fix sets $A' = \{a_1, a_2, \ldots\} \subset A$ and $X' = \{b_1, b_2, \ldots\} \subset X$ and prescribe $f(a_i) = \phi_i$ and $f = 0$ on $A \setminus A'$. If we denote the solution $\psi_i = p(b_i)$, the mapping $\Psi_{X,X',A,A',*}\colon (\phi_i) \mapsto (\psi_i)$ is a linear transformation of sequences, the associated linear mapping (ALM). The problem to find its matrix (or the matrix of the inverse transformation) can often be solved by using the Laplace transformation technique for the partial difference equation for the *weights* $(**)$ even in cases where it is not possible to use directly the

Laplace transformation in the *original* partial difference equation $(*)$. We will see some examples in the following section.

Before we discuss the examples, we close this section by stating a simple path-counting lemma.

Lemma 1 *Suppose the coefficient functions a in $(*)$ satisfy the following invariance property for all $z = (n,k)$ and $z' = (n,k')$ in $X = \mathbb{Z}^2$:*

$$a_z(n+i, k+j) = a_{z'}(n+i, k'+j), \quad \forall i,j \in \mathbb{Z}. \tag{5}$$

Suppose, furthermore, that the column $\{(0,k)\colon k \in \mathbb{Z}\}$ is stable and that p denotes the solution of $(*)$ with prescribed values α_k on $(0,k)$. Then the column $\{(N,k)\colon k \in \mathbb{Z}\}$ is stable for

$$\tilde{p}(z) = \sum_{\{\zeta \in X\}} \bar{a}_z(\zeta)\tilde{p}(\zeta) \tag{$\dagger$}$$

where $\bar{a}_{u+v}(u) := a_u(u+\bar{v})$ and $\overline{(i,j)} := (i,-j)$. Finally, if we prescribe the values α_k on (N,k) for the equation $(\dagger)$, then $\tilde{p}(0,k) = p(N,k)$.

Proof of Lemma 1: We may interpret $(*)$ as a directed graph G with $a_z(\zeta)$ many edges from ζ to z. If we set $\alpha_k := \delta_{k,k_0}$, then $p(N,k)$ is the number of paths in G from $(0,k_0)$ to (N,k). If we flip the graph horizontally by $z \mapsto \bar{z}$ and invert the orientation of the edges, we obtain a graph G'. Now, $(\dagger)$ describes G' and $\tilde{p}(0,k)$ is the number of paths in G' from (N,k_0) to $(0,k)$ which equals, by construction, the number of paths in G from $(0,k_0)$ to (N,k).

For general (α_k) the claim follows by linearity. □

3 Examples and applications

3.1 The Fibonacci numbers and a variant of Faulhaber's formula

Let $X = \{(k,n) : n \geq k \geq 0\}$ and $A = \big\{(k,n) \in X\colon n \in \{k, k+1\}\big\}$. Further let

$$a_{(k,n)}(i,j) = \begin{cases} \delta_{k,i}\delta_{n-1,j} + \delta_{k+1,i}\delta_{n-1,j} & \text{for } (k,n) \notin A, \\ \delta_{k,i}\delta_{n,j} & \text{otherwise,} \end{cases}$$

in the equation $(*)$. This is easily seen to be triangular. For the sets $A' = \{(k,k+1) \in A\}$ and $X' = \{(0,n) \in X\colon n \geq 0\}$, we have that the ALM $\Psi_{X,X',A,A',*}$ applied to the

sequence $(1,1,\ldots)$ yields the Fibonacci sequence $\big(f(n)\big)_n$. Let us calculate the weights via $(**)$:

$$q(k,n) = q(k,n+1) + q(k-1,n+1)$$

with $q(0,l) = 1$. This is (up to renumbering) just the recursion for the binomial numbers, i.e., we get the "shallow diagonal" sum formula connecting Pascal's triangle to the Fibonacci numbers:

$$f(n+1) = \sum_{k=0}^{\lfloor \frac{n}{2} \rfloor} \binom{n-k}{n-2k}.$$

The binomial weights always occur for this type of equation: For another example, let $p(k,n) := \sum_{i=1}^{n} i^k$. Obviously, for fixed k, p is a polynomial in n of degree $k+1$. Faulhaber's famous formula expresses this polynomial in the basis $\{1, n, n^2, n^3, \ldots\}$, and the coefficients in this basis involve the Bernoulli numbers. Here, we want to express the polynomial in the basis $\left\{\binom{n}{0}, \binom{n}{1}, \binom{n}{2}, \binom{n}{3}, \ldots\right\}$. Consider again the "binomial" difference equation $f(k,n) = f(k,n-1) + f(k+1,n-1)$, this time on $X = \mathbb{N}_0^2$, with initial data $f(0,n) = p(k,n-1)$ for fixed k. The weights for the dual equation clearly are, as above, the binomial coefficients; hence, $p(k,n-1) = \sum_{i=1}^{n} \binom{n}{i} f(i,0)$, and it remains to find $f(i,0)$. Since $f(1,n) = n^k$, we use

$$\sum_{i=0}^{n} \binom{n}{i} i! S_2(k,i) = n^k, \tag{6}$$

where S_2 denotes the Stirling number of the second kind (see next section). Indeed, each term in the sum may be interpreted as the number of sequences in $\{1,\ldots,n\}^k$ with exactly i different numbers. Thus, $f(i+1,0) = i! S_2(k,i)$ and we recover the well known formula

$$p(k,n) = \sum_{i=1}^{n} \binom{n+1}{i+1} i! S_2(k,i),$$

which one also gets by summing (6).

3.2 The Stirling numbers

The Stirling numbers of the first kind $S_1(n,k)$ count the permutations of n distinct objects that can be written with exactly k disjoint cycles (cf. [2]). They can be computed recursively as follows:

$$S_1(n+1,k) \;:=\; n \cdot S_1(n,k) + S_1(n,k-1),$$

where $S_1(1,k) := \delta_{1,k}$.

Let $\tilde{S}_n(k) := S_1(n,k)$; then $\tilde{S}_n(k)$ satisfies the recurrence $\tilde{S}_{n+1}(k) = n\tilde{S}_n(k)+\tilde{S}_n(k-1)$. Let $L_n(s)$ denote the Laplace transform of the associated step-function of $\tilde{S}_n(k)$. Then we get

$$L_{n+1}(s) = nL_n(s) + e^{-s}L_n(s) = L_n(s)(n + e^{-s}),$$

with $L_1(s) = \frac{1}{s}(1 - e^{-s})$. Hence,

$$L_n(s) = \frac{1}{s}(1 - e^{-s})\prod_{j=1}^{n-1}(j + e^{-s}).$$

Thus, by Theorem 1 we find that

$$f_n(u) = \prod_{j=1}^{n-1}(j + u)$$

is the generating function for $\big(S_1(n,k)\big)_k$.

The Stirling numbers of the second kind $S_2(n,k)$ count the number of groupings of n distinct objects into k disjoint (nonempty) groups. They can be computed recursively as follows:

$$S_2(n+1,k) \;:=\; k \cdot S_2(n,k) + S_2(n,k-1),$$

where $S_2(1,k) := \delta_{1,k}$.

Let $\tilde{S}_k(n) := S_2(n,k)$; then $\tilde{S}_k(n)$ satisfies the recurrence $\tilde{S}_k(n) = k\tilde{S}_k(n-1) + \tilde{S}_{k-1}(n-1)$. Let $L_k(s)$ denote the Laplace transform of the associated step-function of $\tilde{S}_k(n)$. Then we obtain $L_k(s) = ke^{-s}L_k(s) + e^{-s}L_{k-1}(s)$. Therefore,

$$L_k(s) = L_{k-1}(s)\frac{e^{-s}}{1 - k\,e^{-s}} = L_1(s)\prod_{j=2}^{k}\frac{e^{-s}}{1 - j\,e^{-s}}$$

with $L_1(s) = \frac{1}{s}$. Thus, by Theorem 1, we get that

$$f_k(u) = \prod_{j=1}^{k}\frac{u}{1 - j\,u}$$

is the generating function for $\big(S_2(n,k)\big)_n$.

It is well known that the matrix of the Stirling numbers of the first and second kind are inverse in the sense that

$$f(n) = \sum_{i=1}^{n} S_1(n,i)e(i)$$

if and only if

$$e(n) = \sum_{i=1}^{n} (-1)^{n-i} S_2(n,i) f(i).$$

Instead of proving this rather special formula, we now investigate more general conditions which still imply an inversion formula of the above type.

3.3 An inversion formula

We consider the following situation: Given a linear equation $(*)$ with $X = \mathbb{N}_0 \times \mathbb{Z}$, which satisfies the invariance property (5), we suppose that with $A := \{(0,k) : k \in \mathbb{Z}\}$ the triple $(X, A, *)$ is triangular. We set $A' := \{(0,k) : k \in \mathbb{N}_0\}$ and $X' := \{(n,0) : n \in \mathbb{N}_0\}$ and consider the mapping $\Psi_{X,X',A,A',*} \colon (\phi_i) \mapsto (\psi_i)$. Notice that the equation $(**)$ for the weights inherits the invariance property (5), and hence we can apply Lemma 1 to $(**)$ and obtain

$$\tilde{p}(z) = \sum_{\{\zeta \in X\}} \bar{a}_z(\zeta) \tilde{p}(\zeta), \tag{$\dagger\dagger$}$$

with $\tilde{p}(n,0) = \delta_{n,0}$, where $\bar{a}_{u+v}(u) := a_{u+\bar{v}}(u)$. Then we have

$$\psi_n = \sum_{i=0}^{\infty} \tilde{p}(n,i) \phi_i. \tag{7}$$

Now we invert the previous equation: Let $Y := \mathbb{N}_0 \times \mathbb{N}_0$ and $Y' := \{(0,k) : k \in \mathbb{N}_0\}$. For any fixed $z \in X$, we can replace $(*)$ equivalently by the equation

$$p(\zeta_0) = \frac{1}{a_z(\zeta_0)} p(z) - \sum_{\{\zeta \in \operatorname{spt} a_z \setminus \{\zeta_0\}\}} \frac{a_z(\zeta)}{a_z(\zeta_0)} p(\zeta) =: \sum_{\{\zeta \in \operatorname{spt} a'_{\zeta_0}\}} a'_{\zeta_0}(\zeta) p(\zeta) \tag{$*'$}$$

for arbitrary $\zeta_0 \in \operatorname{spt} a_z$. Assume that for any $z \in X$ we can—by choosing a suitable ζ_0—replace $(*)$ by $(*')$ in such a way that

- the coefficients a'_z respect the invariance relation (5),
- the triple $(Y, Y', *')$ is triangular.

The equation for the weights for $(*')$ is

$$q(z) = \sum_{\{\zeta \in A_{(0,0)} : z \in \operatorname{spt} a'_\zeta\}} a'_\zeta(z) q(\zeta), \tag{$**'$}$$

with initial condition $q(0,0) = 1$ (because $(**')$ satisfies (5)). Then we have

$$\phi_n = \sum_{i=0}^{\infty} q(i,-n)\psi_i. \tag{8}$$

Hence, in view of (8) and (7), q and $\tilde{p}$ are inverse matrices, where q and $\tilde{p}$ satisfy certain difference equations which are related in the described manner. Notice also that, by choosing ζ_0 (see above), there is a certain freedom in the coefficients a' which can be useful sometimes.

As an example of the previous result we investigate a generalization of the Stirling numbers.

Let us define $a_{(n,k)}(i,j) := c(i)\delta_{i,n-1}\delta_{j,k} + d(i)\delta_{i,n-1}\delta_{j,k+1}$, where c and d are non-vanishing functions. Then the procedure described above yields the following proposition.

Proposition 1 *The numbers $s_1(n,k)$, $s_2(n,k)$ for $(n,k) \in \mathbb{Z} \times \mathbb{Z}$, defined by*

$$s_1(n,k) = c(n-1)s_1(n-1,k) + d(n-1)s_1(n-1,k-1)$$

and

$$s_2(n,k) = -\frac{c(n)}{d(n)}s_2(n,k-1) + \frac{1}{d(n-1)}s_2(n-1,k-1)$$

with $s_1(0,m) = s_2(m,0) = \delta_{m,0}$ are inverse in the sense that

$$\psi_n = \sum_{i=0}^{\infty} s_1(n,i)\phi_i \iff \phi_n = \sum_{i=0}^{\infty} s_2(i,n)\psi_i\,.$$

For special choices of the functions c and d, one easily gets e.g., the inversion formulas for the Stirling numbers ($c(n) = n$, $d(n) = 1$), the binomial numbers ($c(n) = 1$, $d(n) = 1$), or the numbers $Q_l(n) := \binom{n}{l} l!$ counting the number of ways to build sequences of length l with n objects without repetitions ($c(l) = -\frac{1}{l}$, $d(l) = \frac{1}{l}$)—guess what the inverse numbers are!

3.4 The partition numbers

As a further example, we consider the number $p(n,k)$ of partitions of an integer n into parts larger than or equal to k. This leads to the (non-local) partial difference equation

$$p(n,k) = p(n-k,k) + p(n,k+1), \tag{9}$$

with $p(n,k) = 0$ for $k > n > 0$ and $p(n,n) = 1$. In the above setting, the problem reads as follows: $X = \mathbb{N}^2$, $A = \{(n,k) : k \geq n\}$, $A' = \{(n,n) : n \in \mathbb{N}\}$ and $X' = \{(n,1) : n \in \mathbb{N}\}$, and for $(n,k) \in X \setminus A$ we have

$$p(n,k) = \sum_{i,j \in \mathbb{N}} (\delta_{i,n-k}\delta_{j,k} + \delta_{i,n}\delta_{j,k+1})p(i,j)\,. \tag{10}$$

The ALM $\Psi_{X,X',A,A',(10)}$ maps the sequence $(1,1,\ldots)$ into the sequence $p(n,1) = P(n)$ of the partition numbers. The equation for the weights is given by

$$q(n,k) = q(n,k-1) + q(n+k,k)$$

with initial conditions $q(n,1) = 1$ for $n \leq N$ and $q(n,k) = 0$ for $n > N$. Then we have $P(N) = \sum_{i=1}^{N} q(i,i)$. By renumbering, this is equivalent to saying

$$\tilde{q}(n,k) = \tilde{q}(n,k-1) + \tilde{q}(n-k,k) \tag{11}$$

with $\tilde{q}(n,1) = 1$ for all n, $\tilde{q}(n,k) = 0$ for $n \leq 0$, and $P(N) = \sum_{i=1}^{N} \tilde{q}(i, N-i+1)$. Note that $\tilde{q}(n,k)$ no longer depends on N. Laplace transformation of (11) with respect to the first variable with k fixed yields

$$r_k(s) = \frac{1}{1-e^{-sk}} r_{k-1}(s)$$

with initial value $r_1(s) = \frac{1}{s}$ (since $\tilde{q}(1,k) = 1$ for $k \in \mathbb{N}$). Thus, we have

$$r_k(s) = \frac{1}{s} \prod_{j=2}^{k} \frac{1}{1-e^{-js}}$$

and, by Theorem 1, the generating function $g_k(u)$ of $\big(\tilde{r}_k(n)\big)_n$ is given by

$$g_k(u) = \prod_{j=1}^{k} \frac{1}{1-u^j}\,.$$

From this, it is easy to derive Euler's classical generating function $E(u)$ of the partition numbers $P(N)$. But, by interpreting $\tilde{q}(n,k)$ as the number of partitions of $n-1$ into k or less parts (and hence $P(n-1) = \tilde{q}(n,n-1) = \tilde{q}(n,n)$), we immediately get from the above calculation together with Corollary 1 that

$$E(u) = \prod_{j=1}^{\infty} \frac{1}{1-u^j}\,. \tag{12}$$

Also, if $f(s)$ denotes the Laplace transform of E, it follows from (12) that

$$\frac{1}{s}(1-e^{-s})\prod_{j=1}^{\infty}(1-e^{-js}) = f(s)\sum_{j=1}^{\infty}(-1)^{\lfloor\frac{j}{2}\rfloor}e^{-st_j},$$

where $t_j = 0, 1, 2, 5, 7, \ldots$ are the pentagonal numbers. Laplace inversion of the last equation yields Euler's formula $\sum_{j=1}^{\infty}(-1)^{\lfloor\frac{j}{2}\rfloor}P(n-t_j) = \delta_{n,0}$.

What about counting weighted partitions? Let $f\colon \mathbb{N}\to\mathbb{R}$ be a weight function with the meaning that we count partitions into i parts $f(i)$ many times, or—what is the same thing by considering Ferrers diagram—count partitions which largest part of size i, $f(i)$ many times. Then the calculation above gives the generating function for this problem:

$$\sum_{i=1}^{\infty}\frac{f(i)u^i}{\prod_{j=1}^{i}1-u^j}.$$

So, choosing, e.g., f as the characteristic function of the even numbers, we compute $\big(e(n)\big)_n = (0, 1, 1, 3, 3, 6, 7, 12, 14, \ldots)$.

To conclude this section let us compute the inverse of the ALM $\Psi_{X,X',A,A',(10)}$. Let us put a red mark on (L, L). In view of (10) we can replace a red mark on (n, k) (for $n \geq k > 1$) by a red mark on $(n, k-1)$, a negative red mark on $(n-k+1, k-1)$ and a blue mark on (n, k). This game terminates when all red marks are in $A \setminus A'$ (these marks are multiplied by 0) or in X' (where a mark on $(i, 1)$ is multiplied by ψ_i). Hence, $\phi_L = \sum_{n=1}^{L}\psi_n\,\omega(L, n)$, where $\omega(L, n)$ denotes the number of red marks on $(n, 1)$.

To compute $\omega(L, n)$, we consider the directed, finite graph G_L with vertices $\{(n, k) : L \geq n \geq k \geq 1\}$ and an edge from (n, k) to (n', k') if $k' = k-1$ and $n' = n$ (this edges are called v-edges) or if $k' = k$ and $n' = n-k$ (this edges are called h-edges of length k). Now let $W_L(n)$ be the number of paths through the graph G_L from the vertex (L, L) to $(n, 1)$, such that all h-edges have different length and each path is weighted by $+1$ if the number of h-edges contained in the path is even, otherwise it is weighted by -1. It is easy to see that $W_L(n) = \omega(L, n)$. To compute $W_L(n)$, let us first define the function $w(m, l, s)$, which is the number of weighted paths from (m, m) to $(m-l, 1)$, such that the maximum of the lengths of h-edges contained in the path equals s (where $s = 0$ means that the path contains no h-edge). For the function $w(m, l, s)$, we have

$$w(m,l,s) = \begin{cases} 1 & \text{if } l = s = 0, \\ 0 & \text{if } s > l \text{ or } s > \lfloor\frac{m}{2}\rfloor, \\ -\sum_{j=1}^{s} w(m-s, l-s, s-j) & \text{otherwise.} \end{cases}$$

Now, by construction, we obtain

$$W_L(n) = \sum_{s=0}^{\lfloor \frac{L}{2} \rfloor} w(L, L-n, s).$$

For example, for $L = 12$, we get $\big(W_{12}(n)\big)_n = (1, -1, -2, 0, 2, 0, 1, 0, 0, -1, -1, 1)$ and, in fact, $P(12) - P(11) - P(10) + P(7) + 2P(5) - 2P(3) - P(2) + P(1) = 77 - 56 - 42 + 15 + 2 \cdot 7 - 2 \cdot 3 - 2 + 1 = 1$.

3.5 A path counting problem

We consider paths in a three-dimensional lattice: Starting point of the paths is a point $(x, 0, 0)$, $x \in \mathbb{N}_0$, on the x-axis. If (x, y, z) is a point on the path, then a unit step in positive y or z direction is allowed or a step of length $y + z + 1$ in negative x direction. We want to count the number $H_M(x)$ of allowed paths starting in $(x, 0, 0)$ which end in a given set $M \subset \mathbb{Z}^3$.

The dual of this problem is given by the non-local linear difference equation

$$q_{z,y}(x) = q_{z-1,y}(x) + q_{z,y-1}(x) + q_{z,y}(x - y - z - 1) \tag{13}$$

with $q_{z,y}(x) := 0$ if one of the numbers x, y, or z is negative and $q_{0,0}(0) := 1$. We already used an index notation because we want to Laplace-transform equation (13) with respect to the variable x. First, we have $Q_{0,0}(s) = \frac{1}{s}$, since $q_{0,0}(x) = 1$ for $x \geq 0$. Laplace transformation of (13) yields

$$Q_{z,y}(s) = Q_{z-1,y}(s) + Q_{z,y-1}(s) + e^{-s(y+z+1)} Q_{z,y}(s).$$

Considering s as a parameter, the solution of this difference equation in y and z is given by

$$Q_{z,y}(s) = \frac{1}{s} \binom{z+y}{z} \frac{1}{\prod_{j=2}^{z+y+1} (1 - e^{-js})}.$$

Thus, the generating function of $q_{z,y}(x)$ is

$$f_{z,y}(u) = \binom{z+y}{z} \prod_{j=1}^{z+y+1} \frac{1}{1-u^j}.$$

Hence, using the notation of Section 3.4,

$$q_{z,y}(x) = \tilde{r}_{z+y+1}(x) \binom{z+y}{z}.$$

Finally, the solution to our path counting problem is given by the formula

$$H_M(\xi) = \sum_{(\xi-x,y,z)\in M} \tilde{r}_{z+y+1}(x)\binom{z+y}{z}.$$

For example, let us count the paths starting in $(\xi,0,0)$ with at most h unit steps in z direction and such that the total number of unit steps in negative x and in positive y direction equals ξ. This corresponds to the set $M = \{(x,y,z) \in \mathbb{Z}^3 : x = y,\, z \le h\}$, and the solution formula yields

$$H_M(\xi) = \sum_{z\le h, x\le \xi} \tilde{r}_{z+\xi-x+1}(x)\binom{z+\xi-x}{z}.$$

3.6 Local linear difference equations

For $X = \{(k,l) : 0 \le k \le l\}$ and $A = \{(k,l) : l \in \{k, k+1, k+2\}\}$, we consider the model equation

$$z(k,l) = a_1 z(k,l-1) + a_2 z(k+1,l-1) + a_3 z(k+2,l-1). \tag{14}$$

$(X, A, (14))$ is triangular and, for $X' = \{(0,l) : l \ge 3\}$, the equation for the weights is

$$q(k,l) = a_1 q(k,l+1) + a_2 q(k-1,l+1) + a_3 q(k-2,l+1) \tag{15}$$

with initial condition $q(k,L) = \delta_{k,0}$ for a fixed $L \ge 0$. Laplace transformation of (15) with respect to the variable k with l fixed gives $Q_l(s) = Q_{l+1}(s)(a_1 + a_2 e^{-s} + a_3 e^{-2s})$ with initial condition $Q_L(s) = \frac{1}{s}(1 - e^{-s})$. The solution is

$$Q_l(s) = \frac{1}{s}(1 - e^{-s})(a_1 + a_2 e^{-s} + a_3 e^{-2s})^{L-l},$$

and Theorem 1 gives, for the generating function of the sequence $\big(q(k,l)\big)_k$, the function $(a_1 + a_2 u + a_3 u^2)^{L-l}$. Multinomial expansion yields

$$q(k,l) = \sum_{k_2+2k_3=k} \binom{L-l}{L-l-k_2-k_3, k_2, k_3} a_1^{L-l-k_2-k_3} a_2^{k_2} a_3^{k_3}.$$

Since (15) does not stop the iteration when a mark lies on A, we have to compensate by setting $\tilde{q}(k,k+2) = q(k,k+2)$, $\tilde{q}(k,k+1) = q(k,k+1) - a_1 q(k,k+2)$, and $\tilde{q}(k,k) = q(k,k) - a_1 q(k,k+1) - a_2 q(k-1,k+1)$. Then, if α_z is given on $z \in A$ as initial data for (14), we get the solution

$$z(0,l) = \sum_{i=2}^{l} \sum_{j=0}^{2} \alpha_{(i-j,i)} \tilde{q}(i-j,i). \tag{16}$$

In particular, if $\alpha_{(k+j,k)} = x_j$ (for $j = 0,1,2$), $z(0,l)$ is the solution of $x_n = a_1 x_{n-1} + a_2 x_{n-2} + a_3 x_{n-k}$ with initial values x_0, x_1, x_2 and (16) is a root-free representation of the solution.

Abstract

In this paper, we consider certain cardinals in ZF (set theory without AC, the Axiom of Choice). In ZFC (set theory with AC), given any cardinals $\mathcal{C}$ and $\mathcal{D}$, either $\mathcal{C} \leq \mathcal{D}$ or $\mathcal{D} \leq \mathcal{C}$. However, in ZF this is no longer so. For a given infinite set A consider $seq^{1\text{-}1}(A)$, the set of all sequences of A without repetition. We compare $\left|seq^{1\text{-}1}(A)\right|$, the cardinality of this set, to $\left|\mathcal{P}(A)\right|$, the cardinality of the power set of A. What is provable about these two cardinals in ZF? The main result of this paper is that $\text{ZF} \vdash \forall A(\left|seq^{1\text{-}1}(A)\right| \neq \left|\mathcal{P}(A)\right|)$ and we show that this is the best possible result. Furthermore, it is provable in ZF that if B is an infinite set, then $\left|fin(B)\right| < \left|\mathcal{P}(B)\right|$, even though the existence for some infinite set B^* of a function f from $fin(B^*)$ onto $\mathcal{P}(B^*)$ is consistent with ZF.

Section 0: *Introduction, Definitions and Basic Theorems*

Introduction: In ZFC the cardinality of ordinal numbers plays an important role, since by AC each set has the cardinality of some ordinal.
We use "alephs" for the cardinalities of ordinals. Thus in ZFC each cardinal number is an aleph. However this need not be the case in ZF.
If we have a model M of ZF in which the axiom of choice fails, then we have more cardinals in M than in a model V of ZFC, even if we have fewer sets in M than in V. (This occurs when the choice-functions are not all in M). This is because the ordinals are in M and hence the alephs as well.

[1] Parts of this work are of the first author's Diplomarbeit at the ETH Zürich. He is grateful to his supervisor, Professor H. Läuchli.

In this paper we are interested in the relation between three cardinals arising in connection with a set S, namely,

1) the cardinality of the power set of S
2) the cardinality of the finite subsets of S
3) the cardinality of the finite sequences without repetition of S

This section contains definitions and basic theorems provable in ZF.
In the next section we present two relative consistency proofs illustrating possible relations between these cardinals.
The last two sections contain three results provable in ZF. The proofs of these are based on the same idea originally from E. Specker, who used it to prove that the axiom of choice follows from the generalised continuum hypothesis [Sp1]. Assuming the existence of a function we derive a contradiction to Hartogs' Theorem.

Because we do not use AC, our proofs are constructive. But we will see that sometimes arithmetic is powerful enough for our constructions, making it an adequate substitute for AC.

Cardinals: A *cardinal number* $\mathcal{C}$ is the equvalence class of all sets which have the *same size*. (Two sets are said to have the same size *iff* there is a bijection between them.)

Alephs: A cardinal number $\mathcal{C}$ is an *aleph* if it contains a well-ordered set.

We use calligraphic letters to denote cardinals and $\aleph$'s to denote the alephs.
We denote the cardinality of the set s by $\left|s\right|$.

Relations between cardinals: We say that the cardinal number $\mathcal{C}$ is less than or equal to the cardinal number $\mathcal{D}$ *iff* there are sets $c \in \mathcal{C}$, $d \in \mathcal{D}$ and a 1-1 function from c into d.
In this case we write $\mathcal{C} \leq \mathcal{D}$. We write $\mathcal{C} < \mathcal{D}$ for $\mathcal{C} \leq \mathcal{D}$ and $\mathcal{C} \neq \mathcal{D}$.
If $c \in \mathcal{C}$, $d \in \mathcal{D}$ and we have a function from d onto c, then we write $\mathcal{C} \leq^* \mathcal{D}$.

We also need some well-known facts provable in ZF:

Hartogs' Theorem: Given a cardinal $\mathcal{C}$ there is a least aleph, $\aleph(\mathcal{C})$, such that $\aleph(\mathcal{C}) \not\leq \mathcal{C}$.

Proof: See [Je1] p.25 ■

Cantor-Bernstein Theorem: If $\mathcal{C}$ and $\mathcal{D}$ are cardinals with $\mathcal{C} \leq \mathcal{D}$ and $\mathcal{D} \leq \mathcal{C}$, then $\mathcal{C} = \mathcal{D}$.

Proof: See [Je1] p.23 ■

Cantor Normal Form Theorem: Any ordinal α can be written as

$$\alpha = \sum_{i=0}^{j} \omega^{\alpha_i} \cdot k_i$$

with $\alpha \geq \alpha_0 > \alpha_1 > \ldots > \alpha_j \geq 0$, $1 \leq k_i < \omega$, $0 \leq j < \omega$.
Proof: See [Ba] p.57*ff* ■

Corollary 1: The Cantor Normal Form does not depend on AC.
Proof: The proof of the Cantor Normal Form requires no infinite choices. ■

Corollary 2: If $\alpha = \sum_{i=0}^{j} \omega^{\alpha_i} \cdot k_i$ is a Cantor Normal Form, then define $\overleftarrow{\alpha}$ by

$$\overleftarrow{\alpha} := \sum_{i=j}^{0} \omega^{\alpha_i} \cdot k_i = \omega^{\alpha_0} \cdot k_0.$$

Then (in ZF) $|\alpha| = |\overleftarrow{\alpha}|$
Proof: See [Ba] p.60 ■

Corollary 3: For any ordinal α, ZF implies the existence of the following bijections.

$$\begin{array}{lcll} F^{\alpha}_{seq^{1-1}} & : & \alpha \Leftrightarrow\!\!\!\!\rightarrow seq^{1-1}(\alpha) & (=: \text{ finite sequences of } \alpha \text{ without repetition}) \\ F^{\alpha}_{seq} & : & \alpha \Leftrightarrow\!\!\!\!\rightarrow seq(\alpha) & (=: \text{ finite sequences of } \alpha\,) \\ F^{\alpha}_{fin} & : & \alpha \Leftrightarrow\!\!\!\!\rightarrow fin(\alpha) & (=: \text{ finite subsets of } \alpha\,) \end{array}$$

Proof: Use the Cantor Normal Form Theorem, Corollary 2, order the finite subsets of α and then use the Cantor-Bernstein Theorem. ■

Section 1: *Consistency results*

In this section we work in the Mostowski permutation model to derive some relative consistency results. The permutation models are models of ZFA, set theory with atoms, (see [Je2] p.44*ff*).
The atoms $x \in A$ may also be considered to be sets which contain only themselves, this means: $x \in A \Rightarrow x = \{x\}$ (see [Sp2] p.197 or [La] p.2).
Thus the permutation models are models for ZF without the axiom of foundation.
However, the Jech-Sochor Embedding Theorem (see [Je] p.208*ff*) implies consistency results for ZF.

In the permutation models we have a set of atoms A and a group $\mathcal{G}$ of permutations of A. Let $\mathcal{F}$ be a normal filter on $\mathcal{G}$ (see [Je] p.199). We say that x is *symmetric* if the group $\mathrm{sym}_{\mathcal{G}}(x) := \{\pi \in \mathcal{G} : \pi(x) = x\}$ belongs to $\mathcal{F}$.

Let us further assume that $\mathrm{sym}_{\mathcal{G}}(a) \in \mathcal{F}$ for every atom a, that is, that all atoms are symmetric (with respect to $\mathcal{G}$ and $\mathcal{F}$) and let $\mathcal{B}$ be the class of all hereditarily symmetric objects.

The class $\mathcal{B}$ is both a permutation model and a transitive class: all atoms are in $\mathcal{B}$ and $A \in \mathcal{B}$. Moreover, $\mathcal{B}$ is a transitive model of ZFA.

Given a finite set $E \subset A$, let $\mathrm{fix}_{\mathcal{G}}(E) := \{\pi \in \mathcal{G} : \ \pi a = a \text{ for all } a \in E\}$ and let $\mathcal{F}$ be the filter on $\mathcal{G}$ generated by $\{\mathrm{fix}_{\mathcal{G}}(E) : \ E \subset A \text{ is finite}\}$.
$\mathcal{F}$ is a normal filter and x is symmetric *iff* there is a finite set of atoms E_x such that $\pi(x) = x$ whenever $\pi \in \mathcal{G}$ and $\pi a = a$ for each $a \in E_x$. Such an E_x is called a support for x.

Now the Mostowski model is constructed as follows: (see also [Je2] p.49*ff*)

1) The set of atoms A is infinite.
2) R is an order-relation on A.
3) With respect to R, A is a dense linear ordered set without endpoints.
4) Let Aut_R be the group of all permutations of A such that for all atoms $x, y \in A$ and each $\pi \in \mathrm{Aut}_R$, if Rxy then $R\pi(x)\pi(y)$.
5) Let $\mathcal{F}$ be generated by $\{\mathrm{fix}(E) : \ E \subset A \text{ is finite }\}$.

We will write $x < y$ instead of Rxy.

The subsets of A (in the Mostowski model) are symmetric sets. Hence each subset of A has a finite support.

If $x \subseteq A$ (in the Mostowski model) and x has non-empty support E_x, then an $a \in E_x$ may or may not belongs to x.

Fact: If $b \notin x \cup E_x$ and there are two elements $a_0, a_1 \in E_x$ with $a_0 < b < a_1$ such that $\forall c(a_0 < c < a_1 \to c \notin E_x)$, then $\forall c(a_0 < c < a_1 \to c \notin x)$.

Otherwise we construct a $\pi \in \mathrm{Aut}_R$ such that $\pi a_i = a_i$ for all $a_i \in E_x$ and $\pi c = b$. Then $\pi(x) \neq x$, which is a contradiction.

We can similarly show that if $a_0 < b < a_1$ and $b \in x \setminus E_x$, then $\forall c(a_0 < c < a_1 \to c \in x)$. The cases when $\neg\exists a_1(a_1 \in E_x \ \wedge \ b < a_1)$ or $\neg\exists a_0(a_0 \in E_x \ \wedge \ b > a_0)$ are similar.

Hence, given a finite set $E \subset A$ ($\left|E\right| =: n$), we can construct $2^n \cdot 2^{n+1} = 2^{2n+1}$ subsets $x \subseteq A$ such that E is a support of x.

Given a finite subset E of A, consider the set $\mathcal{E}$ of subsets of A with support E. We use R to order $\mathcal{E}$ as follows. Given $E_1 = \{a_1, \ldots, a_n\}$ and $E_2 = \{a_1, \ldots, a_n, \ldots, a_{n+k}\}$ with $a_i < a_j$ whenever $i < j$ and given $x \in \mathcal{E}$, if x is the l^{th} subset with support E_1, then x is also the l^{th} subset with support E_2.

Finally, we define the function F: $\mathit{fin}(A) \leftrightarrows \mathcal{P}(A)$ by
$E \quad \leftrightarrows$ $\left|E\right|^{th}$ subset of A
constructible with support E.

It is easy to see that F is onto.

If $E \subset A$ is finite, then use R to order the subsets of E and use the corresponding lexicographic order on the set of permutations of subsets of E. The set of permutations of subsets of E is isomorphic to $seq^{1\text{-}1}(E)$. In fact we can order $seq^{1\text{-}1}(E)$ for each finite $E \subset A$.

For each subset $x \subseteq A$ there is exactly one smallest support E_x (=:supp(x)).

If $\big|\text{supp}(x)\big| = n$, then put $\overline{x} := \big|\{y \subseteq A : \text{supp}(y) = \text{supp}(x)\}\big| \leq 2^{2n+1}$ and for $l \leq \overline{x}$ define as above the l^{th} element of $\{y \subseteq A : \text{supp}(y) = \text{supp}(x)\}$.
We say that: "$y \subseteq A$ is the l^{th} subset of A with support supp(x)".

Now choose 24 distinct elements $a_0, \ldots, a_{23} \in A$ and define $A_{24} := \{a_0, \ldots, a_{23}\}$.
A simple calculation shows that

$$\text{if } n \geq 12, \text{ then } 2 \cdot 2^{2n+1} < n! \qquad (*)$$

Take a finite subset E of A and let $y \subseteq A$ be the l^{th} subset of A with $\text{supp}(y) = E$.
Put $D := \text{supp}(y) \Delta A_{24}$ (where Δ denotes symmetric difference) and $d := \big|D\big|$.
Define the function $Seq_A : \mathcal{P}(A) \Leftrightarrow\!\!\!\rightarrow seq^{1\text{-}1}(A)$ by

$$Seq_A(y) := \begin{cases} \text{the } l^{th} \text{ permutation of supp}(y) & \text{if } \big|\text{supp}(y)\big| \geq 12, \\ \text{the } (d! \Leftrightarrow l \Leftrightarrow 1)^{th} \text{ permutation of supp}(y) & \text{otherwise.} \end{cases}$$

Seq_A is well defined because of $(*)$ and $d \geq 13$.
It is easy to see that Seq_A is 1-1. If there is a bijection between $\mathcal{P}(A)$ and $seq^{1\text{-}1}(A)$, then we find an ω-sequence$^{1\text{-}1}$ in A using an analogous construction. But this is a contradiction (see section 3).

Even more is true in the Mostowski model, $(\mathcal{A} := \big|\text{Atoms}\big|)$,

$$\mathcal{A} < \mathit{fin}(\mathcal{A}) < \mathcal{P}(\mathcal{A}) < seq^{1\text{-}1}(\mathcal{A}) < \mathit{fin}(\mathit{fin}(\mathcal{A})) < seq(\mathcal{A}) < \mathcal{P}(\mathcal{P}(\mathcal{A})).$$

(We omit the proof).

Our interest here is in the following result.

Theorem 1: The following theories are equiconsistent:
(i) ZF
(ii) ZF + $\exists \mathcal{A}(\mathcal{P}(\mathcal{A}) < seq^{1\text{-}1}(\mathcal{A}))$
(iii) ZF + $\exists \mathcal{A}(\mathcal{P}(\mathcal{A}) \leq^* \mathit{fin}(\mathcal{A}))$

Proof: It was shown above that in the Mostowski model there is a cardinal $\mathcal{A}$, namely the cardinality of the set of atoms, for which both (ii) and (iii) hold.
Unfortunately, the Mostowski model is only a model of ZFA. But it is well-known that Con(ZF)⇒Con(ZFC) and the Jech-Sochor Embedding Theorem provides a model of (ii) and (iii). ■

Theorem 2: The following theories are equiconsistent:
(i) ZF
(ii) ZF + $\exists\mathcal{A}(seq(\mathcal{A}) < fin(\mathcal{A}))$

Proof:
By the Jech-Sochor Embedding Theorem it is enough to construct a permutation model $\mathcal{B}$ in which there is a set A, such that:

(a) there is a 1-1 function from $seq(A)$ into $fin(A)$,
(b) there is no bijection between $seq(A)$ and $fin(A)$.

We construct by induction on $n \in \omega$ the following:

(α) $A_0 := \{\{\emptyset\}\}$; $Sq_0(\{\emptyset\})$:=the empty sequence;
G_0 := the group of all permutations of A_0.

Let k_n be the number of elements of G_n, and $\mathcal{E}_n$ be the set of sequences of A_n in length less or equal than n which are not in range(Sq_n), then

(β) $A_{n+1} := A_n \dot\cup \{(n+1, \zeta, i) : \ \zeta \in \mathcal{E}_n \text{ and } i < k_n + k_n\}$.

(δ) Sq_{n+1} is a function from A_{n+1} to $seq(A_n)$ defined as follows:

$$Sq_{n+1}(x) = \begin{cases} Sq_n(x) & \text{if } x \in A_n, \\ \zeta & \text{if } x = (n+1, \zeta, i) \in A_{n+1} \setminus A_n. \end{cases}$$

(γ) G_{n+1} is the subgroup of the group of permutations of A_{n+1} containing all permutations h such that for some $g_h \in G_n$ and $j_h < k_n + k_n$ we have

$$h(x) = \begin{cases} g_h(x) & \text{if } x \in A_n, \\ (n+1, g_h(\zeta), i +_n \ j_h) & \text{if } x = (n+1, \zeta, i) \in A_{n+1} \setminus A_n. \end{cases}$$

Where $g_h(\zeta)(m) := g_h(\zeta(m))$ and $+_n$ is the addition modulo $k_n + k_n$.

Let $A := \bigcup\{A_n : \ n \in \omega\}$ and $Sq := \bigcup\{Sq_n : \ n \in \omega\}$, then Sq is a function from A onto $seq(A)$.
Further define for each natural number n partial functions f_n from A to $A \cup \{\emptyset\}$ as follows. If $lg(x)$ denotes the length of $Sq(x)$ and $n < lg(x)$, then $f_n(x) := Sq(x)(n)$, otherwise let $f_n(x) = \emptyset$.
Let Aut(A) be the group of all permutations of A.
Then $\mathcal{G} := \{H \in \text{Aut}(A) : \forall n \in \omega(H|_{A_n} \in G_n)\}$ is a group of permutations of A.
Let $\mathcal{F}$ be the normal filter on $\mathcal{G}$ generated by $\{\text{fix}(E) : E \subset A \text{ is finite}\}$ and $\mathcal{B}$ be the class of all hereditarily symmetric objects.
Now $A \in \mathcal{B}$ and for each $n \in \omega$, supp$(f_n) = \emptyset$, hence f_n belongs to $\mathcal{B}$, too.
Now define on A a equivalence relation as follows,

$$x \sim y \quad \textit{iff} \quad \forall n(f_n(x) = f_n(y)).$$

Facts:

1. Every equivalence class of A is finite.
   (Because of each A_n is finite, hence each k_n).

2. $seq(A) = \{\varsigma_x : x \in A\}$ where $\varsigma_x(n) := f_n(x)$, (if $f_n(x) \neq \emptyset$).

3. For every finite subset B of A, there are finite subsets C, Y of A and a natural number $k > 1$ such that $B \subseteq C$, $\forall x \in A \setminus C$ ($\left|\{H(x) : H \in \mathrm{fix}_{\mathcal{G}}(C)\}\right| > k$) and $\left|\{H[Y] : H \in \mathrm{fix}_{\mathcal{G}}(C)\}\right| = k$.
   (Choose A_n ($n \geq 1$) such that $B \subseteq A_n$ and let $C := A_n$. Let $k := k_n + k_n$ and $Y := \{(n+1, \zeta, i) \in A_{n+1} : \ i \text{ is even}\}$. Then Y has exactly two images under $\{h : h \in \mathrm{fix}_{\mathcal{G}}(C)\}$ and $\forall x \in A \setminus C(\ \left|\{h(x) : \ h \in \mathrm{fix}_{\mathcal{G}}(C)\}\right| \geq k_{n+1} + k_{n+1})$.)

Now the function

$$\begin{array}{rccc} \Psi \ : & seq(A) & \Leftrightarrow\!\!\!\rightarrow & fin(A) \\ & \varsigma & \Leftrightarrow\!\!\!\rightarrow & \{x : \ \varsigma_x = \varsigma\} \end{array}$$

is a 1-1 function in $\mathcal{B}$ from $seq(A)$ into $fin(A)$ (by the facts 1 and 2).
Hence (a) holds in $\mathcal{B}$.

To prove (b), assume there is a 1-1 function $\Phi \in \mathcal{B}$ from $fin(A)$ into $seq(A)$.

Let B be a support of Φ and let C, Y, k be as in fact 3.

If the sequence $\Phi(Y)$ belongs to $seq(C)$, then for some $H \in \mathrm{fix}_{\mathcal{G}}(C)$, $H[Y] \neq Y$, hence $\Phi(H[Y]) \neq \Phi(Y)$. But this contradicts that H maps Φ to itself, (by definition of C, Y and H).

Otherwise there exists an $m \in \omega$ such that $x := \Phi(Y)(m)$ does not belong to the set C.
Hence $\left|\{H(x) : \ H \in \mathrm{fix}_{\mathcal{G}}(C)\}\right| > k$ and $\left|\{H[Y] : \ H \in \mathrm{fix}_{\mathcal{G}}(C)\}\right| = k$, (by fact 3).
Every $H \in \mathrm{fix}_{\mathcal{G}}(C)$ maps Φ to itself, hence $\Phi(Y)$ to $\Phi(H[Y])$. So we have a mapping from a set with k members onto a set with more than k members.
But this is a contradiction. ■

Section 2: ZF $\vdash$ ($\left|fin(S)\right| < \left|\mathcal{P}(S)\right|$) for any infinite set S.

Theorem 3: ZF $\vdash fin(\mathcal{C}) < \mathcal{P}(\mathcal{C})$

Proof: Take $S \in \mathcal{C}$. The natural map from $fin(S)$ into $\mathcal{P}(S)$ is a 1-1 function, hence $\left|fin(S)\right| \leq \left|\mathcal{P}(S)\right|$ is always true.
Assume that there is a bijective function $B : \ fin(S) \Leftrightarrow\!\!\!\rightarrow \mathcal{P}(S)$. Then, given any ordinal α, we can construct an α-sequence$^{1\text{-}1}$ in $fin(S)$. But this contradicts Hartogs' Theorem.

First we construct an ω-sequence$^{1\text{-}1}$ in $\mathit{fin}(S)$ as follows:

$S \in \mathcal{P}(S)$ and, because S is infinite, $S \notin \mathit{fin}(S)$.
But $B^{-1}(S) \in \mathit{fin}(S)$. So put $s_0 := B^{-1}(S)$ and $s_{n+1} := B^{-1}(s_n)$ $(n \in \omega)$.
Then the set $\{s_i : i < \omega\}$ is an infinite set of finite subsets of S and the sequence $\langle s_0, s_1, \ldots, s_n, \ldots \rangle_\omega$ is an ω-sequence$^{1\text{-}1}$ in $\mathit{fin}(S)$.

If we have already constructed an α-sequence$^{1\text{-}1}$ $\langle s_0, s_1, \ldots, s_\beta, \ldots \rangle_\alpha$ in $\mathit{fin}(S)$ (with $\alpha \geq \omega$), then we define an equivalence relation on S by

$$x \sim y \;\; \mathit{iff} \;\; \forall \beta < \alpha (x \in s_\beta \leftrightarrow y \in s_\beta)$$

Take $x \in S$ and suppose that $\mu < \alpha$. Define

$$\begin{aligned} D_{x,\mu} &:= \bigcap_{\iota < \mu} \{s_\iota : x \in s_\iota\} \\ g(x) &:= \{\mu < \alpha : x \in s_\mu \wedge (s_\mu \cap D_{x,\mu} \neq D_{x,\mu})\}. \end{aligned}$$

Fact: Given $x, y \in S$, $g(x) = g(y) \Leftrightarrow x \sim y$.
(In other words $x^\sim = y^\sim$ whenever $g(x) = g(y)$).
Hence there is a bijection between $\{x^\sim : x \in S\}$ and $\{g(x) : x \in S\}$.
Furthermore, $g(x) \in \mathit{fin}(\alpha)$.

Since $\{g(x) : x \in S\} \subseteq \mathit{fin}(\alpha)$, apply F^α_{fin} to obtain $F^\alpha_{\mathit{fin}}[\{g(x) : x \in S\}] \subseteq \alpha$.
Let γ be the order-type of $F^\alpha_{\mathit{fin}}[\{g(x) : x \in S\}]$. Then $\gamma \leq \alpha$ and for each $g(x)$ we obtain an ordinal number $\eta(g(x)) < \gamma$.
Each s_ι $(\iota < \alpha)$ is the union of at most finitely many equivalence classes. Thus there is a 1-1 function

$$\begin{aligned} h : \quad \alpha &\;\leftrightarrows\; \mathit{fin}(\gamma) \\ \iota &\;\leftrightarrows\; \{\xi : \eta(g(x)) = \xi \;\wedge\; x \in s_\iota\}. \end{aligned}$$

Since F^γ_{fin} is a bijection between $\mathit{fin}(\gamma)$ and γ, $F^\gamma_{\mathit{fin}} \circ h$ is a 1-1 function from α into γ and because $\gamma \leq \alpha$ we also have a 1-1 function from γ into α.
The Cantor-Bernstein Theorem yields a bijection between γ and α and hence a bijection G from $\{\eta(g(x)) : x \in S\}$ onto $\{s_\iota : \iota < \alpha\}$.
Now consider the function , $:= B \circ G \circ \eta \circ g$ from S into P(S):

$$, : S \overset{g}{\leftrightarrows} \{g(x) : x \in S\} \overset{\eta}{\leftrightarrows} \{\eta(g(x)) : x \in S\} \overset{G}{\leftrightarrows} \{s_\iota : \iota < \alpha\} \overset{B}{\leftrightarrows} \mathcal{P}(S)$$

Fact: $S_\alpha := \{x \in S : x \notin , (x)\} \notin \{B(s_\iota) : \iota < \alpha\}$.

Otherwise Take $S_\alpha = B(s_\beta)$ (for some $\beta < \alpha$).
We identify each $x^\sim$ with $g(x)$ using the bijection above.
Then there is a $g(x)$ such that $G \circ \eta((g(x)) = s_\beta$.
Now if $y \in x^\sim$ then , $(y) = S_\alpha$.
But $y \in S_\alpha \Leftrightarrow y \notin , (y) \Leftrightarrow y \notin S_\alpha$, which is a contradiction.

But $S_\alpha \subseteq S$ and $B^{-1}(S_\alpha) =: s_\alpha \in \mathit{fin}(S)$ with $s_\alpha \notin \{s_\iota : \iota < \alpha\}$ and we have an $(\alpha+1)$-sequence$^{1\text{-}1}$ in $\mathit{fin}(S)$, namely $\langle s_0, s_1, \ldots, s_\beta, \ldots, s_\alpha \rangle_{\alpha+1}$.

We now see that for an infinite set S there is no bijection between $\mathit{fin}(S)$ and $\mathcal{P}(S)$ and this completes the proof. ■

We note the following facts.

Given a natural number n,	$\mathrm{ZF} \vdash (n \times \mathit{fin}(\mathcal{C}) = \mathcal{P}(\mathcal{C}) \to n = 2^k$ for a $k \in \omega)$.
Moreover, for each $k \in \omega$	$\mathrm{Con(ZF)} \Rightarrow \mathrm{Con(ZF} + \exists \mathcal{C}(2^k \times \mathit{fin}(\mathcal{C}) = \mathcal{P}(\mathcal{C}))$
	(If $k = 0$, then this is obvious for finite cardinals.)

Sketch of the proof:

For the consistency result, consider the permutation model with an infinite set of atoms A and the empty relation. Then the automorphism group is the complete permutation group. It is not hard to see that any subset of A in this model is either finite or has a finite complement. Take a natural number k and consider (in this model) the set $k \times A$. The cardinality of the set $\mathcal{P}(k \times A)$ is the same as that of the set $2^k \times \mathit{fin}(A)$.

To prove the other fact, assume that n is a natural number which is not a power of 2 and that for some infinite set S there is a bijection B between $n \times \mathit{fin}(S)$ and $\mathcal{P}(S)$. Use the function B to construct an ω-sequence$^{1\text{-}1}$ in $\mathit{fin}(S)$. Then, using Theorem 3, $\omega \leq \mathit{fin}(S) < \mathcal{P}(S)$ and it is easy to see that $n \times \mathit{fin}(S) \leq \mathit{fin}(S) \times \mathit{fin}(S) =: \mathit{fin}(S)^2$. Then $\omega < \mathcal{P}(S) = n \times \mathit{fin}(S) \leq \mathit{fin}(S)^2$ contradicts the fact that if $\aleph_0 \leq \mathcal{P}(\mathcal{C})$, then for any natural number n, $\mathcal{P}(\mathcal{C}) \not\leq \mathit{fin}(\mathcal{C})^n$. (Here $\aleph_0$ denotes the cardinality of ω). The proof of this fact is similar to the proof of Theorem 3. ■

Section 3: $\mathit{seq}^{1\text{-}1}(S)$, $\mathit{seq}(S)$ and $\mathcal{P}(S)$ when S is an arbitrary set.

We show that $\mathrm{ZF} \vdash \mathit{seq}^{1\text{-}1}(\mathcal{C}) \neq \mathcal{P}(\mathcal{C})$ for every cardinal $\mathcal{C} \geq 2$. But we first need the following result.

Lemma: $\mathrm{ZF} \vdash \aleph_0 \leq \mathcal{P}(\mathcal{C}) \to \mathcal{P}(\mathcal{C}) \not\leq \mathit{seq}^{1\text{-}1}(\mathcal{C})$.

Proof:

Take $S \in \mathcal{C}$. Then, because $\aleph_0 \leq \mathcal{P}(\mathcal{C})$, we have a 1-1 function $f_\omega : \omega \Leftrightarrow\!\!\!\rightarrow \mathcal{P}(S)$.
Assume that there is a 1-1 function $J : \mathcal{P}(S) \Leftrightarrow\!\!\!\rightarrow \mathit{seq}^{1\text{-}1}(S)$.
Then $J \circ f_\omega : \omega \Leftrightarrow\!\!\!\rightarrow \mathit{seq}^{1\text{-}1}(S)$ is also 1-1 and we get an ω-sequence$^{1\text{-}1}$ in $\mathit{seq}^{1\text{-}1}(S)$.
Using this ω-sequence$^{1\text{-}1}$ in $\mathit{seq}^{1\text{-}1}(S)$ we can easily construct an ω-sequence$^{1\text{-}1}$ in S.
If we already have constructed an α-sequence$^{1\text{-}1}$ $\langle s_0, s_1, \ldots, s_\beta, \ldots \rangle_\alpha$ $(\alpha \geq \omega)$ in S, put $T := \{s_\iota : \iota < \alpha\}$. This gives rise to bijective functions,

$$\begin{array}{lrcl} h_0 : & T & \Leftrightarrow\!\!\!\rightarrow & \alpha \\ h_1 : & \mathit{seq}^{1\text{-}1}(\alpha) & \Leftrightarrow\!\!\!\rightarrow & \mathit{seq}^{1\text{-}1}(T). \end{array}$$

Let J^{-1} be the inverse of J and denote the inverse of F^{α}_{seq} by $\mathrm{inv}F^{\alpha}_{seq}$.
Further define

$$,\ := J^{-1}\circ h_1\circ \mathrm{inv}F^{\alpha}_{seq}\circ h_0$$

Note: $\mathrm{dom}(,\ ) \subseteq T$ and $\mathrm{range}(,\ ) \subseteq \mathcal{P}(S)$ (because J is 1-1).

Fact: $S_\alpha := \{x \in S :\ x \notin ,\ (x)\} \notin J^{-1}[seq^{1\text{-}1}(T)]$.
Assume not, then $x \in S$ such that $J(S_\alpha) = h_1\circ \mathrm{inv}F^{\alpha}_{seq}\circ h_0(x)$ yields a contradiction.

Because $J(S_\alpha) \notin seq^{1\text{-}1}(T)$, the sequence $J(S_\alpha)$ has a first element which is not in T, say s_α. Finally, the sequence $\langle s_0, s_1, \ldots, s_\alpha\rangle_{\alpha+1}$ is an $(\alpha+1)$-sequence$^{1\text{-}1}$ in S.
So the existence of a 1-1 function $J :\ \mathcal{P}(S) \leftrightarrow\!\!\!\rightarrow seq^{1\text{-}1}(S)$ contradicts Hartogs' Theorem. ■

Theorem 4: If $\mathcal{C} \geq 2$ is any cardinal, then $\mathrm{ZF} \vdash (seq^{1\text{-}1}(\mathcal{C}) \neq \mathcal{P}(\mathcal{C}))$

Proof:
By the Lemma it is enough to prove that if $\mathcal{C} \geq 2$, then $seq^{1\text{-}1}(\mathcal{C}) = \mathcal{P}(\mathcal{C}) \Rightarrow \aleph_0 \leq \mathcal{C}$.
For finite cardinals $\mathcal{C} \geq 2$ the statement is obvious. So let $S \in \mathcal{C}$ be an infinite set and assume that there is a bijective function

$$B : seq^{1\text{-}1}(S) \leftrightarrow\!\!\!\rightarrow \mathcal{P}(S).$$

We use this function to construct an ω-sequence$^{1\text{-}1}$ in S.
Let $n^\star$ $(n < \omega)$ be the cardinality of $seq^{1\text{-}1}(n)$.
Then $0^\star = 1;\ 1^\star = 2;\ 2^\star = 5; \ldots\ 16^\star = 56,874,039,553,217; \ldots$ (see [Sl], No. 589), and, in general

$$n^\star = \sum_{i=0}^{n} \frac{n!}{i!}$$

We begin by choosing four distinct elements of S, $S_4 := \{s_0, s_1, s_2, s_3\}$ and use these elements to construct a 4-sequence$^{1\text{-}1}$ $\langle s_0, s_1, s_2, s_3\rangle_4$ in S. This sequence will give us an order on the set $seq^{1\text{-}1}(S_4)$ (e.g. we order $seq^{1\text{-}1}(S_4)$ by length and lexicographically).
If we have already constructed an n-sequence$^{1\text{-}1}$ $\langle s_0, s_1, \ldots, s_{n-1}\rangle_n$ in S $(n \geq 4)$, put $S_n := \{s_i :\ i < n\}$. Then $B[seq^{1\text{-}1}(S_n)] \subseteq \mathcal{P}(S)$ has cardinality $n^\star$.
We now define an equivalence relation on S by

$$x \sim y \quad \textit{iff} \quad \forall q \in seq^{1\text{-}1}(S_n)(x \in B(q) \leftrightarrow y \in B(q)).$$

It is easy to see that for each $q \in seq^{1\text{-}1}(S_n)$

$$B(q) \text{ is the } \textit{disjoint union} \text{ of } \textit{less} \text{ than } n^\star \text{ equivalence classes.} \qquad (1)$$

Take the above order on $seq^{1\text{-}1}(S_n)$. This induces an order on the set of equivalence classes eq:$= \{x^\sim :\ x \in S\}$ and also an order on $\mathcal{P}(\mathrm{eq})$.

If there is a first $r \in \mathcal{P}(\text{eq})$ such that $r \notin B[seq^{1\text{-}1}(S_n)]$, then $q_r := B^{-1}(r)$ is a "new" sequence in S. This is $q_r \notin seq^{1\text{-}1}(S_n)$ and we choose the first element s_n of q_r which is not in S_n.
Hence, the sequence $\langle s_0, s_1, \ldots, s_n \rangle_{n+1}$ is now an $(n+1)$-sequence$^{1\text{-}1}$ in S.
If there is an $s_i \in S_n$ such that $\{s_i\} \notin B[seq^{1\text{-}1}(S_n)]$, then use $B(\{s_i\})$ to construct an $(n+1)$-sequence$^{1\text{-}1}$ in S.
Otherwise our construction stops at S_n and we write $\text{stop}(S_n)$.

Our construction only stops if

$$\begin{array}{ll} \text{for each } s_i \in S_n: & \{s_i\} \in \text{eq and} \\ \text{for each } r \in \mathcal{P}(\text{eq}) & \text{there is a } q_r \in seq^{1\text{-}1}(S_n) \text{ such that } B(q_r) = r. \end{array}$$

If κ ($\kappa < \omega$) is the cardinality of eq, then 2^κ is the cardiniality of $\mathcal{P}(\text{eq})$ and because of (1) we have $\text{stop}(S_n) \Rightarrow 2^\kappa = n^\star$.
It is known that $0^\star = 1 = 2^0$; $1^\star = 2 = 2^1$; $3^\star = 16 = 2^4$ and $n^\star$ is a power of 2 for some $n > 3$, then n has to be bigger than 10^8.
If there are only finitely many $k, n < \omega$ such that $2^k = n^\star$, then there is a least n_0 such that $2^k = {n_0}^\star$ and $\forall n > n_0(\neg\text{stop}(S_n))$.

Refining our construction removes the need for this strong arithmetic condition.

Assume $\text{stop}(S_n)$.
If $x \notin S_n$ then let $S^x_{n+1} := S_n \dot\cup \{x\}$ and $S^x_{n+k} := S^x_{n+1} \dot\cup \{Y\}$ with Y of cardinality $k \Leftrightarrow 1$. Because (n is even)$\Leftrightarrow$ ($n^\star$ is odd) and $\text{stop}(S_n)$, we cannot have $\text{stop}(S^x_{n+1})$ for any $x \notin S_n$.

Now we recommence our construction with the set S^x_{n+1} and construct an $(n+k)$-sequence$^{1\text{-}1}$ $\langle s_0, s_1, \ldots, s_{n+k-1} \rangle_{n+k}$ $(k \geq 2)$ in S.
If the construction also stops at the $(n + \text{stop})^{th}$ stage at the set $S^x_{n+\text{stop}}$ $(\text{stop} \geq 2)$, then we write S^x instead of $S^x_{n+\text{stop}}$.

If there is an $x \in S$ such that S^x is infinite, then our construction does not stop when we recommence with S^x_{n+1} and we can construct an ω-sequence$^{1\text{-}1}$ in S. But this contradicts our Lemma.

So there cannot be such an x and each $x \in S$ is in exactly one *finite* set S^x. If for each $x \in S$, S^x is the union of some elements of eq, then S must be finite, because eq is finite. But this contradicts our assumption that S is infinite.

A subset of S is called *good* if it cannot be written as the union of elements of eq.

Consider the set $T_{\min} := \{x : S^x \text{ is good and of least cardinality}\}$ and let m_{T} be the cardinality of S^x for some x in $T_{\min}$. Further for $x \in T_{\min}$ let $x_= := \{y : S^y = S^x\}$ (this elements of S^x we cannot distinguish) and $m_=$ denote the least cardinality of the sets $x_=$.
If $T_{\min}$ is good, use $B^{-1}(T_{\min})$ to construct an $(n+1)$-sequence$^{1\text{-}1}$ in S.
Otherwise take $x \in T_{\min}$. Because S^x is good

$$B^{-1}(S^x) \notin seq^{1\text{-}1}(S_n).$$

Thus there is a first y in $B^{-1}(S^x)$ which is not in S_n. It is easy to see that $S^y \subseteq S^x$ and if $S^y \neq S^x$ then S^y is not good (because of $x \in T_{\min}$).
But then $B^{-1}(S^x \setminus S^y) \notin seq^{1\text{-}1}(S^y)$ and we may proceed.

So for each $x \in T_{\min}$ construct an m_{T}-sequence$^{1\text{-}1}$ SEQ^x in S such that

$$S^x = S^y \implies \mathrm{SEQ}^x = \mathrm{SEQ}^y.$$

For $i < m_{\mathrm{T}}$ define

$$Q_i := \{s \in S : \ s \text{ is the } i^{th} \text{ element in } \mathrm{SEQ}^x \text{ for some } x \in S\}$$

Assume there is some $j < m_{\mathrm{T}}$ such that Q_j is good. Then $B^{-1}(Q_j) \notin seq^{1\text{-}1}(S_n)$. But $B^{-1}(Q_j) \notin seq^{1\text{-}1}(S)$ and we get an $(n+1)$-sequence$^{1\text{-}1}$ in S.

It remains to justify our assumption.

Note that if for some $i \neq j$, $z \in Q_i \cap Q_j$, then S^z cannot be good. Furthermore for each $x \in T_{\min}$ there is exactly one i_x such that $x \in Q_{i_x}$ and if $z, y \in x_=,\ z \neq y$, then $i_x \neq i_y$. If there are no good Q_i's, $m_=$ cannot exceed κ, (the cardinality of eq). But by the following this is a contradiction:

An easy calculation modulo 2^r $(r \leq 4)$ shows that for each n, if $2^r | n^\star$, then $2^r | (n+2^r)^\star$ and $2^r \not| (n+t)^\star$ if $0 < t < 2^r$.

Assume there is a smallest k $(k \geq 4)$ such that $2^{k+1} | n^\star$ and $2^{k+1} | (n+t)^\star$ for some t with $0 < t < 2^{k+1}$.

Then, because $2^k | 2^{k+1}$, we have $2^k | n^\star$ and $2^k | (n+t)^\star$. Since k is by definition the smallest such number, we know that t must be 2^k.

$$\begin{array}{lrcccccl}
(n+2^k)^\star = \sum\limits_{i=0}^{n+2^k} \frac{(n+2^k)!}{i!} = & 1 \cdot 2 \cdot & \ldots & \cdot 2^k \cdot (2^k+1) \cdot & \ldots & \cdot (2^k+n) & & (1) \\
+ & 2 \cdot & \ldots & \cdot 2^k \cdot & \ldots & \cdot (2^k+n) & & (2) \\
 & & \ddots & & & & & \vdots \\
+ & & & 2^k \cdot & \ldots & \cdot (2^k+n) & & (2^k) \\
 & & & & \ddots & & & \vdots \\
+ & & & & & (2^k+n) & & (2^k+n) \\
+ & & & & & 1 & & (2^k+n+1)
\end{array}$$

It is easy to see that 2^{k+1} divides lines $(1) - (2^k)$ since $k \geq 2$ and $n \geq 2$.

If we calculate the products of lines $(2^k+1) - (2^k+n+1)$, then we only have to consider sums which are not obiviously divisible by 2^{k+1}. So, for a suitable natural number ε we have

$$(n+2^k)^\star = 2^k \cdot (\sum_{j=0}^{n-1} \sum_{i>j}^{n} \frac{n!}{i \cdot j!}) + n^\star + 2^{k+1} \cdot \varepsilon. \tag{2}$$

We know that $2^{k+1} | n^\star$ with $n \geq 3,\ k \geq 4$. And because $n^\star$ is even n has to be odd. If j is $n \Leftrightarrow 1,\ n \Leftrightarrow 2$ or $n \Leftrightarrow 3$, then $\sum\limits_{i>j}^{n} \frac{n!}{i \cdot j!}$ is odd. Moreover, if $0 \leq j \leq (n \Leftrightarrow 4)$, then $\sum\limits_{i>j}^{n} \frac{n!}{i \cdot j!}$ is even. So $\sum\limits_{j=0}^{n-1} \sum\limits_{i>j}^{n} \frac{n!}{i \cdot j!}$ is odd. Hence $2^{k+1} \not| (n+2^k)^\star$, (by (2) and $2^{k+1} | n^\star$).

We return to the proof.

We know that if $2^k = n^\star$ and $(n+t)^\star$ is a power of 2, then 2^k divides t. $(**)$

Take $x \in T_{\min}$ such that $\left|x_=\right| = m_=$. If $y \in S^x$, then

(i) $\left|S^y\right| = n + t_y$ with 2^κ divides t_y,
(ii) either $y \in x_=$ or S^y is not good.

This is because $2^\kappa = n^\star$ and $(**)$.

Hence (for a suitable natural number ε) $m_{\mathrm{T}} = \left|S^x\right| = n + 2^\kappa \cdot \varepsilon + m_=$ (by (ii)), and 2^κ divides $m_=$ (by (i)).

But this implies that $m_=$ must be larger than κ, which justifies our assumption. ■

The statement obtained when $seq^{1\text{-}1}$ is replaced by seq is much easier to prove:

Theorem 5: ZF $\vdash$ $seq(\mathcal{C}) \neq \mathcal{P}(\mathcal{C})$ for all cardinals such that $\emptyset \notin \mathcal{C}$.

Proof: Take $S \in \mathcal{C}$. First note the fact that if $\aleph_0 \leq \mathcal{C}$, then $seq(\mathcal{C}) \not\geq \mathcal{P}(\mathcal{C})$.

(The proof is the same as the proof of the Lemma, except that we can skip the first lines of the proof of the Lemma).

Assume there is a bijection B from $seq(S)$ onto $\mathcal{P}(S)$. Choose an $s_0 \in S$, and define a 1-1 function f_{s_0} from ω into $\mathcal{P}(S)$ by $i \mapsto \xi_i := B(\langle s_0, s_0, \ldots, s_0\rangle)$ (i-times). Use the ξ_i's to construct pairwise disjoint subsets $c_i \subseteq S$ $(i < \omega)$.

Given an n-sequence$^{1\text{-}1}$ $\langle s_0, s_1, \ldots, s_{n-1}\rangle_n$ in S, let $S_n := \{s_i : i < n\}$ and the natural order on S_n induce a well-ordering on the set $seq(S_n)$ with order type ω. Then there is a bijection $h : \omega \leftrightarrow seq(S_n)$. Now the function $, := B \circ h$ is a 1-1 function from ω into $\mathcal{P}(S)$ and $t := \dot{\cup}\{c_i : c_i \subseteq , (i)\} \notin \{, (k) : k \in \omega\}$.

Hence $B^{-1}(t)$ is a sequence in S which does not belongs to S_n. Choose $s_n \in S$ to be the first element of $B^{-1}(t)$ not in S_n. Then $\langle s_0, s_1, \ldots, s_n\rangle_{n+1}$ is an $(n+1)$-sequence$^{1\text{-}1}$ in the set S.

We thus construct an ω-sequence$^{1\text{-}1}$ in S, contradicting the previous fact. ■

Abstract

Computer-assisted and automated conjecture-making in graph theory is reviewed, focusing on the three operational systems GRAPH, Graffiti and AutoGraphiX (AGX). A series of possible enhancements, mostly through hybridisation of these systems, are proposed as well as several research paths for development of the area.

Keywords: graph, conjecture, computer-assisted, automated.

Résumé

On passe en revue la génération de conjectures assitée par ordinateur et automatisée en théorie des graphes, en considérant plus particulièrement les trois systèmes opérationnels GRAPH, Graffiti et AutoGraphiX (AGX). Une série d'améliorations possibles, le plus souvent par hybridation de ces systèmes, sont proposées ainsi que plusieurs voies de recherche pour le développement du domaine dans son ensemble.

Mots clés: graphe, conjecture, assisté par ordinateur, automatisé.

1 Introduction

1.1 Conjectures

Roget's New thesaurus [147] defines *conjecture* as

> "a judgment, estimate or opinion arrived at by guessing: guess, guesswork, speculation, supposition, surmise".

So, uncertainty is stressed. In mathematics, the word "conjecture" has a more precise meaning. In their *Dictionary of Mathematics*, Bouvier and George [22] define it as follows:

> "Conjecture: An *a priori* hypothesis on the exactness or falseness of a statement of which one ignores the proof".

Knowledge should back this hypothesis, and make the conjecture valuable, as stressed by Mac Lane [128]:

> "Conjecture has long been accepted in mathematics, but the customs are clear. If a mathematician has really studied the subject and made advances therein, then he is entitled to formulate an insight as a conjecture, which usually has the form of a specific proposed theorem. Riemann, Poincaré, Hilbert, Mordell, Bieberbach, and many others have made such deep conjectures".

Further examples of important conjectures, this time in graph theory, are the four-color conjecture [149], proved in 1976 by Appel and Haken [7] [8] [9] (see also the more recent proof of Robertson *et al.* [146]) and the strong perfect graph conjecture of Berge [16] [17] very recently proved by Chudnovsky *et al.* [47] [48]. The former may have initially been a happy guess of a student, Francis Guthrie, but was popularized by a major mathematician, Augustus de Morgan. Its (correct) proof took 125 years and was computer-assisted. No proof without partial automation is known. The latter was proposed in 1961 by one of the most prominent graph theorist of the time. It took 41 years and the work of scores of mathematicians to be finally proved (without computer assistance). So, conjecturing supposes knowledge and insight. Guessing is easy but conjecturing is hard; we will see that this holds for computers as for humans.

1.2 Automation

Again according to Mac Lane [128], the sequence for the understanding of mathematics may be:

> "Intuition, Trial, Error, Speculation, Conjecture, Proof".

Proof is the ultimate goal and has attracted the most attention, including in attempts to automate mathematics. Yet, it is far from the whole story. Hardy [114] reminds us that

> "All physicists and a good many quite respectable mathematicians are contemptuous about proof".

Discovering interesting or beautiful conjectures, even if someone else proves (or refutes) them, is of importance.

Clearly, theorems are first conjectures, possibly known as such only to those who prove them. Often, only the final result, i.e., the theorem, is published. The discovery process is not explained, and further discoveries may be made more difficult than necessary. A few mathematicians and philosophers of science have focused on this process. Prominent among them are Euler, Polya [138] [139] and Lakatos [123]. Recent studies of the application of Popper's ideas in mathematics [140] and their development are also of interest [94] [95].

Automated theorem proving is a well-developed field, with numerous researchers, tens of books and a rapidly increasing record of successes [162]. A good example is the recent 16-line automated proof by Mc Cune [133] of the Robbins conjecture:

"All Robbinsonian algebras are Boolean algebras",

which had been open for 63 years.

In graph theory, only simple propositions can at present be proved in an entirely automated way (see Section 2 for a brief discussion). Computer-assisted proofs, mostly based on enumeration routines, are becoming common. To illustrate, the survey of Radzizowski [145] on small Ramsey numbers mentions computer-assisted results from 71 papers.

In contrast, computer-assisted and automated conjecture-making in mathematics, the mathematical branch of discovery science, has attracted few researchers up to now, despite some notable successes. Outside of graph theory one may mention the important work of several mathematicians on integer relation detection [115] [11] [21]. This led, among other applications to Apéry-like formulae for $\zeta(4n+3)$, new Euler sums and formulae for various constants including one for π with the astonishing consequence that one can compute, in base 2, the digits of π beginning at any place (e.g. from the trillionth' one) without knowing the previous ones. While the important work of Wu [163] [164], and Chou *et al.* [42] [44] [45] in plane geometry is mostly aimed at automating proofs, it includes conjecture-making routines. This led to the discovery of new families of Pascal conics [44]; recently a procedure for finding *all* relations implied by a given configuration of lines and curves in the plane has been obtained [45]. Hájek and Havránek [100] [101] and Hájek and Holeňa [102] have studied mathematical formulations for a general theory of the mechanization of hypothesis formation. They introduce formal logics for that purpose and may have been one of the sources of inspiration for the system GRAPH discussed below.

Graph-theoretic work will be discussed throughout this paper. This will be done by a study and discussion of some of the best developed systems, no general mathematical framework for making conjectures in graph theory being in current use. But a preliminary question should be addressed:

How far should conjecture-making in graph theory be automated?

Langley [121] comments as follows on discovery science systems:

> "Although the term *computational discovery* suggests an automated process, close inspection of the literature reveals that the human developer or user plays an important role in any successful project. Early computational research on scientific discovery downplayed this fact and emphasized the automation aspect

> in general keeping with the goals of artificial intelligence at the time. However, the new climate in AI systems that advise humans rather than replace them, and recent analyses of machine learning applications... suggest an important role for the developer".

Two things should be distinguished here: on the one hand, that knowledge due to the developer, and possibly many others (e.g. numerous algorithms for computing graph theoretic invariants) is embedded in the system appears to be necessary to obtain conjectures; on the other hand, that the user may interact or not with the system, leading to computer-assisted or to automated discoveries.

In graph theory, three additional reasons may be adduced for preferring computer-assisted systems to automated ones:

(i) the difficulty of automation may limit the scope of problems addressed;

(ii) the ultimate goal being proof, interaction with the system is more likely to lead to insights about how to prove the conjectures found than just reading their statement;

(iii) such interaction may also be very fruitful from the pedagogical point of view. This question will be discussed further in Section 3.

However, automating a system for making conjectures in graph theory is a challenge, and may lead to original ways of addressing this problem. Moreover, comparison of this work with the treatment of similar problems within close fields such as automated theorem proving or data mining, may foster cross-fertilization.

This author's view is that both computer-assisted and automated conjecture-making are of interest; in this paper, the main focus is on the latter.

1.3 Definitions

We will adopt the following terminology: an *automated system* will be synonymous with a *fully* automated one, and this means that

(i) *input should be limited to the problem statement* which implies further information on the problem or closely related ones cannot be introduced *at that time*, but may of course already belong to one or another of the systems databases;

(ii) *there should be no human intervention between problem statement and output of the results*;

(iii) *output of the results should be the final step*, which implies there should be no human selection of those conjectures about the problem under study which are publicized; of course the users are then free to choose those they will try to prove.

Otherwise, the system will be called *computer-assisted*.

This is in keeping with usual practice. To illustrate points (i) and (ii), "Deep Blue" [30] [118] is an automated system which includes considerable knowledge about chess-playing (and Kasparov's way to play chess) due to the developers. In competition it can be tuned before a game but not when this game is in process, and it only receives notice of the opponent's moves [118].

To illustrate point (iii) observe that some researchers (e.g. [120]) claim that computers can compose poetry and try to make their point by selecting among a large output, obtained by their system from some poets vocabulary, usually very short "poems" which appear to make sense. If one generates a sufficiently large number of "poems" and selects drastically among them, this is bound to work (to some extent), but the conclusion is far from clear.

When an automated system makes conjectures we will say they are obtained *by* the system; when a computer-assisted system does so, we will say the conjectures are obtained *with* the system.

Refuting or corroborating conjectures known beforehand with a computerized system will be referred to as *testing* them; conjectures which are corroborated may be improved (e.g. stronger bounds may be considered) and this will be called *strengthening* them; finding new conjectures will be called *conjecture-making*, and can be unassisted (or done by hand), computer-assisted or automated.

To the best of our knowledge, present systems for conjecture-making in graph-theory are either computer-assisted or can be used both in computer-assisted mode and, in rare cases, in automated mode. The question of whether one computer-assisted system is more automated than another cannot be answered in a clear-cut way as different systems perform different tasks. Therefore, we will describe these tasks, state which of them are automated and how, which are not and how they are done, and let the reader judge.

About half a dozen systems for conjecture-making in graph theory and other close purposes have been developed. We distinguish between *experimental* and *operational* systems. An experimental system explores an idea, without necessarily leading to new results (or to just a few, due to its developers); its aim is often to understand the way mathematicians reason or to help them in various tasks. Such systems, while they may be inactive for the time being, have potential, particularly in conjunction with others, as discussed briefly in various places of this paper. They include:

(a) the *INGRID* system of Brigham and Dutton [25] [26] [27] [28], which manipulates formulae on graph invariants from a database to compute bounds on some invariants when others are limited to some range. INGRID can be used to

  (i) help solve practical problems,

  (ii) derive new theorems (by selecting relations leading to them),

  (iii) test the effectiveness of new theorems (by showing they are or not consequences of one or several previously known ones),

  (iv) test conjectures (viewed as "temporary theorem" to see if this implies some contradiction),

  (v) resolve open problems (by showing they imply some contradiction), and

  (vi) help to study graph theory.

  As explained in [113], some of these functions may be viewed as obtaining particular types of conjectures.

(b) the *graph theorist* system of Epstein [73] [74] [75] [76]; this knowledge intensive, specific domain learning system uses algorithmic descriptions of classes of graphs such as connected, acyclic, bipartite and so forth. It mainly uses theory-driven discovery of concepts, conjectures and theorems, based upon search heuristics, but also infers explanations from factual input about graphs.

There are three main operational systems:

(a) the GRAPH system, developed by Cvetković and co-workers [59] [60] [54] [61] [55] [56] [62] [63], which pioneered the man-machine type of research in graph theory. Built between 1980 and 1984 this system was extensively used to find conjectures and prove theorems in graph theory (usually the latter only being published), with an emphasis on algebraic graph theory. Cvetković and Simić [64] review 92 papers by 23 authors on GRAPH, its uses and results obtained with it from 1982 onwards. GRAPH comprises

  (i) a bibliographic component, BIBLI,

  (ii) an algorithmic component, ALGOR, and

  (iii) an automated theorem proving one, THEOR.

(b) the Graffiti system, due to Fajtlowicz [81] [80] [82][83] [84] [85] [79] [87] and developed since the mid-eighties, with from 1990 onwards collaboration of De La Vina, notably in the development of its DALMATIAN version. This system generates a large number of *a priori* conjectures, under the form of algebraic relations between graph invariants, then selects among them, by eliminating false or uninteresting conjectures through testing them on a database of graphs, applying heuristics and building counter-examples. Conjectures which pass these correctness and interestingness tests are proposed, after further selection, to the mathematical community in the large email file "Written on the Wall" which is updated from time to time. More than 70 mathematicians, among them some famous ones, sent proofs, or refutations of those conjectures, listed in that file. Many papers on proofs, and more often disproofs, sometimes with corrected results which led to further developments or strengthened conjectures, have been published. De La Vina [67] lists 75 such papers, technical reports and theses from 1986 onwards.

(c) the AutoGraphiX (AGX) system, due to Caporossi and Hansen [37] [31] [65] [34] [35] [106] [33] [6] [32] [36] [107] which generates many extremal or near-extremal graphs for some invariant or formula involving several invariants, then derives various results from them. This system may be used to

  (i) find a graph satisfying given constraints;

  (ii) find optimal or near-optimal values for a graph invariant on a family of graphs with given constraints;

  (iii) refute, corroborate or strengthen a conjecture;

  (iv) make a conjecture in computer-assisted or automated mode;

(v) suggest ideas of proof.

A series of papers on the system, its uses, results and comparative performance have been published. Aouchiche [5] lists 40 papers on AGX and its results, or related to its results, published since 1999, submitted, or to appear.

Collectively, this number of papers (over 200) is among the largest in the field of discovery science.

Some programs from graph theory not designed specifically for making conjectures may be useful to do so, either on their own or in conjunction with others. This is the case in enumeration where e.g. programs such as *Nauty* and *geng* of McKay [131] [132] helped to conjecture and then determine many Ramsey numbers.

Conjectures can also be obtained by serendipity. As explained in more detail in [104], a program for coloring planar graphs written in Mathematica by Wagon, always used 3 colors when applied to rhombic Penrose tilings; Sibley and Wagon [152] then proved 3 colors suffice, a problem that had been open for 20 years. Another example relies on a program from mathematical programming: a mixed-integer formulation of the problem of determining the Clar number of a benzenoid [110], due to Hansen and Zheng [111], never used branching. The conjecture that linear programming sufficed to solve this problem was later proved by Abeledo and Atkinson [1] [2].

1.4 Plan of the paper

This paper has two complementary aims:

(i) *assess the state-of-the art* in computer-assisted and automated conjecture-making in graph theory. This will be done in the next three sections, devoted respectively to GRAPH, Graffiti and AGX, with special emphasis on their conjecture-making functions;

(ii) *make a series of proposals for advancement* of this field. They will be interspersed in the next three sections and will take two forms. First, *Proposed Enhancements* (PE) will suggest ways to improve specific steps or functions of the system under study; they will often be suggested by ways to solve similar problems in other systems and the suggestions will then amount to hybridizing them. Second, *Research paths* (RP) will draw attention upon open problems or general questions related to conjecture-making in graph theory, as well as links to establish with other domains of research. They are often long-term goals, sometimes quite speculative. Separation between study of systems and proposals will be indicated by numbering them PEk or RPk, with a □ sign as the end of the corresponding statement.

The three operational systems GRAPH, Graffiti and AGX will be studied in sections 2, 3 and 4 respectively. Conclusions will be drawn in Section 5.

2 Graph

As mentioned in the introduction, GRAPH has three components, BIBLI, ALGOR and THEOR. ALGOR is the most directly related to conjecture-making but both BIBLI and THEOR bear upon problems of importance for conjecture-making systems too. So we examine all three of them in turn.

2.1 BIBLI

The GRAPH system uses a formalized subset of the everyday English language, called Graph Theoretic Computer Language. It is described in [59]. It is an interactive language used from a terminal keyboard; in recent versions a mouse can be used also for some operations.

The BIBLI component is devoted to bibliographic data processing: it allows storage and retrieval of information on papers, books, proceedings, reports, abstracts, manuscripts and documents. Its functions, rarely available at the time of inception, are now in wide use in systems accessible on the web such as *Google, Web of Science* or *Citeseer*, but it remains useful for tailor-made bibliographies such as that one of the book of Cvetković *et al.* "*Recent Results in the Theory of Graph Spectra*" [57].

While very large amounts of data are now available online and special sites devoted to graph theory, such as the *Graph Theory White Pages* are open to the general public, the documentation problem in graph theory is far from solved (All those who have painstakingly derived a series of conjectures, transformed them by proof into theorems only to find in a last check most or all results to be known but expressed in a different language are well aware of this problem). Indeed, the graph theory literature is vast, dispersed over many fields, growing in a savage way and, as a consequence, terminology is far from unified. Moreover, due to dependence between concepts, the same results can take different forms e.g. in the graph G or its complement $\bar{G}$, or after eliminating one or another invariant by a linear equation such as those of Gallai's theorem [92]. Finally, some results can be expressed in different ways because concepts have a nonlinear dependence. To illustrate, even if one knows that the Wiener index of a tree T [72] is another name for the sum of distances between pairs of vertices of T, one might miss equivalent results expressed in terms of average distance between pairs of distinct vertices of T.

Brigham and Dutton [26] [27] have gathered 458 relations between graph invariants, used in their system INGRID. They can help in checking whether a result is new, but if this has to be done with a chance of success, a much more comprehensive system should be built, in a collaborative effort, similar to that which gave rise to Sloane's On-line Encyclopedia of Integer Sequences [157]. The following research paths sketch how this might be done:

RP1. *Find linear equality relations between graph invariants.* Consider a large number of graph invariants and programs to compute them (available in the cited systems, in Graphbase [119] or LEDA [134] and on the Web). Compute values of these invariants for a large set of graphs. Then use the numerical relation-finding routine of AGX (see Section 4)

to obtain a basis of affine relations on these invariants. If some new relations are found, prove them. □

RP2. *Define a standard set of invariants* in terms of which all others will be expressed and (one or several) *standard forms for relations in graph theory.* Write a translator program which will express (as far as possible) any formula in standard form and conversely express a standard-form formula in one or all equivalent forms. Programs for algebraic manipulations such as Mathematica [161] or Matlab [130] might be used for that purpose. □

RP3. *Organize a site* for interactive addition to and consultation of a database of graph theory relations. These relations might be valid for all graphs, or for important families of subgraphs, e.g. bipartite, triangle-free, of girth at least 5, and so forth. □

Another important open problem, related to storing graph theory relations is to find if a given relation is redundant, i.e., implied by one or more relations already in the database. This can be done by finding a graph within a database for which it is not the case, as in the DALMATIAN version of Graffiti [84] (see Section 3) or in an algebraic way as in INGRID [28] or by showing that the relation is not best possible (assuming a best possible relation is known).

Given invariants $i_1, i_2, \ldots, i_p$ of a graph G one can define, as in [109], a *canonical form* for relations involving these invariants as

$$i_k \leq f(i_1, i_2, \ldots, i_{k-1}, i_{k+1}, \ldots, i_p) \tag{2.1}$$

or

$$i_k \geq g(i_1, i_2, \ldots, i_{k-1}, i_{k+1}, \ldots, i_p); \tag{2.2}$$

such relations are *sharp* (or best possible) if for all values of $i_1, i_2, \ldots, i_{k-1}, i_{k+1}, \ldots, i_p$ compatible with the existence of a graph there is a graph such that the relation is satisfied as an equality. A set of canonical relations is *complete* if the $2p$ relations (2.1) and (2.2) on $x_1, x_2, \ldots, x_p$ are sharp. One such set for the three parameters $\alpha(G)$ (independence number), n (order) and m (size) is given in [109]. The relation [105] [88]

$$\alpha(G) \geq \left\lceil \frac{2n - \frac{2m}{\lceil \frac{2m}{n} \rceil}}{\lceil \frac{2m}{n} \rceil + 1} \right\rceil \tag{2.3}$$

is sharp, while the following one, derived from Turan's theorem [159],

$$\alpha(G) \geq \frac{n^2}{2m + n} \tag{2.4}$$

is not. It is thus redundant but might be kept also if one is more interested in simplicity than in sharpness. Observe also that if a sharp relation is known one might consider that it is not useful to compare it to another one, yet the latter could also be sharp and simpler as is the case for (2.3) which is equivalent to but simpler than the relation given in [105].

2.2 ALGOR

This part of the system GRAPH is directly connected to conjecture-making ([59], p20):

> "The part of the system "GRAPH" described is primarily meant as a means for quick[ly] checking, disproving or making conjectures in graph theory. Facilities provided by the system enable to get the answer on a great number of questions on graphs of a reasonable size in a few seconds (of course, what does a reasonable size mean depends on the problem considered)."

Also:

> "Another situation in which the system can help is the following. Many results in graph theory begin with an observation which proves the desired statement for all but a finite number of graphs. These exceptional graphs are, as a rule, of a small size. The next part of the proof consists then in checking whether the statements hold for these graphs and that can be performed with the help of the system."

ALGOR solves a series of problems on particular graphs. They can be divided as follows: ([59], p11):

(a) manipulative tasks (setting and displaying values of the mentioned objects (i.e., graphs, values of the type integer, real and complex, and families of sets of integer values),

(b) creating common graphs (e.g. complete graphs, circuits, etc) or random graphs,

(c) creating graphs by performing graph-theoretic operations (e.g. complement of a graph, product of two graphs, etc),

(d) relabelling (points or lines of) graphs (by given permutations, at random, etc),

(e) determining integer invariants in graphs (e.g. number of some subgraphs, order of some point, etc.),

(f) determining real invariants of a graph (e.g. eigenvalues, eigenvectors, etc),

(g) checking properties of graphs, (e.g. whether a graph is planar or hamiltonian, whether two graphs are isomorphic, etc),

(h) listing families of graph characteristics (e.g. point degrees, components; etc).

Each group of operations is characterized by a verb in the commands used. They have a simple and transparent form, e.g.

CREATE < g-name > [AS] < type of graph > [OF] [ORDER] < integer >,

for instance:

CREATE $G1$ CIRCUIT OF ORDER 12

or

FORM [g-name] [AS] [THE] < integer > [TH] < operations > [GRAPH]

[OF] < g-name >,
for instance:

FORM H AS THE 4TH SUBDIVISION GRAPH OF G

The operations are: DISTANCE, (PATH), POWER, SUBDIVISION, (TRAIL), (WALK). Names in parentheses correspond to operations not yet implemented when [53] was written.

PE1. Complete GRAPH by enriching its functions as planned. This task is in progress in the system NEWGRAPH, currently developed. □

Determining invariants is broken down in four categories:

(a) Invariants of the graph
(b) Invariants of point of the graph
(c) Invariants of a given size
(d) Invariants of two points of the graph

Commands for invariants of a graph have two forms:

(i) determining the number of objects in the graph, which can be (AUTOMORPHISMS), BLOCKS, BRIDGES, CENTRAL POINTS, (CIRCUITS), CLIQUES, (COCLIQUES), COMPONENTS, CUTPOINTS, (INDEPENDENT LINES), LINES, LOOPS, MAXDEGREE, MINDEGREE, (ORBITS), PENDANT LINES, (PENTAGONS), POINTS, QUADRANGLES, TRIANGLES;

(ii) computing the value of an invariant such as (CHROMATIC CLASS), (CHROMATIC INDEX), CHROMATIC NUMBER, CIRCONFERENCE, (CLIQUE NUMBER), (COARSENESS), (COMPLEXITY), (CROSSING NUMBER), CYCLOMATIC NUMBER, (DETERMINANT), DIAMETER, (EXTERIOR STABILITY), (GENUS), GIRTH, (INTERIOR STABILITY), (LINE CONNECTIVITY), (PERMANENT), (POINT CONNECTIVITY), RADIUS, RANK, (THICKNESS).

For instance:

DETERMINE THE NUMBER OF TRIANGLES OF G,
DETERMINE DH THE DIAMETER OF H.

A point invariant such as DEGREE, ECCENTRICITY, etc would be found by making a command such as

DETERMINE DEGREE OF 7 OF G

where 7 is the label of a point. Commands for invariants involving two points or real invariants of a graph are similar. Possible objects are (CIRCUITS CONTAINING), COMMON NEIGHBOURS, (DISJOINT PATHS), DISTANCE, LINE LABEL, LINES INCIDENT, (PATHS), (TRAILS), (WALKS) in the former case and (ADMITTANCE SPECTRUM), (ANGLES), BOND ORDERS, CHARGES, DISTANCE, INDEX, (DISTANCE SPECTRUM), EIGENVALUES, EIGENVECTORS, ENERGY, (MAIN ANGLES), (R-SPECTRUM), SEIDEL SPECTRUM in the latter.

The GRAPH system can check many properties of graphs such as ACYCLIC, BIPARTITE, BLOCK, (BLOCK CUTPOINT GRAPH), (BLOCK GRAPH), CIRCUIT, (CLIQUE GRAPH),

COMPLETE, CONNECTED, (CUTPOINT GRAPH), EULERIAN, FOREST, HAMILTONIAN, HYPOHAMILTONIAN, (INTERVAL GRAPH), LINE GRAPH, LOOPLESS, (MOORE GRAPH), (OUTERPLANER), (PERFECT), PLANAR, (PRIME), (SELFCOMPLEMENTARY), (SELFDUAL), SEMI REGULAR, (SEMITOTAL LINE GRAPH), (SEMITOTAL POINT GRAPH), STRONGLY REGULAR, (SUBDIVISION GRAPH), (TOTAL GRAPH), TOTALY DISCONNECTED, (TRAVERSIBLE), TREE, TRIANGLE FREE, TRIVIAL, UNICYCLIC, WHEEL, WITHOUT MULTIPLE LINES.

Commands are for instance

CHECK WHETHER $G1$ IS PLANAR,
CHECK WHETHER $G2$ IS A TREE.

or, for properties of a point of a graph:

CHECK WHETHER THE POINT 5 IS ISOLATED IN G,

or of two graphs

CHECK WHETHER $G1$ AND $G2$ ARE ISOMORPHIC.

Clearly the system GRAPH can answer a large number of questions regarding particular graphs. It can also check for graphs with some property among several lists of graphs, e.g. connected graphs up to 6 points, regular graphs up to 7 points, trees up to 10 points, cubic graphs op to 12 points, etc.

Results of GRAPH consist, as mentioned above, of computer-assisted conjectures, refutations and proofs. Most of the published results are theorems, and while mention of system GRAPH is made, details on how it led interactively to conjectures, refutations or proofs are unfortunately not given except in [59] (automated theorem-proving is discussed in more detail [62] [56]).

We list a couple of results obtained with GRAPH, see [64] for a more comprehensive set. Let G be a graph, v a distinguished vertex, and $N_1(v)$, $N_2(v)$ a partition of the neighbours of v. If G' is obtained from $G - v$ by adding vertices v_1, v_2 and edges $\{v_1, w\}$ with $w \in N_1(v)$ and $\{v_1, w\}$ with $w \in N_2(v)$, G' is obtained by *splitting* vertex v.

The following result was conjectured with the system GRAPH and proved in [153]: *If G is a connected graph and G' is obtained from G by splitting a vertex then $\lambda_1(G') < \lambda_1(G)$* (where $\lambda_1(G)$ is the *index* of G or largest eigenvalue of its adjacency matrix).

Denote by $\rho(k)$ the largest eigenvalue of the graph obtained from the cycle C_n with $n \geq 6$ by adding an edge between two vertices at distance $k = 2, 3, \ldots, \lfloor n/2 \rfloor$. On the basis of experiments conducted with GRAPH it was conjectured that $\rho(k)$ is monotonous and decreases. This was proved in [148] [154].

2.3 THEOR

The THEOR component of GRAPH is designed for computer-assisted or automated theorem-proving in graph theory, and is described in Cvetković and Pevac [62]. We only discuss it briefly as this paper's topic is not automated theorem proving. Graph theory

is formalized using a special first-order predicate calculus, called "arithmetic graph theory" (AGT). It contains point variables, line variables, integer variables, graph names, constraints, function names, operations over graphs and predicates.

The effectiveness of the prover depends largely on a set of lemmas which represent beginner's knowledge of graph theory. The user may select more advanced lemmas.

A resolution-based prover is a subsystem of a natural deduction interactive theorem prover. The interactive prover provides a proof for a given goal sentence P by splitting it into subgoals, which are further split, thus generating a proof tree memorized by the system. This tree is a rooted one, and the user can move the current root, i.e., select the subgoal next considered. He can also inform the system about the truth of a subgoal. The resolution-based prover can be applied to any subgoal and the proof is completed when all subgoals are proved. Subgoals may be processed by case analysis, forward chaining, *reductio ad absurdum*, simplification or extension of the formula, expressing it in an equivalent form, etc.

A completely automated proof of the simple sentence

> "If the graph is connected, then the graph is trivial or there is no point x such that x is isolated"

is obtained and has 10 lines. The sentence

> "If the graph is not connected, then the complement is connected"

is proved interactively, in 38 lines. Further examples are given in [56].

These examples show the difficulty inherent in full formalization of graph theory. Its language, close to English, is deceptively simple. The situation is much easier in logic [162], or in plane geometry where a method of reduction of problems to systems of linear and quadratic equations applies, see e.g. Chou [43]. But as the speed of equally priced computers has augmented since the time GRAPH was developed by a factor of 10^4 to 10^5 and automated theorem proving made much progress, another attempt might be worthwhile.

PE2. Test the automated theorem proving approach of THEOR with a modern computer and a prover such as OTTER [136]. □

Should this attempt be successful, it should meet a wish of Fajtlowicz [84]:

> "the problem of trivial conjectures could be solved if we had automated theorem provers capable of proving the easiest conjectures of Graffiti ..."

3 Graffiti

3.1 Structure

The Graffiti program is discussed in the series of papers "*On conjectures of Graffiti*" [81] [80] [82] [83] [84] a paper "*On conjectures and methods of Graffiti*" [87] as well as in the more recent paper "*Towards fully automated fragments of graph theory*" [85], and a couple of papers of Larson [124] [125]. De La Vina [68] presents the system Graffiti.pc and, very

recently, some recollections about early development and use of Graffiti [69]. Conjectures obtained with Graffiti and their status i.e., proved, refuted or open, are listed in [79].

There are many versions of Graffiti, not all of which appear to have been fully documented [69]. The two main ones appear to be the initial version (with a few developments) described in [80] [81] [82] [83] [87] and the DALMATIAN version described in [84] [85] [124] [125] and [68]. In this subsection we list the steps of both of them. These steps will be discussed in detail in the following subsections.

Unfortunately, no complete and precise description of all steps of the process of obtaining conjectures with Graffiti has been provided. Instead, partial and informal descriptions of the automated steps are scattered over a good half-dozen publications; information about the other steps is given similarly, but in much less detail. This makes rational discussion of the Graffiti system and its applications extremely difficult as it must be preceded by a long reconstruction process, i.e., finding what really happened, or happens, from scant and sometimes contradictory information (as e.g. when computing invariants is attributed to Graffiti in one place and to Algernon in others). The paper of De La Vina [68], written after the first version of the present paper was completed, and remarks of an anonymous referee have been very helpful in this reconstruction process.

Graffiti uses two databases; a database of graphs and a database of conjectures. The former contains graphs proposed by the authors or other researchers, which have refuted some conjectures, together with precomputed values for all invariants considered in the system. The latter contains conjectures generated by the system and not refuted or viewed as non-interesting, or possibly in the DALMATIAN version, viewed as non-informative.

Steps of the process of finding conjectures with the initial version of Graffiti appear to be the following:

Step 1. Problem statement: Find relations between a set of invariants $i_1(G), i_2(G) \ldots$ chosen by the user.

Step 2. Conjecture generation: The program generates a set of inequalities of the forms $i_1(G) \leq i_2(G)$, $i_1(G) \leq i_2(G) + i_3(G)$, or similar ones using the selected invariants and possibly small integers (mostly 1).

Step 3. Correctness Test: The program evaluates the inequalities obtained. If one graph refutes them, they are deleted.

Step 4. Heuristic Tests (see below): The program deletes the conjectures which do not pass the test.

Step 5. Counter-example: Find by hand (a) counter-example(s) to at least one of the new conjectures. If one is found, delete the corresponding conjecture.

Step 6. Update of Graph Database: If at least one counter-example has been found compute values of all invariants for the corresponding graph(s). Adds these graphs to the database of graphs and return to Step 3.

Step 7. Elimination of true conjectures: Prove by hand easy new and true conjectures and eliminate them from the database of conjectures (if they are not judged to be interesting).

Step 8. Selection of conjectures: Select, by hand, among the remaining conjectures those considered to be worthy of publication. Make them known, e.g. by including them in the "Written on the wall" file.

Fajtlowicz ([80] p.189) comments as follows on this process, and its interactive character:

"Graffiti makes conjectures by first verifying that it does not know a counter-example to a formula and then by deciding whether the formula makes an interesting conjecture. The first function of the program is highly interactive because a user is expected to find counterexamples to false conjectures and then describe them to the program."

Steps of the process of finding conjectures with the DALMATIAN version of Graffiti appear to be the following:

Step 1. Problem statement: Find lower (or upper) bounds for a user-selected invariant.

Step 2. Conjecture Generation: The program generates an inequality and evaluates the values of both sides of all graphs in the database.

Step 3. DALMATIAN test for informativeness (see below): The program deletes the conjecture if it does not pass the test.

Step 4. Correctness test: The program deletes the conjecture if the inequality does not hold for at least one graph in the database.

Step 5. Other heuristic tests (see below): The program deletes the conjecture if it does not pass one of these tests.

Step 6. Database updating: The program shelves conjectures viewed as less informative due to the addition of the new conjecture.

Step 7. Test for ending conjecture generation: If for each graph in the database of graphs, there is a conjecture for the selected invariant and direction of inequality in the database of conjectures which is sharp (i.e., satisfied as an equality), proceed to the next step. Otherwise, return to Step 2.

Step 8. Counter-example: Find, by hand, a counter-example to one at least of the inequalities generated.

Step 9. Updating database of graphs: If a counter-example has been found, compute with an auxiliary program (Called Algernon) the values of all invariants for this graph, introduce it, together with those values in the database of graphs and return to Step 2.

Step 10. Elimination of true conjectures: Prove by hand easy new and true conjectures and eliminate them from the database of conjectures.

Step 11. Selection of conjectures: Select by hand among the remaining conjectures, those considered to be worthy of publication. Make them known, e.g., by including them in the "Written on the Wall" file.

Note that the correctness test now follows the first interestingness test; the reason appears to be that the DALMATIAN test is quicker than the other one on average.

Observe that as the new conjectures have the same left-hand side invariant and direction of inequality they may be viewed as a system. Note that the procedure described does not necessarily converge (a simple example is given below). It may thus have to be stopped manually, after some time.

At this point, a divergence of opinion between the authors of the Graffiti system and the present author should be clearly stated. Fajtlowicz focuses on what is automated and wishes to limit Graffiti to Steps 1 to 7 above. When they are finished, which constitutes a *round*, the user takes over, does whatever he wishes (eventually with the help of Algernon) and may proceed or not to a further round. So the non-automated part of the conjecture generation process is viewed to be in some sense, outside of Graffiti, while the final conjectures are still attributed to Graffiti alone, as shown by referring to them as "conjectures of Graffiti" or "conjectures obtained by Graffiti".

This author could only accept this view if what is not automated did not substantially affect the final result, i.e., the list of conjectures to be publicized. That steps 8 to 11 play an important role will be documented in the following subsections. Note also that isolating automated parts from the other ones, and giving them a name, then considering the remaining parts to be outside of the process, can lead to a claim that the resulting process is (fully) automated, for any interactive process. The present author cannot agree with such an argument and therefore views Graffiti as a computer-assisted system and not a (fully) automated one. The reader is left to judge.

3.2 Problem statement and generation of *a priori* conjectures.

In the initial version, the problem statement consists in specifying the invariants to be studied (e.g., a set of 20 from the rich library of Graffiti) as well as, possibly, operators such as sum, maximum, minimum, complement etc acting on them, and the desired form of the relations derived. The program then generates systematically such relations.

Forms of conjectures are simple ones, such as $i_1 \leq i_2$ or $i_1 \leq i_2 + i_3$ or sometimes $i_1 + i_2 \leq i_3 + i_4$. Later, ratios were introduced and finally a real algebra on the invariants.

In the DALMATIAN version, the problem statement step has the following form: Find lower (or upper, instead) bounds for a (user selected) invariant. The system then generates a term, as right-hand side of the inequality. This term is obtained by selecting invariants and performing unary or binary operations on them. Examples of such operations are the reciprocal, the natural logarithm, ceiling, addition and multiplication [68].

Details on how this is done, i.e., how many invariants and operations are chosen, within which set, according to which rules and whether or not there is any further user intervention before the session or at the moment the user states his query, are not given. As a consequence, results of Graffiti cannot be reproduced by other researchers.

As the conjecture-generation step conditions the results obtained, it should be analyzed carefully.

First, one may note that the system does not *at this stage*, use any knowledge of graph theory at all, so one should speak of *guesses* rather than *conjectures* (that the subsequent process, which uses graph theoretic algorithms as well as heuristics transforms or not these guesses into conjectures by its selection process will be the crucial point).

In view of this lack of knowledge, one may expect that initially

(i) many conjectures will be false;

(ii) many conjectures will be true but trivial;

(iii) if a very large number of conjectures are generated some of them may be interesting.

Reading all papers written on Graffiti and its conjectures suggests that all three propositions, including the redeeming third one, are true. Fajtlowicz comments as follows on trivial conjectures ([81], p.113) obtained with the initial version of Graffiti. "The number of conjectures, particularly those which are completely trivial, is the main problem and more than half of the program consists of various heuristics whose purpose is detection of trivial and otherwise non-interesting but true conjectures". As documented below in the subsection on selection of conjectures, a substantial number of the selected ones remains false with the initial version and also, to a lesser extent, with the DALMATIAN one.

Second, generation of some important formulae may be, in practice, out of reach of Graffiti, even if the necessary invariants and operations are available, because their algebraic expression is too complex. To illustrate, consider again the bound (2.3) on the stability number $\alpha(G)$. It implies only 2 invariants, m and n, but 12 product, division, sum, subtraction or upper bound operation. The probability that the right invariants and operations, as well as their order can be found *a priori* must be extremely small.

Consequently, Graffiti is not a good tool for obtaining strongest conjectures, i.e., graph theoretical bounds which are best possible in the strong sense, that is, as formula (2.3), tight for all m and n. That other systems, together with a few algebraic manipulations, can do so is illustrated in [107] for the case of an upper bound on the irregularity of a graph.

A related problem arises if the formulae have numerical coefficients; Graffiti introduces a few, usually small, integers. However, if the coefficients are real ones, the number of possible formulae is infinite even in the linear case. How could Graffiti guess *a priori* the right values in such a case?

Third, observe that no computer is needed to generate systematically relations between graph invariants: the (tedious) task of writing down $i_1 \leq i_2, i_1 \geq i_2, i_1 \leq i_3$ and so on can be done by hand without any difficulty; enumerating relations with more complicated forms as done in the DALMATIAN version is only slightly more complicated. Programming this task is also easy.

Fourth, while some *a priori* conjectures are simple and appealing, more complicated ones might not be attractive. To illustrate, the formulae

$$\bar{l}(G) \leq \alpha(G) \qquad \text{(Graffiti 2)}$$

where $\bar{l}(G)$ denotes the average distance between distinct vertices of G and

$$r(G) \leq \alpha(G) \qquad \text{(Graffiti 0)}$$

where $r(G)$ denotes the radius of G, or minimum over all vertices of the largest distance to another vertex, have attracted mathematicians and led to several papers; contrarywise, most mathematicians might consider that the conjecture

"The minimum of derivative of eigenvalues of the gravity matrix is $\leq n$/average distance" (Graffiti 150)

is too complicated and specialized.

Fifth, *a priori* conjectures of Graffiti may not have the simplest form they may take. To illustrate the *temperature* t_j of a vertex j is defined by Fajtlowicz as

$$t_j = \frac{d_j}{n - d_j}$$

where d_j is the *degree* of j. The conjecture

$$\bar{l}(G) \leq 1 + \max_j t_j(\bar{G}) \qquad \text{(Graffiti 834)}$$

where $\bar{G}$ is the complementary graph of G, can be reformulated into

$$(1 + \delta(G))\bar{l}(G) \leq n$$

which is simpler, more intuitive, and was refuted [37].

PE3. Add to Graffiti a translation routine which would automatically simplify conjectures. □

3.3 Dalmatian and other heuristics

We now describe and discuss the various heuristics designed to select *interesting* conjectures among those listed *a priori*. The DALMATIAN one [84] is the most recent and apparently also the most powerful. It is based on the notion of *information content* (or informativeness). Basically, a conjecture on an invariant is considered as interesting if and only if it provides some new information for at least one graph in the system's database, i.e. it provides for that graph a strictly better bound than all previous relations. Otherwise, the conjecture is deleted. If it is added to the database of conjectures it may happen that some other conjectures are no more informative and are *shelved*, i.e., kept separately of the database of conjectures (or tagged); if later on some conjecture(s) giving a better or equal bound on i_1 is (are) refuted they can be *unshelved*, or considered as interesting conjecture once again.

Several comments are in order. First, the definition of interestingness on which the dalmatian heuristic is based is *local*, as it depends on the database of conjectures and the database of graphs of Graffiti, and *unstable*, as these databases evolve over time. This implies this definition is not *universal*, i.e., contrary to other mathematical definitions, it cannot be used by all researchers in all places with consistent answers as to whether a conjecture is or not interesting.

Second, the definition may be too *lax*, if the database of conjectures is small or the database of graphs is large (but this would be only temporary as new conjectures are introduced and initial ones shelved), or too *severe* if the database of conjectures is large. Indeed, the situation in which the values of a large set of invariants and many relations on the invariant i_1 under study are known is atypical in graph theory research. Much more often, graph theorists study one invariant as a function of two or three others, ignoring temporarily the other ones.

Four other heuristics were used in early versions of Graffiti. The IRIN heuristic "deletes conjectures which follow from others by transitivity" [81]. The CNCL heuristic deletes conjectures "...in which one invariant on the left is always smaller than an invariant on the right" [81]. The ECHO heuristic [80] applies to conjectures defined for restricted classes of graphs: "its main idea is that a conjecture about a class of objects A is considered noninteresting if it can be generalized to a larger class B ..., the background of A". This heuristic appears still to be used in recent versions of Graffiti. The BEAGLE heuristic is based upon the idea that conjectures involving concepts of a different type are more likely to be interesting [82].

The idea of difference in concept types is related to a representation of concepts as a rooted tree: a graph G is associated with the root and various numerical invariants to its vertices. A concept is a *descendant* of another one if it is computed in terms of that one. The distance between vertices in the tree can be viewed as a distance between the corresponding concepts.

The BEAGLE heuristic removes conjectures involving concepts that are too close; it appears that the DALMATIAN also removes most but not all of them. Larson ([124] p.12) comments on this as follows:

"The BEAGLE heuristic of Graffiti was central to early versions of the program [82]. The function was largely superseded with the introduction of the DALMATIAN heuristic."

Note that the BEAGLE heuristic, as the DALMATIAN one, is defined in terms of the Graffiti system. One may wonder if distance between concepts in graph theory could be defined in a more general mathematical way. This seems to be the case, as lattices of graph theoretic concepts are considered by the Graph Theorist system of Epstein [74] [75] [76] as well as by the Hardy-Ramanujan system of Colton [50] (which is more often applied, however to algebra or number theory than to graph problems). A concept of distance follows. It seems worthy of further study to see to what extent this framework, or more general ones, apply:

RP4. Apply the theory as *formal concept analysis* [93] to graph theory definitions and see if a concept of distance between concepts can be derived. In particular, study to what extent concepts in graph theory can be represented by a lattice (or several). Deduce new concepts from this(these) lattice(s). □

Note that Graffiti is not designed for finding new concepts (except in the trivial sense that any inequality can be viewed as defining a new concept); it is claimed however in one place ([84]) that

> "*the current version can define its own properties.* One of the properties discovered by Graffiti is the class of all graphs in which the smallest eigenvalue has multiplicity 1. Graffiti defined this concept because it knew many examples of such graphs".

However, as no routine for concept discovery is described in the papers on Graffiti, this appears to be more an observation of the user than a discovery of the system.

PE4. Add to Graffiti a data mining routine to find frequent patterns in its database of graphs, as well as a routine and a database to check if they correspond or not to known concepts. □

Considering results of the heuristics, one may note that

(i) some of the conjectures of Graffiti which passed the tests are simple and attracted much attention of graph theorists;

(ii) the simplest ones are of the form $i_1 \leq i_2$, and the best known is probably conjecture Graffiti 2: *For any graph* G

$$\bar{l}(G) \leq \alpha(G),$$

(where $\bar{l}$ denotes average distance and α the independence number) proved by Chung [49].

It is surprising, as it connects very different concepts, on the one hand average distance, based on paths and on the other hand independence, based on non-adjacency. Perhaps this is the reason why it was not suggested by anyone before.

Other conjectures of the same form involve concepts which had been little studied, or not studied at all, by mathematicians at the time they were introduced into Graffiti; this is the case for the Randić index [144] defined for any graph $G = (V, E)$ by

$$Ra(G) = \sum_{i,j/v_i,v_j \in E} \frac{1}{\sqrt{d_i d_j}}$$

where d_j is the degree of vertex v_j. This concept appears in the following conjecture: *For any connected graph* G

$$\bar{l}(G) \leq Ra(G), \qquad \text{(Graffiti 3)}$$

which is still open (conjectures involving the Randić index tend to be hard to prove as the value of this invariant may increase or decrease upon addition of an edge to the graph considered).

Yet other conjectures use concepts invented by Fajtlowicz. The Havel-Hakimi operation on the set of degrees of vertices of a graph, ranked in order of non-increasing values, consist in deleting the first degree d_1 and reducing by 1 the next d_1 degrees. Havel [116] and Hakimi [103] independently proved that a degree sequence is *graphical*, i.e., corresponds to a graph, if and only if the degree sequence obtained by the above operation does. Iterating this operation finally leads to a series of zeros; their number is the *residue* $Re(G)$ Fajtlowicz considered it as an invariant and obtained with Graffiti the conjecture: *For any graph* G,

$$Re(G) \leq \alpha(G), \qquad \text{(Graffiti 69)}$$

which was proved by Favaron, Mahéo and Saclé [88]. Several further papers [66] [90] [96] followed.

The question of whether or not the concepts involved in a conjecture bear upon its interestingness has not been much studied. Fajtlowicz notes that finding new concepts is

not difficult at all, contrary to the case of conjectures. Indeed concepts are not true or false, but simple or not, convenient or not and, more importantly, able or not to unify previous results. Finding new ones by computer is as easy as making guesses, but finding interesting ones may be another matter. Fajtlowicz argues that any sufficiently simple concept is interesting. While this may be true for most concepts which Fajtlowicz invented, as he found several nice ones (see Written on the Wall, *passim*), and attracted attention of mathematicians to them, it is hard to agree with his argument in general. Indeed, graph theory suffers from a plethora of concepts, the number of which suggests several questions.

First, to illustrate, one might argue that average distance is a simpler, or more central, concept than residue, and that the independence number is simpler and more central than both. Indeed, independence depends only on the basic concept of adjacency, average distance on the central concept of paths and their length while Residue depends on a particular algorithm. Of course, both average distance and residue give lower bounds on the independence number, and could be used in a branch-and-bound algorithm to determine its value. This may not be their main attraction, particularly for average distance which gives a usually loose bound.

Then considering general questions, we may propose:

RP5. Define the *simplicity* of a concept by the *minimal* number of operations to be applied to a graph G to compute it (operations not being considered here as elementary operations as in complexity theory but in more abstract terms as "checking adjacency for all pairs of vertices" or "computing all shortest distances between pairs of vertices"). This research would continue that of Graffiti on distance between concepts. □

RP6. Do the same as RP5 but using the concept of *Information (or Kolmogorov) Complexity*[127], i.e. the minimum length of a program to compute the invariant considered.

RP7. Evaluate empirically the importance of concepts in graph theory by a statistical analysis of their use in the literature. □

The next research proposal is inspired by the analysis of research networks as done in scientometrics [141] [126].

RP8. Construct a network of graph-theoretical concepts by associating them to the the vertices of a complete graph, and weighting edges by the number of times concepts corresponding to their end vertices are used in the same paper of some chosen corpus. Then analyze this network with standard tools of scientometrics to find central concepts, cliques of concepts used jointly, distance between concepts and other information. □

3.4 Refutation

Conjectures which passed the heuristic tests (or some of them) are tested on the database of graphs for correctness. If they do not hold for one of these graphs they are deleted.

Several remarks on the selection of graphs, heuristic or exact algorithms and graph representation are in order, as these questions bear upon the efficiency of the refutation process.

First, checking conjectures on the few hundred graphs of the database is not a severe test. Indeed, the classes of graphs under consideration are usually infinite.

Other systems are more powerful and/or more original in this respect: GRAPH uses interactive modifications, which constitute an informal descent method and can also get out of local optima; AGX applies the efficient and versatile Variable Neighborhood Search metaheuristic (see below); *Geng* and other enumeration programs list systematically much larger sets of graphs; INGRID combines relations between graph invariants, assuming the conjecture to be true, i.e., a *temporary theorem*, in order to derive a contradiction.

Some hybrids of Graffiti and enumeration programs have been sporadically explored: Fajtlowicz mentions using the CaGe program of Brinkmann [29] to generate fullerenes and De La Vina [68] applies Makeg of Mc Kay to obtain all trees satisfying given constraints and uses them in Graffiti.pc. She proposes as criterion of interestingness the *touch number* or number of graphs for which the conjecture is sharp (a criterion already used informally in [31] where it seems to have been mentioned in print, without the name, for the first time). In a recent paper, De La Vina [69] claims it was used in Graffiti since the early 90's, but for some reason it was not mentioned in the previous papers on that system, and notes that with a large database, conjectures with an important touch number tend to be true. Such a development appears to be promising.

Second, graphs in the Graffiti database are often those which refuted some conjecture and were proposed by various researchers. A set of 195 of them is described in the "*Graphs of Graffiti*" file [156]. The implicit assumption behind their selection appears to be that graphs which have refuted some conjecture may be more useful than randomly generated ones to refute others. This appears to be worthy of further study.

RP9. Study statistically which graphs are the most efficient for refuting conjectures of a given corpus, representative of the various types of algebraic ones. Examine also which conjectures are hardest to refute. □

Third, Graffiti (or Algernon) uses heuristics to compute the value of invariants such as the independence number, which are NP-complete to determine. This introduces an unnecessary error for small graphs; moreover up-to-date heuristics and metaheuristics could be used for evaluating such invariants, instead of simple heuristics such as MAXINE ([83]) for the independence number which are adequate for small graphs but not competitive for larger ones (see e.g. [14] [112] for state-of-the-art heuristics for the clique or independence number).

PE5. Replace heuristics for NP-hard invariants in Graffiti by exact algorithms, coupled with the best available heuristics for the same problems, to be used on large instances. □

In addition to automated refutation the process of finding conjectures with Graffiti uses further counter-examples obtained by hand by the user. In the DALMATIAN version, after introducing the corresponding graph(s) into the system a conjecture is generated again.

Here, knowledge and work of the user is incorporated and may strongly influence the quality of the conjectures obtained. Indeed, it is well known that when discovering and proving a theorem one often goes through a sequence of conjectures and refutations getting

progressively closer to the correct statement. So this procedure is certainly reasonable and appears to be efficient; however, it is not automated. Probably, as discussed above, in the present state of graph theoretical theorem proving, it could not be. However, what is examined here is the impact of the counter-example obtained by hand on the new, further conjectures obtained. This is essential to evaluate how far the process of finding conjectures with Graffiti is automated.

To illustrate, consider Graffiti conjecture 117. Initially, this conjecture was stated as follows: *For any connected graph*

$$\bar{l}(G) \leq \sum_{j=1}^{n} \frac{1}{d_j}$$

It was disproved by Erdös, Pach and Spencer [77]. Fajtlowicz then proposed the weaker version:

For any connected graph G with girth $g(G) \geq 5$, average distance is not more than inverse degree (where inverse degree is shorthand for the sum of inverses of degrees of all vertices) and surmised that given the known counter-examples, Graffiti would come up with that version. Granting the hypothetical, it remains that a non-trivial result by famous graph theorists was needed to transform an initial conjecture which turned out to be false into an interesting and still open one.

Another example is Graffiti's conjectures 67 and 119; they involve the new invariant $f(G)$ defined as the *maximum frequency of occurrence of a degree in G* (or mode of the degree sequence). For conjecture 67, i.e.,

For any graph G without K_3 (i.e., *with* $g(G) \geq 4$)

$$\chi(G) \leq f(G)$$

counter-examples were found by Staton and later by Erdös and Staton [78]; knowing some counter-examples, conjecture 119 was obtained:

For any graph G without K_3 or K_4, (i.e., *with* $g(G) \geq 5$) $\chi(G) \leq f(G)$.

So, once again, a counter-example obtained by hand was needed to transform a false conjecture into an interesting open one. Recently, Caro [39] proved that this last conjecture is true for all sufficiently large graphs.

The fact that this step is not automated does not appear to be discussed in the parts of papers on Graffiti which concern automation. One may wonder how often one had recourse to counter-examples obtained by hand before reaching the conjectures publicized in "Written on the Wall". Very recently some information on that point has been provided in [80], it is stated that

"... in the 1980's once the conjectures were output, then as described by Fajtlowicz in [81] he would categorize the program's conjectures as *false*, *proven* and *open*. Counter-examples to conjectures were reported to the program, the program was re-executed and again the conjectures would be categorized. As further described in [80] after a few rounds of this process, as is the academic custom, Fajtlowicz announced the open conjectures".

3.5 Proofs

Many conjectures of Graffiti are true but trivial. Some of them are deleted as they are not informative according to the criterion of the DALMATIAN heuristic. This selection process could be made much more efficient by considering true relations (theorems) as well as conjectures.

PE6. Add to Graffiti a database of theorems containing both classical ones and others, proved with possible help of that or other systems. Then apply the DALMATIAN heuristic with a joint database of conjectures and theorems. □

True conjectures which pass the DALMATIAN heuristic test are studied by the user, and discarded if they appear to be trivial (which is not synonymous with, but implies the conclusion that they are trivial to prove). No operational system for theorem-proving in graph theory being available, this is done by hand.

Note that if a database of theorems is available it can also be used, as in INGRID [28], to find if a conjecture is implied by one or several theorems from that database and which. Then, if the resulting system is not too complicated, a proof might be obtained automatically by a system for algebraic manipulations such as Mathematica [161] or Matlab [130].

Presently, that one conjecture obtained with Graffiti (or a theorem if it has been proved) follows from another is only discovered with a web database or by a chance remark from one or another graph theorist.

To illustrate, the conjecture Graffiti 1 is: *For any graph G,*

$$\chi \leq 1 + rank(A(G))$$

where $A(G)$ is the adjacency matrix of G. Jaeger told Fajtlowicz ([79], p5) that Van Nuffelen [160] had proposed earlier the stronger conjecture

For any graph G,

$$\chi \leq rank(A(G)).$$

Both conjectures were refuted by Alon and Seymour [4].

This example shows the interest of a database of graph theory formulae, as discussed in Section 2.

3.6 Selection of conjectures

Until the version of Graffiti comprising the DALMATIAN heuristic, conjectures which passed the tests of the heuristics and could neither be refuted nor proved were further selected by the user. This new heuristic raised big hopes ([84], p 370):

> "There are strong indications that the new version of Graffiti can be used so that it will make very few trivial conjectures ... If these early indications, based on test runs, are right, it would mean that the program can be fully automated and can make conjectures without any help of humans. By contrast, as I was always clearly stating this, conjectures of previous versions of Graffiti had to be approved by myself, before they were included in "Written on the Wall"."

However, it seems that proofs of easy true conjectures are still done by hand, perhaps some non-automated selection of conjectures still takes place and counter-examples obtained by hand are added to the database within the conjecture-making process. Automation of Graffiti is further discussed when considering the "Little Red Riding Hood" version of Graffiti in Subsection 3.8 below.

A few studies allow evaluation of the proportion of conjectures of "Written on the Wall" which are false. The two first of them correspond to the initial version. Favaron, Mahéo and Saclé [88] studied extensively eigenvalue properties of graphs conjectured with Graffiti. They proved 3 of them in their original form, 9 others as corrolaries of stronger results and disproved 49 of them. Brewster, Dineen and Faber [24] program a series of invariants and tested about 200 conjectures of Graffiti using a database of all graphs with up to 10 vertices. They refuted 49 of these conjectures (some with such simple graphs as a single edge and proved one).

As the DALMATIAN heuristic is more selective than previous ones, one may wonder if conjectures obtained with the DALMATIAN version of Graffiti are more often true than before. They are numbered from 700 upwards in "Written on the Wall". Pujol [142] studied 12 conjectures, in that range pertaining to cubic graphs. For that purpose he used the AutoGraphiX system (see Section 4 below) in interactive mode together with a program for cubic graph enumeration, due to Brinkmann [29]. 5 out of the 12 conjectures could be refuted. For the other ones, it was shown that a minimal counter-example would have at least 18 vertices. While this is a small sample, it nevertheless indicates that the proportion of false conjectures obtained with the DALMATIAN version of Graffiti, and after elimination of false or trivially true conjectures by both automated and non-automated methods may still be large.

3.7 Minuteman and Discriminant Analysis

The Minuteman version of Graffiti [86] is designed to solve problems of discriminant analysis, i.e., separating entities from given sets by values of a function, which corresponds geometrically to a surface, often a hyperplane. A motivating application was to discover stability sorting patterns of fullerenes. An additional routine works as follows ([85] p.21):

> "To study conjectures, objects are sorted by the difference between both sides of the inequality and sometimes when this is done for fullerene conjectures they show a conspicuous pattern by displaying the known stable examples on the top of the list and those with the largest sum of eigenvalues (i.e., presumed candidates for the least stable) at the bottom".

We do not discuss the chemical relevance of the patterns and conjectures so found here. Regarding the routine, note that checking if there is a pattern in the one-dimensional data obtained for a conjecture is done visually. It could of course easily be automated and simple statistical tests applied.

Now, if computer-assisted or automated systems for conjecture-making in graph theory are still rare, the situation is completely different in discriminant analysis. Indeed, this is a well established field, beginning in statistics at least 65 years ago [91] and presently central to data mining. Automated methods to find separating planes or surfaces in low or high dimensional spaces are operational for various criteria. Let us just mention that if perfect separation by a plane is possible this can be done by linear programming [129] and that otherwise one can use *decision trees* [143] [23], *support vector machines* [46], *logical analysis of data* (LAD, [19]) or other methods.

So while Minuteman is far from the state of the art in discriminant analysis, it suggests the interest of using more powerful discrimination methods in graph theory. In a similar vein, Colton [52] recently stressed that mathematics could be viewed as a new field for data mining. Some techniques using Boolean variables appear particularly well-suited to the case of graph problems, e.g. LAD and decision trees.

RP10. Apply decision trees and LAD to discriminant problems in graph theory. Such problems may be mathematical ones (e.g. belonging or not to a particular class of graphs) or applications based on measurements relative to the problem under study (as in the fullerene example discussed above). Compare results with those of other conjecture-making systems. □

RP11. Study criteria for approximate separation in graph theory using various discriminant analysis methods, both for mathematical problems and for applications. Examine when and how an approximate separation (e.g. a linear one) can lead to an exact one (e.g. by restricting the class of graphs considered or barring exceptional cases). □

3.8 Pedagogical versions of Graffiti

Computer systems have long been used with success in teaching graph theory. This was already the case of GRAPH [59], Chinn [41] reports on her use of INGRID for that purpose and the "CABRI-graphes" system [38] developed in Grenoble led to the widely distributed "CABRI-géomètre" package.

Recently, versions of Graffiti devoted to teaching graph theory with an active pedagogy were developed. They met with equal success when used in special project classes. Pepper [137] gives an enthusiastic record of his discovery and use of Graffiti, and Chervenka [40] describes more briefly how she used De La Vina's Graffiti.pc [68].

The main difference with previous versions of Graffiti is in use: initially the database of graphs is empty. When a first graph is entered, conjectures are formulated and the corresponding invariants studied. These conjectures are often easy to prove or refute. For that reason, more work is asked from the students than merely to provide a counter-example: they are requested

(i) if the conjecture is refuted, to find a smallest counter-example in terms of number of vertices and, as a secondary criterion, of number of edges;

(ii) if the conjecture is true, to determine whether it is NP-hard or not to determine if a graph G satisfies the relation (assumed to be an inequality) as an equality.

While such tasks are initially easy to accomplish, their difficulty will augment with the number of graphs in the database. Graffiti does not contain routines to do them automatically or in computer-aided mode. At an early stage, this is reasonable if one wants the students to practice their refuting and proving skills. Later, they might want to have some help, which could be provided by a system such as GRAPH or AGX.

PE7. Add to the pedagogical versions of Graffiti a program for visualizing graphs on screen, modifying them online and computing automatically a series of invariants or formulae involving invariants. □

While the main advantage of such an enhancement would be to make interaction with the system easier and more effective, another one would be to show students that tedious computations may be delegated to the machine, so that they may concentrate on reasoning.

PE8. Add to the pedagogical versions of Graffiti a routine similar to AGX's function for evaluating invariants subject to constraints: then use it if the relation is false to find smallest counter-examples by parametrizing on numbers of vertices and edges and attempting to find a graph which does not satisfy the given relation. □

Such an enhancement should be made available only after students have tried to find minimum counter-examples on their own, and submitted them to the system.

PE9. With the same function, and assuming that the relation is true, find graphs which satisfy it as an equality, to help estimate how difficult it is to recognize them. □

The same comment as for PE8 holds here too.

In the "Little Red Riding Hood" version, the task of proving true conjectures is ignored. It is then claimed ([85] p. 18) that it is "an offshot aimed at fully automating the program apart from the invention of concepts".

Observe however that no additional functions have been automated since the last general version. Some tasks have been abandoned (proving true conjectures) and some others, done by hand, made harder (finding counter-examples which are smallest possible). As previously, the fact that generation of counter-examples is not automated is overlooked in the comment cited above. In fact, steps of automated generation of conjectures alternate with steps of finding smallest counter-examples, in what appears to be a typically interactive man-machine process.

3.9 Complexity and the $P = NP$ problem

Some considerations on the condition for stopping of "Red Burton" and its relation to complexity issues, i.e., the $P = NP$ problem, are given in ([85] p.24). As many researchers (e.g. Smale [158]) consider this last problem as the most important one of computer science we examine this text in detail.

A first paragraph tells us that:

> "Once in a while it may happen that all conjectures of a given round are true. The natural interpretation of this situation-called *bingo*- is that for every object (under consideration, not just those in the database of the program) there is

> a conjecture made in this round such that the left and the right sides of the inequality have the same value for this object. Unless this indeed is the case, supplying the program with a counter-example to this situation will still break the stalemate and one can proceed to the next round."

One may wonder if this interpretation is "natural"; the set of objects (graphs) under consideration may be very large, and in some cases, discussed below, infinite. Extrapolating the fact that there is a tight relation for every object in the database to this much larger set is a very risk step. But, clearly, as indicated, if this property does not hold and one can find an object for which there is no tight relation, one can proceed to the next round. Note that this task is different from those of Red Burton as described earlier in [85], in which one asks for objects which *refute* a conjecture, not for objects for which no conjecture is *tight*.

The next paragraph of the text begins as follows

> "Most of the interesting runs of the program will yield at least one false conjecture in each round. This will always happen if the leading invariant L is NP-hard and all the remaining invariants from N are polynomially computable. These versions of the program will run forever modifying some of its conjectures after each round. Some of the conjectures are cyclically and some are continuously repeated in rounds providing more and more experimental evidence for their correctness."

The second sentence does not appear to be true. No proof is given and a counter-example is easy to find: let the leading invariant L be the independence number α, the class of graphs under consideration being all non-trivial graphs, i.e., all graphs with at least one edge and the only graph in the database in the first round a star, say S_4. Then the system will give the relation $\alpha(G) \leq n - 1$ and the first round will end without a false conjecture. If another graph, say C_4, is introduced, there will be an infinite, incomplete second round, still without a false conjecture. Moreover, if as stated at the beginning of the third sentence

> "These versions of the program will run forever ...",

it does not seem they can lead to a "bingo" which implies that they stop. This contradicts the first statement of the remainder of this second paragraph, next reproduced, which gets to the main question:

> "One can still end up with a correct *bingo* but this would imply $P = NP$ in which case the more appropriate term for the situation would be "big bang". Penrose does not question that in a sense a machine's insights may be superior to human. It is not unthinkable that $P = NP$ can be proved, because machines may conjure up hundred of novel radius, average distance, residue, and δ-like bounds, constituting a valid bingo."

For the last sentence to make sense, one should write "big bang" instead of "bingo". Then, one may wonder if it is true, and if it has information content. Recall from elementary

logic that B holds because of A is equivalent to the implication $A => B$ and means that A is false or B is true. Let B denote the proposition "It is not unthinkable that $P = NP$". As long as it has not been proved that $P \neq NP$ this is a tautology, i.e., certainly true. But then the implication holds regardless of the antecedent A, i.e., one can adopt for A any statement whatsoever, true or false, instead of "machines may conjure...". So for the last sentence to have information content, one must show that a "big bang" has some *plausibility* not that it is merely *possible*. For this to be done along the proposed lines one must show it is plausible that one can:

(a) find relations given sets of graphs (various systems do this);

(b) find in each round graphs which are not tight for any of the relations involving the chosen invariant and direction in the database of conjectures. This task increases in difficulty with the size of that database. Moreover, such graphs are likely to be increasingly and finally enormously large (clearly no machine could find such graphs if they must have billions of vertices).

(c) prove that *all* relations considered in the last round are true;

(d) prove that there exists *no* graph under consideration, the set of which is necessarily *infinite* for the problem under study to bear upon $P = NP$, for which none of the relations considered in the last round are tight.

Clearly, this proof scheme is incredibly difficult to carry out. Except for step (a) the necessary steps are not even listed, nor of course discussed. As no argument is provided for a "big bang" to be plausible, the last sentence of the cited text has no information content. In other words, that "machines may conjure up hundred of novel ... bounds" provides no argument of any weight for or against $P \neq NP$.

4 AutoGraphiX (AGX)

4.1 Uses and structure

As mentioned in the introduction AGX has several aims. We focus here on computer-assisted and automated conjecture-making. Indeed, AGX can be used in both modes, and the steps involved as well as their sequence must be carefully distinguished.

When working in computer-assisted mode, AGX's follows the following ones.

Step 1. Problem formulation.

Step 2. Obtention of a set extremal or near-extremal graphs for the chosen objective subject to the stated constraints.

Step 3. Visual display of the graphs found and parametric value curves.

Step 4. Interactive improvement of graphs which do not appear to be optimal.

Step 5. Interactive derivation of structural and algebraic conjectures.

When AGX is used in automated mode, steps 3 to 5 are replaced by the following ones

Step 6. Recognition of extremal graphs belonging to known families.

Step 7. Determination of linear equations between invariants associated with all or some subset of the external graphs obtained by the numerical method.

Step 8. Determination of linear inequality relations between invariants by the geometric method.

Step 9. Determination of linear or nonlinear relations between invariants by the algebraic method.

Step 10. Results: output external graphs found, families to which they belong, parametric curves of values for the objective, and conjectures found.

Note that not all methods for finding conjectures automatically need be used in the same experiment: one of steps 7, 8 or 9 suffices; step 6 is also optional except if step 9 is used.

4.2 Problem formulation

When the aim of using AGX is conjecture-making, one leading invariant is usually selected and others (most often n and m) used as parameters. Moreover, the class of graphs considered is specified by constraints, which will be added to the objective function with large coefficients (as in Lagrangian relaxation). Such coefficients must be chosen to be sufficiently large to exclude any graph not in the class considered; if this is not possible, a large value indicating a contradiction will be obtained.

Moreover, in some cases it is necessary to add a secondary criterion or progressive series of weights in order to transform the graphs in directions which will tend to satisfy the constraints.

An example occurred at Graph Theory Day 42, where after a presentation on *Computers in Graph Theory* [104] a demonstration of AGX was made. Cowen [53] asked for graphs with a maximum number of K_4 for a given number of K_3. This last number was chosen as a parameter and the number of K_4 maximized, which led on the spot to rediscovery of a series of extremal graphs for those parameters. Running AGX for a longer time gave a series of further extremal graphs of larger size.

At another (early) demonstration of the system, Seymour [151] asked for cubic graphs of diameter 3 with a maximum number of vertices. A first try where the diameter was minimized under the constraint that all degrees be equal to 3 yielded examples with 14 and 16 vertices but not more (the constraint on the degree was imposed by penalizing the numbers of vertices of degree smaller or greater than 3 increasingly with their distance to that value). Adding as secondary criterion minimization of the average distance, and so smoothing the objective function, led to cubic graphs of diameter 3 with 18 and 20 vertices in 35 seconds and 1 minute respectively; the latter graph is optimal.

Presently AGX disposes of about 60 invariants to be used in the objective function and constraints. They are *order*, *size*, *independence number*, *chromatic number*, *chromatic index*, *minimum degree*, *maximum degree*, *average distance*, *degrees of the vertices*, *eigenvalues of the adjacency matrix* and others.

However, this is not a very large set, as compared with those of GRAPH, Graffiti, LEDA or other systems.

PE10. Add to AGX routines to compute the main graph theoretic invariants not yet included (e.g. *matching* number, *domination* number, etc) □

Graph invariants are invented every day, so if AGX is to accommodate all needs of the users, it must let them add their own routines for their favorite invariants.

PE11. Construct a version of AGX in which the user can add routines to compute new invariants. □

This enhancement is being implemented in the new version, AGX2, of AGX, which is currently being built.

At present, standard algebraic expressions can be taken in the objective function and constraints as well as some simple graph transformations such as complementation. Other operations should be made possible.

PE12. Add to AGX routines for the main graph operations, such as sum or product of graph, etc, as done in GRAPH.

4.3 Finding extremal graphs

The principle of *AGX* is to use heuristic optimization to find a family of extremal or near-extremal graphs for some objective, subject to constraints, then to exploit the corresponding information.

Heuristic optimization in *AGX* follows the Variable Neighborhood Search (VNS) metaheuristic [108], or framework for building heuristics. VNS exploits the still rather new idea of systematic change of neighborhood within the search. This is done in two ways: first in a descent routine, called Variable Neighborhood Descent (VND), which leads to a local optimum, and, second, in a systematic effort to get away from this local optimum by applying increasingly strong perturbations and descents.

Rules of VNS are as follows:

0. Select the set of neighborhood structures $N_k, k = 1, \ldots, k_{\max}$ that will be used in the search for a better local optimum, and a stopping condition. Find an initial solution (or graph) x.

Repeat until the stopping condition is met:

1. Set $k = 1$;
2. Until $k = k_{\max}$, repeat the following steps
   (a) (*shaking*) generate a point x' at random from the k^{th} neighborhood of x (i.e., $x' \in N_k(x)$):
   (b) (*descent*) Apply the Variable Neighborhood Descent routine with x' as initial solution: denote by x'' the local optimum obtained;
   (c) (*improvement or continuation*) If the solution x'' so obtained is better than the best known one x, move there ($x \leftarrow x''$) and continue the search within $N_1(x)(k = 1)$; otherwise set $k \leftarrow k + 1$.

The stopping condition may be a maximum number of iterations, a maximum CPU time or a maximum number of iterations or CPU time since the last improvement.

Rules of VND are as follows:

0. Select the set of neighborhood structures $N'_k, k = 1, 2, \ldots, k'_{max}$ that will be used in the descent. Consider an initial solution x.

Main step: Set $k = 1$ and $i = FALSE$ (*improvement indicator*).

Until $k = k'_{max}$, *repeat the following steps:*

(a) Find the best neighbor x' of x in $N'_k(x)$;

(b) If the solution x' so obtained is better than x, set $x \leftarrow x'$ and $i = TRUE$;

(c) Set $k \leftarrow k + 1$;

(d) if $k = k'_{max}$ and $i = TRUE$ set $k = 1$.

In words, VND applies a series of transformations to the current graph, keeping each time that transformation giving the best improvement. It there is no improvement within the current neighborhood, VND proceeds to the next one. If there is no further improvement when considering all neighborhoods in turn, VND stops; otherwise it begins again at the first neighborhood.

Moves corresponding to the different VND neighborhoods in AGX are the following: *rotation* of an edge, *deletion* of an edge, *addition* of an edge, *move* of an edge, i.e., deletion plus addition, *detour*, i.e., removal of an edge and addition of two edges between endpoints of the deleted one and a vertex not adjacent to either of their endpoints, *short cut*, i.e., the operation that is the reverse of detour, 2-*opt*, i.e., removal of two non adjacent edges, and addition of two different edges connecting the endpoints of the removed ones: *add pendant vertex*: i.e., add a new edge from an old vertex to a new one; *delete vertex* of bounded degree and all adjacent edges.

The neighborhoods rotation, addition, deletion and move are the most frequently used, and the least time consuming ones.

If all moves within a neighborhood are examined before choosing the last one, only graphs of moderate size may be considered, particularly if the objective function to be computed after each potential move is hard to evaluate. A speed-up can be obtained by using a "first improvement" instead of a "best improvement" rule.

The choice of moves is presently left to the user (with a standard option of using them all). However, this choice could be automated:

PE.13 Add a routine which evaluates the effect of all moves during an initial period, then selects for continuation of the search those which proved to be the most efficient. □

One could also try to find new moves systematically:

PE.14 Construct moves by all possible transformations on a small graphs (e.g. with 4 vertices). Eliminate redundant ones which are the same as others up to symmetry. □

Contrary to VND, which uses systematically a series of different local moves, VNS makes random use of more global moves, often deriving from a simple principle. The most

frequently used one is to repeat a move k times, e.g., one first moves an edge chosen at random (a move in $N_1(x)$) then 2 (a move in $N_2(x)$) and so on.

VNS appears to be quite powerful, i.e., very often, but not always, it gives extremal graphs. Cases where it does not give the best graph, which can often be recognized by comparison with graphs obtained for close values of the parameters, can be exploited to define new neighborhoods.

RP12. Systematically explore cases in which the neighborhoods of VND and VNS are not enough to find consistently extremal graphs. Define new neighborhoods accordingly and study the complexity of implementing them.

4.4 Display of results

Results of *AGX*, when used in interactive mode are of two types:

a) Extremal or near-extremal graphs;

b) Parametric curves of values of the objective function.

Extremal graphs can be visualized on screen or printed. Drawings can be modified interactively by moving vertices; classes of vertices or of edges can also be highlighted, in various colors (e.g. edges which are critical for some invariants, edges of a spanning tree or a shortest path tree, vertices of various degrees, ...)

Up to now only simple tools of graph drawing have been implemented in *AGX*, i.e., a specialized routine for representation of trees with edges parallel to the axes, a "spring" type heuristic to avoid cluttering parts of the drawing with closely spaced vertices, and a few more. As the field of graph drawing is very active (see e.g. Di Battista et *et al.* [70] [71]) further results obtained there could be exploited. Note however that the frequently adopted criterion of minimizing edge crossings does not seem adequate for AGX's needs. Easy recognition of subgraphs of one or another type (*cliques*, *cycles*, ...) seems more important.

RP13. Study precise needs of AGX for graph drawing and how they can be met by methods of that field. In particular consider ways to make structure (particular subgraphs, graphs formed from them) visible in individual graphs as well as in sequences of graphs.□

While there may be no closed-form formulae for some invariants on general graphs, there may be some for particular classes of graphs. Recognizing them can lead to conjectures, as discussed further below.

Curves of values can be represented in three dimensions, corresponding usually to some invariant i_1, n, and m. These curves can be rotated, superposed, isolated, etc... Moreover, graphs corresponding to particular points on these curves e.g. minima or maxima can be displayed in a window. Finally, if one has some idea about a conjecture it can be introduced into AGX, checked, displayed with the curves, and both the differences in ordinates and the points of contact highlighted.

These facilities should be extended to higher dimensions.

PE15. Add to *AGX* a routine for projection of points in R^p with $p > 3$ but moderate, corresponding to extremal graphs, on subspaces with 2 or 3 dimensions. □

4.5 Recognizing structure interactively

When visualizing the extremal graphs obtained with AGX, it is not uncommon to find that

(i) they belong to some well-known family, e.g. paths, circuits, trees, stars, bipartite, complete,...,

or

(ii) they have some recognizable but more complicated structure.

There may be some exceptions among them, and one should then find out whether this is due to the VNS heuristic not finding the (or an) extremal graph for the corresponding values of the parameters or to the particularities of the objective function under study.

Usually, significant differences in structure or an outlier position with respect to the curve of values make such exceptions conspicuous. One can then deduce from close examples what might be the true extremal graph for those parameter values and build it by moving edges with the mouse; then the system will compute its value and, if it is better than the previous near-extremal graph, substitute them.

This step is not mandatory, and not used when applying AGX in automated mode (outliers may be removed in other ways, see below). However, it could be automated, or at least more automated than it presently is.

PE16. Augment the number of routines for recognition of classes of graphs in AGX.□

PE17. Add a routine which will test if extremal graphs frequently belong to some parameterized family; for those parameter values for which it is not the case, compute their value and substitute them if there is an improvement. □

Note that such developments are close to those needed in the third (algebraic) way to find conjectures automatically (see below). The automated parts correspond to step 6 of AGX, which will not be discussed further.

4.6 Obtaining conjectures interactively

Conjectures most often made have the two following forms (see also [113])

(i) *Algebraic relations* between graph invariants, valid for some class of graphs (e.g. all graphs, connected, bipartite, split, stars, trees, complete...)

(ii) Description of the *structure* of extremal graphs (i.e., of a known or new class of graphs) or of a subset of them.

Conjectures of the former type can be obtained from the parametric curves of values of the objective. Consider for instance the *energy* E of a graph defined [31] [97] [98] as

$$E = \sum_{i=1}^{n} |\lambda_i|.$$

Minimizing this function with parameters n and m, then superposing the curves of $E(m)$ for fixed n shows very clearly all values to be above a parabola. Its equation is then readily found and leads to the lower bound [31]

$$E \geq 2\sqrt{m}.$$

Moreover, the equation of this curve can be entered in AGX, which represents it in the plane of values and highlights points where it is attained, i.e., graphs reaching the bound, as well as differences for other points. One can thus see if the bound is sharp and if it remains so over the range of parameter values or not. In the case discussed, when m becomes large the curve lies increasingly below observed values. Then, looking at curves for one value of n at a time suggests a linear lower bound for each, from where the inequality

$$E \geq \frac{4m}{n}$$

follows. It is sharp for fewer values than the first bound, though still sharp several times.

Conjectures of the second type are obtained by examining the graphs obtained and, possibly, exploiting conjectures on these graphs obtained automatically (see below). Sometimes, results are straightforward. For instance minimizing with AGX the energy of unicyclic graphs (a problem of interest to chemists) led to extremal graphs which were cycles for $n \leq 7$ or n =9, 10, 11, 13 and 15 and 6-cycles with an appended path for all other values of n considered. The natural conjecture that these and only these graphs were the true extremal ones [31] has recently been partially proved [99] [117].

4.7 Numerical method of conjecture-making

We now turn to the automated mode of using AGX and consider the three ways in which this has been done (up to now). A first method uses the mathematics of principal component analysis to find resemblances between objects, in the form of affine relations they all satisfy, instead of differences as usually done.

The method works as follows [35] [36]:

(a) Find extremal or near-extremal graphs for some objective with AGX;

(b) Filter this set to remove outliers (optional but often useful);

(c) Compute values for a set of invariants on all remaining graphs;

(d) Center the vectors of values for each invariant (thus transforming the problems of finding affine relations into that of finding linear ones);

(e) Compute the variance-covariance matrix V between centered vectors;

(f) Diagonalize V, with, however, some empty lines if there are relations. In the resulting matrix V', $Dim(I_m(V))$ lines contain non-zero terms and correspond to independent variables. The remaining $n - Dim(I_m(V))$ lines contain only zeros and correspond to dependent variables which may be expressed as linear combinations of the independent ones. These relations form a basis of the null-space of V. Using the initial data one can then compute the right-hand sides of the corresponding affine relations.

To illustrate, consider the irregularity $irr(G)$ of a graph G as defined by Albertson [3]: let the *imbalance* imb_{ij} of edge (v_i, v_j) of G be defined by

$$imb_{ij} = |d_i - d_j|$$

and the irregularity $irr(G)$ of (G) by

$$irr(G) = \sum_{i,j|(v_i,v_j)\in E} imb_{ij}.$$

Applying AGX [107] led automatically to the following conjectures valid for graphs G with maximum irregularity:

$$\begin{aligned} r(G) &= 1 \\ \chi(G) &= \omega(G) \\ n &= \Delta + 1 \\ \alpha(G) &= -\omega(G) + \Delta + 2, \end{aligned}$$

from where it follows that

$$\alpha(G) + \omega(G) = n + 1$$

which implies that the extremal graphs are split graphs, i.e., graphs consisting of a clique, a disjoint independent set and edges joining vertices of the clique to those of the independent set. (For further use of this information and of the external graphs found, see [107]).

Several comments are in order. First, note that the algorithm described takes polynomial time: if the number of graphs considered is fixed and t invariants are computed, it requires $O(t^3)$ time.

Second, observe that it gives relations for *subsets* of the set of invariants considered, not necessarily for the whole set. So the combinatorial problem of finding the right subset is avoided. This implies that given a sufficiently large set of graphs of some class, and sufficient computing time, one could find a basis of affine relations among a large set of invariants (maybe several hundred of them). Should such relations exist and be up to now unnoticed, it would prove that interesting relations may be found without focussing on a particular problem, or domain (such as e.g. problems of distances in graphs).

Third, the algorithm subsumes some other ones, which have met with success. For instance the BACON algorithm developed by Simon and co-workers [122], gives *rational reconstructions* (or possible reasonings) for great discoveries of the past in physics and chemistry. It uses four rules, given a set of observations involving several variables:

(a) If a variable is constant, a law has been found;

(b) If a variable is a linear function of another one, a law has been found;

(c) If a variable increases while another one decreases, add a new variable equal to their product, and iterate;

(d) If a variable increases while another one increases, add a new variable equal to their ratio and iterate.

BACON rediscovered Kepler's third law, in three iterations only, as well as several other famous ones. The numerical method of AGX reproduced these results in much less computer time [36]. These laws are expressed as monomials, i.e., products of variables with integer powers. Taking logarithms gives affine functions.

However, there are many more complicated cases: Langley *et al.* [122] have observed that laws in chemistry may take a more general form, the logic of which had, apparently, not yet been studied [155]: in addition to the variables, there are substance-specific constants, such as e.g. *specific heat*. BACON could be extended to this case.

RP14. Study how to extend the numerical method of AGX in order to apply it to problems with both variables and substance-specific constants. □

Fourth, one would clearly like to extend the discovery of conjectures to more general cases than affine relations. Note first that inequalities are obtained in a straightforward way: it suffices to check on which side lie graphs which are not extremal for the objective under study. Then one might add, as new variables, products of variables, or simple powers such as squares, cubes, inverses, square roots and the like.
All this increases the number of variables, and thus augments the number of graphs needed to obtain relations, as well as computing time, but does not change the method itself.

If e.g. only products of two variables are considered it is still possible to consider a few tens of variables. One would like to do better than this brute-force approach, and in view of results obtained by *support-vector machines*, this seems to be possible.

RP15. Study selection of product and power terms in finding nonlinear conjectures between invariants in graph theory. Devise corresponding heuristics. □

Fifth, even more general sets of relations involving *signomial functions* (polynomials in several variables with arbitrary powers and signs) have been studied by using neural networks. These have reconstructed with fairly good precision a set of such equations.

RP16. Compare conjecture-making by the numerical method of AGX and by neural networks; define hybrids where neural networks are used to find the form of the relations and AGX to find the precise values of coefficients. □

Sixth, to determine affine relations, which are equalities, numerical precision is required, and hence control of errors. Standard tools of numerical analysis are used to do so, but the guarantee of finding all affine relations is not complete. To attain such a goal one would need computations in error-free arithmetic (i.e., making computations with rational numbers using a sufficient number of digits to avoid all approximation errors), which has been used in solution of equations associated with Euler sums [12], but are very time consuming.

4.8 Geometric method of conjecture-making

Consider a set of extremal graphs for some objective; they correspond to points in the $\mathbb{R}^p$ space of invariants (or in a sub-space of selected invariants), each of which is associated with

one of the p axes. Then constructing the convex hull of these points with a gift-wrapping algorithm (as e.g. implemented in the package of Avis and Fukuda [10]) immediately yields a set of conjectures in the form of linear inequalities: for each invariant, faces passing below all points, or above all points correspond to lower and upper bounds.

To illustrate, consider chemical graphs, in which $\Delta \leq 4$ due to the valency of carbon. The geometric method of AGX could find the two following relations in a very small computing time:

$$Ra(G) \geq \frac{n}{3} + \frac{m}{12}$$

and

$$Ra(G) \geq \frac{1}{4}(m + n_1).$$

The main difficulty with this approach is to avoid undue extrapolation. In the case of a function of a single invariant say $i_1(n)$, if it is concave, just the next graph could disprove the conjecture.

Therefore the conjectures obtained are systematically tested by looking for the few extremal graph(s) following those used to find them. Also the *touch number* criterion discussed above is of interest here: if the inequality found is sharp at only a couple of points, it appears to be of little interest. Conversely, if it is sharp for many or even most values of the parameters, as is the case for the two relations just cited, it is clearly interesting.

One would then like to obtain often sharp relations even when the relationships between invariants of extremal graphs are nonlinear. Again this could be done by introducing new variables, i.e., going to a higher dimensions. There are some limitations here, as gift-wrapping algorithms may become very time consuming with only 10 variables or so.

RP17. Examine how to transform functions in order to get nonlinear relations through the geometric method. Compare results with those of the numerical approach for the same problems.

4.9 Algebraic method for conjecture-making

The principle of the third method is to recognize extremal graphs for some objective function, then to use relations between invariants valid for those classes of graphs in order to obtain new relations, which are conjectured to hold in general.

To illustrate, consider the objective function $Ra(G) - \bar{l}(G)$, (which corresponds to conjecture Graffiti 3, i.e., $\bar{l}(G) \leq Ra(G)$). Minimizing this relation systematically gave stars, for which the Randić index is equal to $\sqrt{n-1}$ (and is minimum for fixed n as shown by Bollobas and Erdös [18]) and the average distance is $2 - \frac{2}{n}$. This leads to the conjecture *For any connected graph G*

$$Ra(G) - \bar{l}(G) \geq \sqrt{n-1} + \frac{2}{n} - 2,$$

which strengthens Graffiti 3. If true, the new bound is sharp for all $n \geq 1$.

The difficulty of this method is the large amount of information needed: on the one hand, specific algorithms are required to recognize to which class belong extremal graphs, and on the other hand a database of relations between graph invariants is needed for each class considered. Presently this method is working in experimental mode.

PE18. Extend the set of graph recognition routines of AGX. □

PE19. Extend the database of relations between graph invariants. □

PE20. Couple the algebraic method with Mathematica or Matlab to simplify the relations obtained. □

Clearly it will not always be the case that extremal graphs all belong to a single well-defined class, for which relations are known. A first difficulty is then that one will have to use lower or upper bounds (e.g. if all one can find is that extremal graphs are trees), although that would not change the approach too much.

PE21. Extend the algebraic approach to manipulate bounds rather than equalities between invariants. □

Another extension would be to recognize the various classes of graphs which are extremal for some values of the parameters (a problem already evoked above) and modify again the way bounds are computed and relations obtained.

Finally, once again one should compare methods.

RP18. Compare systematically results of the three methods proposed for automated conjecture-making on the same set of problems, including some which led to well-known graph theorems. Deduce from this comparison intimations about what makes a relation difficult to find for one or all of them. □

5 Conclusions

Computer-assisted and automated conjecture-making in graph-theory appears to be very successful and has led collectively to more than 200 papers research reports and theses. This makes it probably the most active subfield of discovery science.

Three systems are operational and largely used: GRAPH, Graffiti and AGX. Their principles are different: interactive computing, generation of a priori conjectures and selection amongst them, heuristic optimization to get extremal graphs and deduction of conjectures from them. All three have large parts which are automated, but only the last can presently be used in (fully) automated mode, that is with a problem statement unaccompanied by further information, no human intervention between problem statement and reading the final results as well as no selection among results so obtained. Note that this is not the only way to use this system, nor necessarily the most efficient one, as interactive modification of the extremal graphs obtained may give insight on how to prove the conjectures it delivers.

All three systems (and others) are susceptible of fuller automation in the near future. A series of suggestions on 21 possible enhancements are given in this paper, as well as a list of 18 more general questions, or research paths, of possible interest to the whole field.

As a final point, observe that the conjectures considered in this paper are mainly algebraic inequalities (or, in some rare case, equalities) among graph invariants. As discussed more fully in [113] there are many other forms which interesting conjectures in graph theory can take. So there is plenty of room for further achievement in this young and promising field.

Abstract

Conjectures in graph theory have multiple forms and involve graph invariants, graph classes, subgraphs, minors and other concepts in premisses and/or conclusions. Various abstract criteria have been proposed in order to find interesting ones with computer-aided or automated systems for conjecture-making. Beginning with the observation that famous theorems (and others) have first been conjectures, if only in the minds of those who obtained them, we review forms that they take. We also give examples of conjectures of such forms obtained with the help of, or by, computers when it is the case. It appears that many forms are unexplored and so computer-assisted and automated conjecture-making in graph theory, despite many successes, is pretty much at its beginning.

Keywords: graph, conjecture, computer-aided system, automated system, invariant, subgraph, minor.

Résumé

Les conjectures en théorie des graphes ont des formes multiples et impliquent des invariants graphiques, des classes de graphes, des sous-graphes, des mineurs et d'autres concepts dans les prémisses et/ou conclusions. Divers critères abstraits ont été proposés afin de trouver des conjectures intéressantes avec l'assistance de l'ordinateur ou à l'aide de systèmes automatisés. A partir de l'observation que les théorèmes célèbres (et les autres) ont d'abord été des conjectures, ne fut-ce que dans l'esprit de ceux qui les ont obtenus, on passe en revue les formes qu'elles peuvent prendre. On donne également des exemples pour les formes pour lesquelles des systèmes assistés ou automatisés ont donné des résultats. Il apparait que de nombreuses formes sont inexplorées et en conséquence la recherche de conjectures assistée par ordinateur ou automatisée, malgré de nombreux succès, en est encore à ses débuts.

Mots clés: graphe, conjecture, système assisté, système automatisé, invariant, sous-graphe, mineur.

1 Introduction

"*What makes a mathematical result interesting?*" This difficult question of mathematical philosophy is seldom discussed, despite its obvious interest. Recently, needs of computer-assisted or automated systems for finding interesting new concepts, theorems or conjectures have given it some actuality, notably in graph theory. Views of several famous scientists on this topic are interspersed with discussions of graph theoretical conjectures in the large *Written on the wall* file of Fajtlowicz [50]. Colton *et al.* [32] and Larson [67], also address this question in detail.

We next mention and briefly discuss a few proposed criteria:

(a) *simplicity*: simple formulae are the most used ones, and thus the most likely to have many consequences. They also have the most potential falsifiers, as explained by Popper in his famous book "*The Logic of scientific discovery*"[76]. However, it may be hard to find many simple, new and true formulae. Moreover, some of them may be trivial, e.g., that the clique number of a graph is not larger than its chromatic number.

In a similar vein, one might suggest the two following criteria:

(b) *centrality*: conjectures should preferably involve the most central concepts of graph theory as e.g. connectedness, stability, colorability, and so forth. To illustrate, some new concepts proved to be interesting and lead to numerous results, as e.g. *pancyclicity* or having elementary cycles of all possible lengths, introduced by Bondy [10], which is close to the basic concept of cycle. This is far from being always the case for the numerous new concepts which nowadays proliferate and, to some extent, threaten the unity of graph theory.

(c) *problem solving*: instead of considering centrality in terms of concepts, one may examine it in terms of problems posed by scientists in a given field. This leads to another criterion, again stated by Popper in *"The Logic of Scientific Discovery"* [76]: "Only if it is the answer to a problem – a difficult, a fertile problem, a problem of some depth – does a truth, or a conjecture about the truth, become relevant to science. This is so in pure mathematics, and it is so in the natural sciences."

A quite different criterion is the following:

(d) *surprisingness*: Conway's answer to the question "What makes a good conjecture?" was "It should be outrageous" [50]. This means a trained mathematician finds something contrary to what suggests his well-educated intuition, and so gets a new insight. Of course, it remains to be examined whether some explanation may be found, together with new results, or the conjecture will remain an isolated curiosity.

(e) *distance between concepts* is one version of surprisingness: a conjecture will be the more interesting the farther the concepts involved are one from another. This implies an operational notion of distance, either in the conjecture-making program or possibly in a lattice of graph-theoretical concepts.

Another view comes from information theory:

(f) *information-content* relative to databases of conjectures and graphs. A conjecture is interesting if it tells more, for at least one graph than the conjunction of all other conjectures. This is the criterion of the "DALMATIAN" version of Graffiti [50], discussed in [60]. It also means the conjecture should not be redundant.

A more demanding related criterion is:

(g) *sharpness:* the conjecture should be best possible in the weak sense, i.e., sharp for some values of the parameters, or in the strong sense, i.e., sharp for all values of the parameters compatible with the existence of a graph [60].

In addition to such abstract criteria one might take a pragmatic view and say that a conjecture is interesting if it has attracted the attention of mathematicians, whoever they may be. This is fairly tautological. Note, moreover, that popularity of a result depends not only on its intrinsic merits but also on its visibility (Journal where it was published, computer systems which mention it or give access to it, as well as relations and aptitude for marketing of its author(s)).

In this paper, we follow a different approach, beginning from the observation that *well-known theorems in graph-theoretical books and papers were first conjectures, if only in the minds of those which proved them.* Instead of seeking an abstract and general criterion we more modestly try to find what forms have a number of well-known results in graph theory. On this base we reflect on what is done by available conjecture making systems, and what remains to be done.

Let us recall the definition of conjecture in Bouvier and George's [13] *Dictionary of Mathematics*:

Conjecture: *An a priori hypothesis on the exactness or falseness of a statement of which one ignores the proof.*

As a *statement* is a very general concept in mathematics, one can expect to find conjectures of many forms. We are, as mentioned above, interested here in the various forms of graph-theoretic conjectures. We therefore make a tentative, and necessarily incomplete, catalog of such forms using books by Berge [6], Biggs [7], Bondy and Murty [12], Busacker and Saaty [20], Cvetković, Doob and Sachs [34], Haynes, Hedetniemi and Slater [61] and a few others prominent among which is Chung and Graham's book *Erdös on Graphs* [30].

We also mention, with an example if possible, if a form has been explored by one or another system for computer-assisted or automated conjecture-making in graph theory. In accordance with the terminology of [60] we say a conjecture has been obtained *with* a system if this was done in computer-assisted mode and *by* a system if this was done in (fully) automated mode. Note that several systems can be used in either of those modes. Moreover, we mention some cases where systems, designed for other purposes, could be used for conjecture-making. As will be seen, many unexplored cases remain, most of which could apparently be explored by some enhanced version of one or another existing system.

2 Algebraic relations

2.1 General form

A first class of graph-theoretic conjectures consist in algebraic relations between graph invariants, i.e., quantities which are independent of vertices and edge labelings. Such relations may be valid for any graph G or for some particular class of graphs.

To date, this class of conjectures is the most studied, but far from the only one, in computer-assisted and automated conjecture-making, see [60] for a discussion.

Let R denote a relation and C a class of graphs; any graph G can be associated with a boolean variable, true (or equal to 1) if G belongs to this class and false (or equal to 0) otherwise [14] [16].

The general form of conjectures considered in this section can then be written

$$R \,|\, C \qquad (\text{or } \; C \Rightarrow R)$$

which reads:

"For any graph of class C, relation R holds".

If a relation holds for all graphs, C can be omitted.

We now review theorems and conjectures of this form, considering first R, then C, and going from the simplest to the more elaborate ones.

2.2 Linear relations and extensions

Let $G = (V, E)$ be a simple undirected graph without loops, with *order* $n = |V|$ and *size* $m = |E|$. Let $\alpha(G)$ denote the *independence number* of G, i.e., the largest number of pairwise non adjacent vertices, $\nu(G)$ the *matching number* of G, i.e., the largest number of pairwise non-incident edges, $\tau(G)$ the *vertex covering number* of G, i.e., the smallest number of vertices in a set such that each edge contains at least one of those vertices, and $\epsilon(G)$, the *edge covering number* of G, i.e., the smallest number of edges in a set such that each vertex belongs to at least one of those edges. Denote by R_1 the class of linear equalities between invariants of G.

Theorem 1 (Norman, Rabin [71], Gallai [55]) *For any graph G with matching number $\nu(G)$, edge covering number $\epsilon(G)$, vertex covering number $\tau(G)$, independence number $\alpha(G)$ and order n,*

$$\nu(G) + \epsilon(G) = n$$

and if G has no isolated vertex

$$\alpha(G) + \tau(G) = n.$$

Such equalities, valid for all graphs (or for a very large class) are rare. They are more common for particular classes of graphs. Recall that a *tree* T is a connected graph without

cycles (paths with the last vertex equal to the first one). Let $\omega(G)$ denote the *clique number* of G, i.e., the largest number of pairwise adjacent vertices and $\chi(G)$ the *chromatic number* of G, i.e., the smallest number of colors to be assigned to the vertices of G such that no pair of adjacent vertices get the same color.

Theorem 2 (Folklore) *For any tree T,*

$$m = n - 1,$$

$$\omega(T) = 2$$

and

$$\chi(T) = 2.$$

Observe that coefficients of invariants in these relations are equal to 1. This need not always be the case.

Let n_1 denote the number of *pending vertices* of G, i.e., the number of vertices each belonging to a single edge. Recall the *distance* l_{ij} between a pair of vertices v_i and v_j of a graph G is the number of edges in a shortest path joining them. The *eccentricity* ecc_i of a vertex v_i is the largest distance between that vertex and another one. A *center* of G is a vertex v_i with smallest eccentricity; this eccentricity is called the *radius* of G. The *diameter* $D(G)$ of a graph G is the maximum eccentricity of its vertices, (or the largest distance between two vertices of G). The *index* (or *spectral radius*) of G is the largest eigenvalue of its *adjacency matrix* $A = (a_{ij})$, where $a_{ij} = 1$ if v_i and v_j are adjacent and 0 otherwise.

Conjecture 1 (Caporossi, Hansen [25] [24]) *For any tree T of size m and order n with n_b black and n_w white vertices, $n = n_b + n_w$, with minimum index, independence number $\alpha(T)$, n_1 pending vertices, radius r and diameter $D(T)$,*

$$2\alpha(T) - m - n_1 + 2r(T) - D(T) = 0.$$

This conjecture, obtained by AGX, is open. It is unlikely that an equality conjecture with as many invariants could be found by hand. Note that coefficients of invariants are small integers. AGX can also obtain conjectures with real numbers (approximated to a reasonable extent, as computations are made by machine).

Let d_j, for $j = 1, 2, .., n$, denote the *degree* of vertex v_j,i.e., the number of edges incident with v_j. Recall that the *Randic index* [79] of a graph $G = (V, E)$ is defined by

$$Ra(G) = \sum_{(i,j)/\{v_i,v_j\}\in E} \frac{1}{\sqrt{d_i d_j}}$$

and the irregularity $irr(G)$ [1] of G by

$$irr(G) = \sum_{(i,j)/\{v_i,v_j\}\in E} |d_i - d_j|.$$

Conjecture 2 *For any tree T of size m with maximum degree $\Delta \leq 3$ and maximum irregularity $irr(T)$, Randic index $Ra(T)$, and n_1 pending vertices,*

$$Ra(T) = -0.027421\, irr(T) + 0.538005\, m - 0.1104848\, n_1 + 0.614014.$$

This conjecture is proved in the Appendix. Extremal trees have vertices of degree 3 and 1 alternatingly, as far as possible. Note that the system GRAPH [33] [35] could also have been used to find such extremal trees interactively, and, after characterizing them, possibly lead to the above result.

Linear inequalities form a class R_2 of relations and are more common in graph theory than linear equalities. Let $\chi'(G)$ denote the *edge-chromatic number* (or chromatic index) of G, i.e., the smallest number of colors needed to color the edges of G such that no two incident edges have the same color.

Theorem 3 (Vizing [85]) *For any graph G with maximum degree Δ and chromatic index $\chi'(G)$*

$$\Delta \leq \chi'(G) \leq \Delta + 1.$$

Many linear inequality conjectures have been obtained by several systems, and proved, refuted or remain open. We mention a few. Let $\bar{l}(G)$ denote the average distance between pairs of vertices of G.

Conjecture 3 (Graffiti 2, Fajtlowicz [50]) *For any connected graph G with average distance $\bar{l}(G)$ and independence number $\alpha(G)$,*

$$\bar{l}(G) \leq \alpha(G).$$

Conjecture 4 (Graffiti 3, Fajtlowicz [50]) *For any connected graph G with average distance $\bar{l}(G)$ and Randic index $Ra(G)$,*

$$\bar{l}(G) \leq Ra(G).$$

Both conjectures were obtained with Graffiti; the former was proved by Chung [29] and the latter is open.

A *chemical graph* G has maximum degree 4 (due to the valency of carbon).

Conjecture 5 (Caporossi, Hansen [25] [24]) *For any chemical graph G with Randic index $Ra(G)$, size m and n_1 pending vertices,*

$$Ra(G) \geq \frac{m + n_1}{4}.$$

This conjecture, obtained by AGX, was proved using arguments based on linear programming.

A shorter proof is the following. Let $G = (V, E)$ and $E = E_1 \cup E_2$ where E_1 denotes the edges of G adjacent to a leaf and E_2 those which have both endvertices of degree at least 2. $|E_2| = |E| - |E_1| = m - n_1$. Moreover, for any edge $\{v_i, v_j\} \in E_1, 1/\sqrt{d_i d_j} \geq 1/2$ as d_i and $d_j \leq 4$ and one of d_i and d_j is equal to 1, and for any edge $\{v_i, v_j\} \in E_2, 1/\sqrt{d_i d_j} \geq 1/4$. Hence, $Ra(G) \geq (m - n_1)/4 + n_1/2 = (m + n_1)/4$. □

A third class of relations, R_3, is obtained by using floor and ceiling operators.

Let $\gamma(G)$ denote the *domination number* of G (or *exterior stability number*), i.e., the smallest number of vertices in a set such that any vertex not in the set is adjacent to one in the set; let $g(G)$, the *girth* of G denote the length of the smallest cycle of G.

Theorem 4 (Brigham, Dutton [15]) *For any graph G with minimum degree $\delta \geq 2$ and girth $g(G) \geq 5$,*

$$\gamma(G) \leq \left\lceil \frac{n - \lfloor g(G)/3 \rfloor}{2} \right\rceil .$$

Not much has been done regarding the use of the operators $\lfloor a \rfloor$ (floor of a, or largest integer not larger than a) and $\lceil a \rceil$ (ceiling of a or smallest integer not smaller than a) in computer-assisted or automated conjecture-making in graph theory. Exceptions are a few conjectures obtained with Graffiti [38] and the following conjecture. Recall that the *distance polynomial* of a graph G is defined as

$$P(G) = n + mx + \sum_{k=1}^{\lfloor \frac{D(G)}{2} \rfloor} p_k x^k,$$

where p_k denotes the number of pairs of vertices v_j, v_l at distance k. Then this polynomial will be *palindromic* if

$$p_k = p_{D(G)-k} \qquad k = 0, 1, 2, .., \lfloor \frac{D(G)}{2} \rfloor.$$

and the *distance to the palindrome condition* is defined as

$$dist(G) = \sum_{k=0}^{\lfloor \frac{D(G)}{2} \rfloor} |p_{D(G)-k} - p_k|.$$

Clearly if $dist(G) = 0$ the polynomial is palindromic. AGX [22] could find trees T with a palindromic distance polynomial $P(T)$ and an even diameter $D(T)$ (finding graphs G with a palindromic distance polynomial is easy) but not with an odd diameter $D(T)$. However, its use led to

Conjecture 6 (Caporossi *et al.*[22]) *For any tree T with odd diameter $D(T)$,*

$$dist(T) \geq \lceil \frac{n}{2} \rceil.$$

This conjecture is open (and apparently hard). It was obtained interactively with AGX; however the non-automated part was easy as AGX produced trees T with odd diameter and distances $dist(T)$ equal to 5,6,6,7,7,8,8 and so forth for $n = 10$ to $n = 50$ without exception, from where the conjecture follows immediately.

2.3 Non-linear relations

A fourth class of relations, $R4$, involves powers of invariants or products of them. Usually powers are squares, cubes, inverses, square or cubic roots. Products usually involve only a pair of invariants. Recall that the *complementary graph* $\bar{G}$ of a graph G has an edge joining vertices v_i and v_j if and only if G has not.

Theorem 5 (Nordhaus, Gaddum [70]) *For any graph G of order n with chromatic number $\chi(G)$,*

$$2\sqrt{n} \leq \chi(G) + \chi(\bar{G}) \leq n + 1$$

and

$$n \leq \chi(G).\chi(\bar{G}) \leq \frac{(n+1)^2}{2} = \frac{n^2}{2} + n + \frac{1}{2}.$$

Systems Graffiti and AGX led to several conjectures with powers or products of invariants. Define [50] the temperature t_j of vertex v_j of G as

$$t_j = \frac{d_j}{n - d_j} \quad j = 1, 2, .., n.$$

Conjecture 7 (Graffiti 834, Fajtlowicz [50]) *For any connected graph G with average distance $\bar{l}(G)$ and temperature of vertices of the complementary graph $t_j(\bar{G})$, $j = 1, \ldots n$,*

$$\bar{l}(G) \leq 1 + \max_j \ t_j(\bar{G}).$$

This conjecture could be reformulated as

$$(1 + \delta(G))\, \bar{l}(G) \leq n,$$

and was refuted by AGX [26]; the counter-example consists of two triangles joined by a path with seven edges. A weaker, but simple and elegant, conjecture is the following:

Conjecture 8 (Graffiti 127, Fajtlowicz [50]) *For any connected graph G*

$$\delta(G).\bar{l}(G) \leq n.$$

After this conjecture remained open for more than 10 years, a stronger result, implying it as a corollary, was obtained by Beezer *et al.* [5].

The *energy* E of a graph G can be defined [57] [56] as

$$E = \sum_{i=1}^{n} |\lambda_i|$$

where the λ_i , $i = 1, 2, \ldots, n$ are the eigenvalues of the adjacency matrix $A(G)$ of G.

Conjecture 9 (Caporossi *et al.* [21]) *For any graph* G,

$$E \geq 2\sqrt{m}$$

and

$$E \geq \frac{4m}{n}.$$

Both relations, obtained with AGX, could easily be proved.

A fifth, rare, class of relations, R_5, involve exponentials or logarithms.

Theorem 6 (Berge [6]) *For any connected graph* G *with a maximum degree* $\Delta \geq 2$ *and radius* $r(G)$,

$$r(G) \geq \frac{log(n\,\Delta - n + 1)}{log(\Delta)}$$

A few other conjectures involving logarithms were recently obtained with Graffiti [38].

Let $\rho(G)$ denote the *path covering number* of G, i.e., the smallest number of vertex disjoint paths needed to cover all vertices of G.

Conjecture 10 and 11 (De La Vina *et al.* [38]) *For any graph* G *with independence number* $\alpha(G)$, *radius* $r(G)$ *and path covering number* $\rho(G)$,

$$\alpha(G) \geq r(G) + ln(\rho(G))$$

and

$$\alpha(G) \geq ln(r(G)) + \rho(G).$$

These conjectures are open.

2.4 Qualitative relations

Relations of another form, i.e., *qualitative* ones, define class R_6. They are rarely used in graph theory but quite frequent in other fields such as economics [81], particularly in *comparative statics*. Qualitative relations describe trends of invariants. e.g:

"invariant i_1 *increases when invariant* i_2 *increases"*

or

"invariant i_1 *decreases when invariant* i_2 *increases",*

which may be expressed by

$$\frac{\Delta i_1}{\Delta i_2} > 0 \qquad \text{and} \qquad \frac{\Delta i_1}{\Delta i_2} < 0$$

respectively, where Δi_2 is an increase in invariant i_2 and Δi_1 the corresponding change in the invariant i_1.

A tree with n vertices is bipartite and its vertices can be colored, say, in black and white; let n_b and n_w denote the numbers of black and of white vertices respectively (with $n_b + n_w = n$). In [37] color-constrained trees, i.e., trees with fixed n and $n_b \geq n_w$, and with minimum index are studied. This led to the following result:

Conjecture 12 (Cvetković *et al.* [37]) *For all trees T with n vertices, n_b black ones and n_w white ones, $n_b \geq n_w$, the minimum value of the index λ_1 (T) increases monotonously with $n_b - n_w$.*

This qualitative conjecture was obtained with AGX and is proved in the cited reference.

2.5 Conditions

We next discuss the classes C of graphs G which are the most used in conjectures of the type $R|C$. Several of them have already been illustrated by examples given above.

A first class, C_1, is composed of *conditions necessary for the invariants $i_1, i_2, ...$ used in the relation R to be defined*. Quite often the graph will have to be *connected*, i.e., any two vertices must be joined by a path.

Examples are conjectures 3,4,7 and 8 above where connectedness is needed for average distance not to be infinite. In other conjectures, such as those on trees, e.g. conjecture 6 above, connectedness is implicit, as a tree is a connected graph without cycles.

Another class C_2 consists of *conditions eliminating trivial cases.* An example is that there should be no isolated points, i.e., the minimum degree $\delta(G) \geq 1$. This is illustrated by the second formula of Gallai's theorem (Theorem 1 above).

Forbidden subgraphs can also be used to obtain well-known classes of graphs, which we denote collectively by C_3.

A first case is *triangle-free* graphs.

Theorem 7 (Fraughnaugh, Locke [54]) *For any connected triangle-free 3-regular graph G with independence number $\alpha(G)$ and order n,*

$$\frac{\alpha(G)}{n} \geq \frac{11}{30} - \frac{2}{15n} \qquad \left(or\ \alpha(G) \geq \frac{11}{30} n - \frac{2}{15} \right)$$

Conjecture 13 (Graffiti 116, Fajtlowicz [50]) *For any triangle-free graph G with index $\lambda_1(G)$ and Randić index $Ra(G)$,*

$$\lambda_1(G) \leq Ra(G).$$

This has been proved by Favaron, Mahéo and Saclé [51].

A generalization is to consider graphs without odd cycles C_{2k+1} for all positive integers k, i.e., *bipartite graphs*.

Theorem 8 (König [64]) *For any bipartite graph G with matching number $\nu(G)$ and vertex covering number $\tau(G)$,*

$$\nu(G) = \tau(G).$$

A more drastic condition is to exclude all cycles, which of course gives trees, if connectivity is assumed, and *forests* otherwise.

Conjecture 1 above does not hold for all trees; the following one does

Conjecture 14 (Caporossi, Hansen [25] [24]) *For any tree T,*

$$\alpha(T) \leq \frac{1}{2}(m + n_1 + D(T) - 2r(T))$$

and

$$\alpha(T) \geq \frac{1}{2}(m + n_1 + D(T) - 2r(T) - [\frac{n-2}{2}]).$$

Symbols are defined above. Both relations were found with AGX; the former is proved in [25] and the latter in [24].

A generalization consists in defining a new class C_4, in terms of excluded subgraphs of G obtained by applying some operations. A first such operation is an homomorphism, i.e., removal of degree 2 vertices: if $d_j = 2$ and the neighbors of v_j are v_i, v_k, remove v_j and replace its two incident edges by an edge joining v_i and v_k. Then G is *planar* if it contains no induced subgraph homomorphic to K_5 or $K_{3,3}$ (see below).

Theorem 9 (the four-color theorem, Appel, Haken [2] [3] [4])
If G is planar and has chromatic number $\chi(G)$ then

$$\chi(G) \leq 4.$$

This result was conjectured already in 1852 and was proved in 1976, with important computer aid; see also the more recent and shorter, but still computer-aided proof of Robertson *et al.* [80].

3 Conditions for belonging to a class of graphs

A second class of graph theoretic conjectures consists in necessary and/or sufficient conditions, expressed as algebraic relations, for a graph G to belong to a particular class C. Sufficient conditions appear most often. Their general form is

$$C \Leftarrow R$$

which reads:

"For any graph G, relation R implies G belongs to class C".

Necessary conditions have the form discussed in section 2, i.e., $C \Rightarrow R$. In rare cases, necessary and sufficient conditions are available: $C \Leftrightarrow R$. One can have also conditions valid only for some classes of graphs, e.g. $(C_1 \Leftarrow R) \mid C_2$. Recall that a graph is *Hamiltonian* if and only if there exists a cycle of G going once and only once through each vertex.

Theorem 10 *A graph G of order $n \geq 3$ with degree sequence $d_1 \leq d_2 \leq \ldots d_n$ is Hamiltonian if one of the following conditions holds:*
(i) (Dirac [40]) $d_k \geq \frac{n}{2}$ for all $k = 1, 2, \ldots n$;
(ii) (Ore [72] $d_u + d_v \geq n$ for all pairs of non adjacent vertices u,v;
(iii) (Pósa [77]) $d_k > k$ for all k with $1 \leq k \leq \frac{n}{2}$;
(iv) (Bondy [9]) $d_j + d_k \geq n$ for all j, k with $d_j \leq j, d_k \leq k - 1$.

Instead of a single relation R, one could have a conjunction or a disjunction of relations (as shown in the previous theorem, when the four conditions are taken jointly) or some more complicated logical combination of relations.

Relations of this form do not appear to have been much studied with computer-assisted or automated conjecture-making systems. One possible approach would be to consider conjectures which have not yet been refuted or proved, for some class C of graphs and test, on a database of examples or with an optimization routine, if one or several of them appear to be sufficient for G to belong to C.

Another approach would be to study conjectures valid for critical graphs related to the property defining C (*i.e.,* graphs G belonging to class C but who cease to be so if a vertex or an edge is removed), then to see if these conjectures hold for all graphs of C, or can be modified for this to be the case.

4 Inclusions between classes of graphs

A third class of graph-theoretic conjectures describes inclusion between classes $C_1, C_2, \ldots$ of graphs. The simplest form is then

$$C_1 \subseteq C_2$$

or, in rare cases,

$$C_1 \equiv C_2$$

which read

"All graphs of class C_1 belong to class C_2"

e.g.

"All trees are bipartite graphs"

and

"A graph belongs to class C_1 if and only if it belongs to class C_2"

e.g.

"A tree is a connected graph without cycles"

(this is sometimes taken as a definition but one can also use the following one: "A tree is a connected graph with $n-1$ edges").

Definitions of classes can be more general, *e.g.,* correspond to boolean expressions on simple classes of graphs or subgraphs in G, or possibly some graph derived from G by transformation such as removing vertices of degree 2.

Theorem 11 (Kuratowski [65]) *A graph G is planar if and only if it does not contain an induced subgraph homeomorphic to K_5 or $K_{3,3}$.*

The system *Graph Theorist* developed by Epstein [42] [43] [44] [45] represents classes of graphs by constructive definitions, *i.e.,* properties are associated with the classes of graphs satisfying them and algorithms are specified to construct (at least in principle) all graphs of these classes. Then inclusion among classes is studied leading to conjectures and their proof.

Such conjectures seldom appear to be new, the aim of Graph Theorist being more to understand mathematical reasoning than derive new results.

Relations of the above form do not appear to have been studied with other conjecture-making systems in graph theory.

5 Implications between relations

A further class of conjectures relates to implications and equivalences between relations $R_1, R_2, \ldots$, *i.e.,* they are of the form

$$R_1 \Rightarrow R_2$$

or

$$R_1 \Leftrightarrow R_2$$

Again these forms may be generalized to consider conjunctions, disjunctions or more complex logical expressions of several relations.

These forms are basic in mathematics and graph theory. They correspond to several problems:

5.1 Corollaries

The conjecture is then that corollary R_2 is a consequence of theorem R_1.

Conjecture 15 *The lower bound (*Berge *[6]) on the independence number $\alpha(G)$ of any graph G of order n and size m*

$$\alpha(G) \geq \frac{n^2}{2m+n}$$

is implied by the lower bound (Favaron *et al.* [52])

$$\alpha(G) \geq \left\lceil \frac{2n - \frac{2m}{\lceil \frac{2m}{n} \rceil}}{\lceil \frac{2m}{n} \rceil + 1} \right\rceil .$$

This is indeed the case, the latter bound being best possible for all n and m compatible with the existence of a simple graph.

Conjecture 16 [52] *The second relation in Conjecture 15 is equivalent to the following one (proposed earlier in* [59]*):*

$$\alpha(G) \geq \left\lceil n - \frac{2m}{1 + \lfloor \frac{2m}{n} \rfloor} \right\rceil + \left\lceil \frac{n - \lceil n - 2m/(1 + \lfloor \frac{2m}{n} \rfloor)(1 + \lfloor \frac{2m}{n} \rfloor) \rceil}{2 + \lfloor \frac{2m}{n} \rfloor} \right\rceil .$$

This conjecture is correct (but stated without proof in [52]).

Corroborating, refuting or strengthening conjectures such as the two last ones can be done in several ways:
(i) enumerating small graphs with systems such as Nauty or geng [69];
(ii) building interactively a counter-example, with a system such as GRAPH [33] [36];
(iii) minimizing the difference between the right hand-sides of both conjectures with AGX while parametrizing on n and m [21] [24].

5.2 Redundancy

If a relation R_2 is implied by a relation R_1 in a database, it may be viewed as redundant (and possibly deleted). Given R_1 and R_2, AGX is well-adapted to test a conjecture for redundancy: it will minimize (or maximize) the latter under the constraint that the former holds. This can be extended to testing a conjecture such as $R_1, R_2, \ldots R_k$ imply R_{k+1}, as well as to equivalence. However, this leads to refuting or corroborating one such conjecture not to finding it.

More generally,

> "When a new inequality relating graph invariants is discovered INGRID can be employed to determine if the same or better bounds can be obtained from previously known results" ([17] p.170).

To that effect, INGRID [17] can find among all relations of a large database if there is a small subset of them which imply a given relation. Thus given a set of relations $\Re = \{R_1, R_2, ...R_p\}$ and a relation R, INGRID discovers a statement of the form

$$R_{i_1} \cap R_{i_2} \cap \ldots R_{i_k} \;\Rightarrow\; R$$

where $k \ll p$. An example follows:

Conjecture 17 (Brigham *et al.* [17]) *The known relation between spectral radius λ_1, chromatic number χ and size m of a graph G*

$$\lambda_1 \leq \sqrt{2m\frac{(\chi-1)}{\chi}}$$

and

$$\chi \leq \lfloor 1 + \frac{1}{2}\sqrt{1+8m} \rfloor$$

imply the relation (Stanley [83])

$$\lambda_1 \leq -1 + \sqrt{1+8m}.$$

INGRID works as follows: it has built into it 458 relations between 37 graph invariants. The user can enter values or ranges of values for any of the invariants and INGRID then returns, using the relations, values or ranges of values for the remaining invariants. There is also a tracking function which allows the user to see the sequence of relations which led to the result, if desired.

INGRID may be used in interactive or in automated mode, i.e., in the latter case, after posing a question one just records the results in terms of values or intervals of values for invariants and of relations used.

It thus appears that the tools it uses for "helping to test the effectiveness of new theorems", as is discussed in this subsection, as well as for "helping derive theorems", which is discussed in the next subsection, are automated.

Brigham *et al.* comment as follows on the above example ([17] p.170):

> "With this insight we were able to show analytically that substitution of the second inequality into the first always produces a better bound than Stanley's except for one class of extremal graphs where they are equal. This in no way diminishes the value of Stanley's result, which gives an elegant direct relationship between λ_1 and e, but the exercise showed we need not include it in INGRID's knowledge base."

So, in this case, INGRID make a conjecture, which was later proved by hand. Observe that INGRID [17], as Graffiti's DALMATIAN heuristic ([49, p. 370]), does not include a relation in its database of relation if it is not informative. In the former case, this means it is implied by the union of all previous ones and in the latter case that this is true for the restricted set of graphs in the database of examples.

5.3 Paths towards new relations

The conjecture making function of INGRID just described can be extended to help finding new relations. Indeed, "INGRID does not of itself find new theorems relating graph

invariants, but it can be a valuable tool in aiding a researcher to do just that" ([17] p.170). Assuming an unknown but interesting relation exists between two invariants i_1 and i_2, one may vary one of them, observe the influence on the bounds of the other and use the tracking function to see which relations (implying quite different invariants than i_1 and i_2) are invoked by the system in computing these bounds. This leads to a conjecture of the form

"Relations $R_1, R_2, \ldots R_k$ in the database lead to a relation between invariants i_1 and i_2."

Then algebraic manipulations can be used to derive this relation, as illustrated by the next example:

Conjecture 18 (Brigham *et al.* [17]) *The relations*

$$\Delta \leq \lambda_1^2,$$

$$\nu \geq \frac{n}{\Delta - 1},$$

$$\epsilon \leq n - \nu$$

and

$$\theta_0 \leq \alpha$$

where the symbols are described above, except for the clique cover number $\theta_0 = \chi(\bar{G})$, imply relation(s) between λ and θ_0.
This indeed led to the relations

$$\theta_0 \leq n[\lambda_1^2/(1+\lambda_1^2)]$$

and

$$\theta_0 \leq \frac{1}{2} + [n(n-1) - \lambda_1(\lambda_1 - 1) + \frac{1}{4}]^2,$$

which could be proved and are new.

6 Structural conjectures

Many theorems in graph theory specify partially or completely the structure of some classes of graphs. In particular extremal graphs, *i.e.,* graphs for which an invariant takes its minimum or maximum value have been much studied, as shown in Bollobas' book [8] on that topic. Critical graphs have also received much attention.

Theorem 12 (Turan [84]): *If G is a graph of order n with independence number $\alpha(G)$, and minimum number of edges, then G is isomorphic to the graph $G_{n,k}$ composed of k disjoint cliques, r of which have q vertices and the others $k-r$ of which have $q-1$ vertices, where r and q are such that $n = q(k-1) + r$.*

This result has been generalized in many ways.

The energy of a graph has been defined above, and two lower bounds in terms of m and n given.

Conjecture 19: *For any graph G with energy $E(G)$, and size m the bound*

$$E(G) \geq 2\sqrt{m}$$

is attained if and only if G is complete bipartite.

This conjecture obtained with AGX, is proved in [21].

The Randic index of a graph has also been defined above.

Conjecture 20: *For any chemical tree T (with a maximum degree 4) of given size m, the Randic index is minimum if and only if it belongs to one of the three families represented in Figure 1 or is obtained from such a tree by iterated removal of three pending edges incident with a same vertex and their addition at another pending vertex.*

This conjecture, obtained with AGX, is proved in [23].

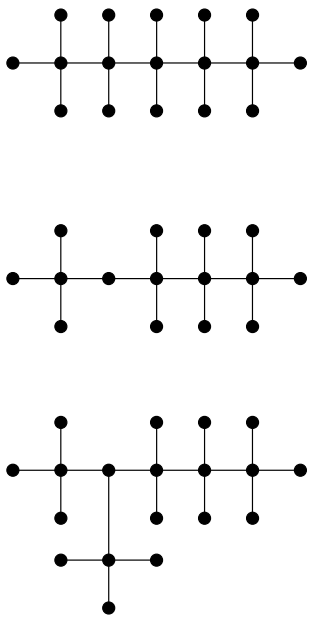

Figure 1: Three classes of chemical trees with minimum Randic index.

Dendrimers [41] are trees with a given maximum degree Δ which are as regular as possible (*i.e.,* regular except for pending vertices) and symmetric around one central vertex (see Figure 2a). It has long been surmised that:

Conjecture 21: [62] [63] *Dendrimers have minimum Wiener index (or total distance between pairs of vertices) among all trees with maximum degree Δ and the same order n.*

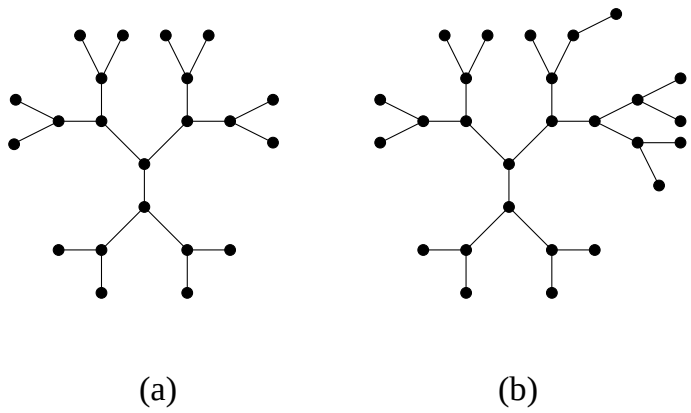

Figure 2: Dendrimers without and with additional edges.

AGX has corroborated this conjecture, and led to observe that if the number of edges does not correspond to that one of a dendrimer, additional edges should be as close as possible (see Figure 2b). This conjecture was recently proved, independently by Fischermann *et al.* [53] and by Zheng [86].

7 Counting and Enumerating

Many graph theoretic theorems give the number of graphs satisfying some specific property, often as a function of size, and sometimes provide also an implicit list of all such graphs. Another related type of problem is to find the minimum order of graphs which satisfy a given property. Computers have been extensively used in enumerative tasks from graph theory. They have led to many computer-assisted conjectures and proofs.

7.1 Counting graphs

A graph is labeled if its vertices are numbered $1, 2, \ldots n$. Two isomorphic graphs are viewed as different when their vertices are not labeled in the same way.

Theorem 13 (Cayley [27]): *There are n^{n-2} labeled trees on $n \geq 2$ vertices.*

An approach to finding conjectures of this type would be to enumerate all graphs satisfying a given property for $n = 1, 2, \ldots$ with a powerful system such as *geng* [69], then *(i)* to check if the resulting sequence of numbers is known with the Online Encyclopedia of Integer Sequences [82] ;
(ii) if not, use tools from algebra to study the sequence (and submit it to the Encyclopedia).

7.2 Enumerating graphs

Benzenoids are molecules which can be represented as planar polyhexes, *i.e.,* simply connected regions of the hexagonal lattice. They can also be viewed as graphs. Many algo-

rithms have been proposed for enumerating polyhexes with a given number h of hexagons (see [18] for a recent survey). The first few values are given in Table 1. However, no closed form formula for these series could be found.

h	N(h)	h	N(h)	h	N(h)
1	1	9	6505	17	1751594643
2	1	10	30086	18	8553649747
3	3	11	141229	19	41892642772
4	7	12	669584	20	205714411986
5	22	13	3198256	21	1012565172403
6	81	14	15367577	22	4994807695197
7	331	15	74207910	23	24687124900540
8	1435	16	359863778	24	122238208783203

Table 1: Number of planar polyhexes ($N(h)$) according to h

Conjecture 22: *There is no closed-form formula giving the number of polyhexes with h hexagons.*

While this conjecture could be refuted, it is hard to see how to prove it.

8 Ramseyian Theorems and Conjectures

Conjectures considered up to now are expressed in terms of invariants of a graph G and structure of such a graph. Another class of results is less direct: one considers a property which must hold for all partitions of a given type defined on G, most frequently all colorings of its edges using a given number of colors. Then the effect of the imposition of this property on an invariant $i(G)$, most often its order, is studied. To illustrate let us consider all bicoloring of the edges of G. The classical Ramsey number $r(k)$ is the smallest order of a graph G such that all such bicolorings induce a K_k in G or in $\bar{G}$.

Very few Ramsey numbers are known [30], so generalized Ramsey numbers in which one considers a subgraph G_1 in G or G_2 in $\bar{G}$ have been extensively studied. Computer enumeration played an important role: in a recent version of his "Dynamic Survey" on "Small Ramsey Numbers", Radzizowski [78] cites 71 papers which report on automated or computer-assisted determination of generalized Ramsey numbers or bounds on them. In this last case, conjectures are sometimes made on what is the most likely value.

More general questions have been asked, often by Erdös and his collaborators.

Conjecture 23 (Burr, Erdös [19]) *For every graph G on n vertices in which every subgraph has average degree at most c,*

$$r(G) \leq c'n$$

where the constraint c' depends only on n.

A conjecture of the same form for subgraphs with maximum degree Δ,

$$r(G) \leq c(\Delta)n$$

was made by the same authors and proved to hold by Chvatal *et al.* [31].

An example in which edge 3-colorings are considered is the following:

Conjecture 24 (Bondy and Erdös [11]) *Let C_p be a cycle with p vertices; then*

$$r(C_p, C_p, C_p) \leq 4p - 3.$$

Luczak [68] has shown that $r(C_p, C_p, C_p) \leq 4p + o(p)$.

Other problems concern the number of classes in a family of partition defined on a graph G.

Conjecture 24 (Erdös, Gallai, 1959 [46]) *Every connected graph on n vertices can be edge-partitioned into almost $\lfloor (n+1)/2 \rfloor$ paths.*

Instead of partitions of edges of G, one may also consider all subgraphs of G of a given type, such as, e.g. cliques. This leads to new questions, e.g.:

Problem 1 (Erdös *et al.* 1992 [47]) *Estimate the cardinality, denoted by $T(G)$, of a smallest set of vertices in G that shares some vertex with every maximal clique of G.*

While computers do not appear to have been used in the study of this problem, it seems that a specialized algorithm could prove useful.

9 Conclusions

In order to get a clear view of what are interesting conjectures in graph theory, we followed up on the observation that famous theorems in this field (as in others) were first conjectures, if only in the minds of those which proved them. This suggests a rich variety of forms. We attempted to classify them, taking into account the work done in computer-assisted or automated conjecture-making. Thus we could provide examples of a number of cases in which one or another system was successful.

Moreover, it appears that

(i) there are many classes of conjectures which have not yet been explored with or by conjecture-making systems (the more so as the present classification is exploratory and certainly not exhaustive).

(ii) different systems appear to each have their strong points and none seems presently able to obtain interesting conjectures in all the cases where the others do.

Therefore, there is much work to do, both in modifying existing systems for doing in different ways tasks done by others and expanding them to tackle new conjecture-making tasks. Clearly, while computer-assisted and automated conjecture-making is successful, the field is still at its beginning.

Appendix. Proof of Conjecture 2

The trees with maximum degree $\Delta \leq 3$ found by *AGX* with (conjectured) maximum irregularity are represented on Figure 3.

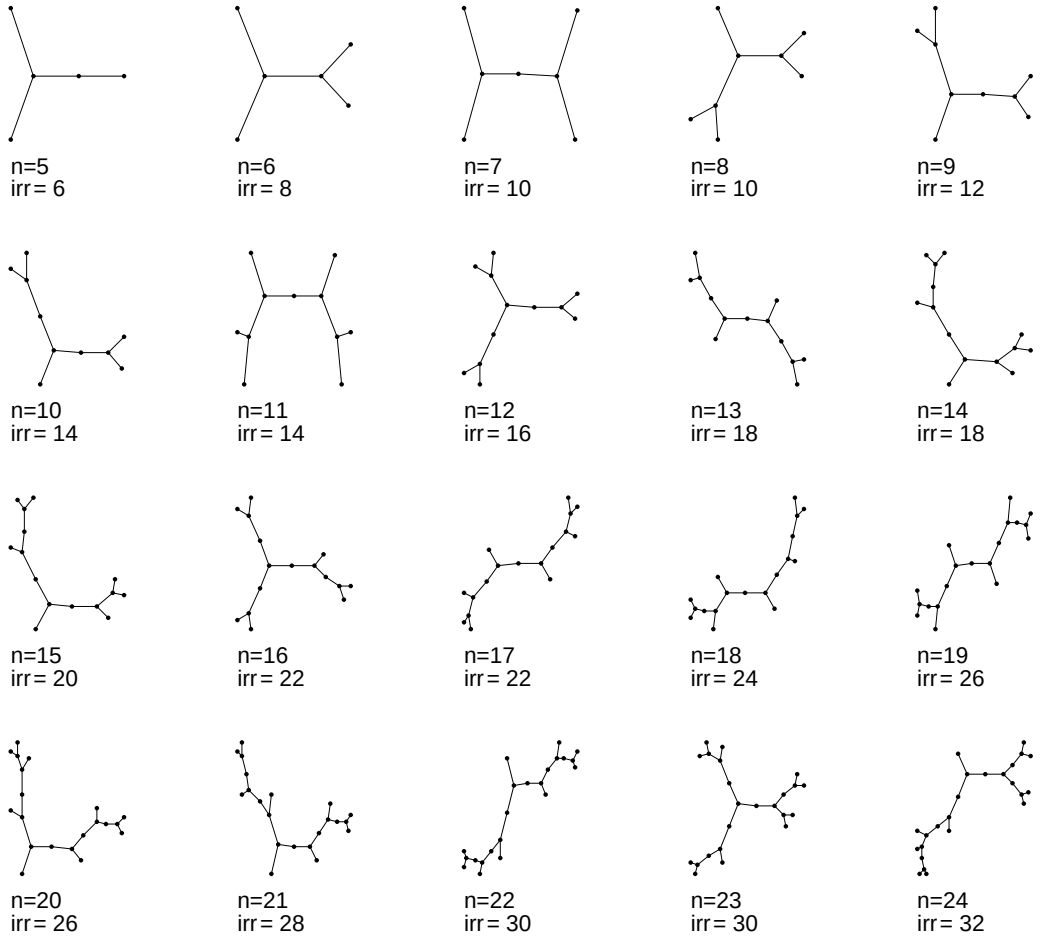

Figure 3: Extremal trees with $\Delta \leq 3$ and maximum irregularity found by *AGX*

These extremal trees are used in the following proofs, illustrating also the help provided by *AGX* in getting proofs.

Theorem 14 *For any tree T with $\Delta \leq 3$,*

$$\begin{aligned} irr(T) &\leq \tfrac{4n+2}{3} && \text{if } n(mod\ 3) = 1, \\ &\leq \tfrac{4n-n(mod\ 3)}{2} && \text{otherwise.} \end{aligned}$$

Proof. Let T be a tree with maximum degree $\Delta \leq 3$ and denote by x_{ij} the number of edges of T with endvertices of degree i and j.

By definition of the irregularity,

$$irr(T) = x_{12} + 2x_{13} + x_{23}. \tag{9.1}$$

We first solve the following system of five linear equations which holds for all trees with $\Delta \leq 3$:

$$\begin{aligned} x_{12} + x_{13} &= n_1 && (9.2)\\ x_{12} + 2x_{22} + x_{23} &= 2n_2 && (9.3)\\ x_{13} + x_{23} + 2x_{33} &= 3n_3 && (9.4)\\ n_1 + 2n_2 + 3n_3 &= 2n - 2 && (9.5)\\ n_1 + n_2 + n_3 &= n. && (9.6) \end{aligned}$$

with unkowns x_{13}, x_{23}, n_1, n_2 and n_3. That gives :

$$\begin{aligned} x_{13} &= \frac{1}{3}(n - 4x_{12} - x_{22} + x_{33} + 5) && (9.7)\\ x_{23} &= \frac{1}{3}(2n + x_{12} - 2x_{22} - 4x_{33} - 8) && (9.8)\\ n_1 &= \frac{1}{3}(n - x_{12} - x_{22} + x_{33} + 5) && (9.9)\\ n_2 &= \frac{1}{3}(n + 2x_{12} + 2x_{22} - 2x_{33} - 4) && (9.10)\\ n_3 &= \frac{1}{3}(n - x_{12} - x_{22} + x_{33} - 1). && (9.11) \end{aligned}$$

Replacing x_{13} by (9.7) and x_{23} by (9.8) in (9.1) gives

$$irr(G) = \frac{1}{3}(4n - 4x_{12} - 4x_{22} - 2x_{33} + 2) \tag{9.12}$$

which is maximal for a fixed number of vertices when the values x_{12} and x_{33} are equal to zero.

If $n(\text{mod } 3) = 1$, we can choose $x_{12} = 0$, $x_{22} = 0$ and $x_{33} = 0$ because the solutions given in Eqs. (9.7) – (9.11) are in integers. In this case, $x_{13} = (n+5)/3$, $x_{23} = (2n-8)/3$ and $irr(T) = (4n+2)/3$.

If $n(\text{mod } 3) = 0$, x_{12}, x_{22} and x_{33} cannot be all equal to zero because the solutions are no more in integers. Looking at (9.12), the best choice is to take $x_{12} = x_{22} = 0$ and $x_{33} = 1$ which is a feasible case. In this case, $irr(T) = 4n/3$.

If $n(\text{mod } 3) = 2$, there are three feasible solutions with the same irregularity value. One can choose $x_{12} = x_{22} = 0$ and $x_{33} = 2$, or $x_{12} = 1$ and $x_{22} = x_{33} = 0$, or $x_{22} = 1$ and

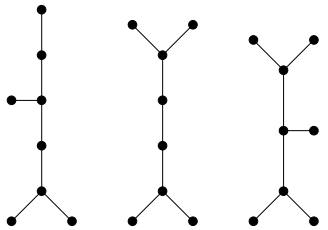

Figure 4: Three trees with maximum irregularity, $\Delta \leq 3$ and $n = 8$

$x_{12} = x_{33} = 0$. These solutions lead to $irr(T) = (4n-2)/3$. Figure 4 shows three different trees with maximum irregularity and $n = 8$. □

The graphs found by *AGX* (see Figure 3) are extremal for the irregularity by Theorem 14. The proof of this theorem gives a good characterization of these graphs in terms of x_{ij}. We now prove Conjecture 2, which was obtained automatically by *AGX* from these extremal trees.

Theorem 15 *For any tree T of size m with $\Delta \leq 3$ and maximum irregularity $irr(T)$, Randic index $Ra(T)$, and n_1 pending vertices,*

$$Ra(T) = -0.027421\ irr(T) + 0.538005\ m - 0.110484\ n_1 + 0.614014.$$

Proof. Before proceeding to the proof itself, we find which real values *AGX* has approximated. To do this, we choose 4 extremal trees given by the system (see Figure 5), compute their values for Ra, irr, m and n_1 and subsitute these values in

$$Ra = a\ irr + b\ m + c\ n_1 + d \tag{9.13}$$

where a, b, c, d are the real values sought for. For instance, the tree T_1 on Figure 5 has $Ra(T_1) = 1/\sqrt{2} + 2/\sqrt{3} + 1/\sqrt{6}$, $irr(T_1) = 6$, $m(T_1) = 4$ and $n_1(T_1) = 3$. That gives the following system of equations with unknows a, b, c and d :

$$\begin{aligned}
6a + 4b + 3c + d &= \frac{1}{\sqrt{2}} + \frac{2}{\sqrt{3}} + \frac{1}{\sqrt{6}}, && (9.14)\\
8a + 5b + 4c + d &= \frac{4}{\sqrt{3}} + \frac{1}{3}, && (9.15)\\
10a + 6b + 4c + d &= \frac{4}{\sqrt{3}} + \frac{2}{\sqrt{6}}, && (9.16)\\
10a + 7b + 5c + d &= \frac{5}{\sqrt{3}} + \frac{2}{3}. && (9.17)
\end{aligned}$$

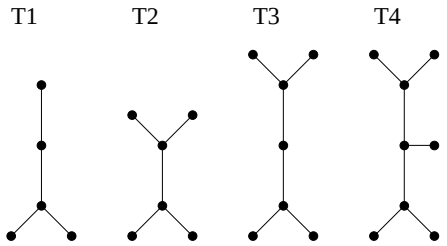

Figure 5: Four extremal trees with $\Delta \leq 3$ and maximum irregularity found by *AGX*

The unique solution of this system is

$$a = -\frac{\sqrt{2}}{4} + \frac{\sqrt{3}}{6} + \frac{\sqrt{6}}{12} - \frac{1}{6}, \tag{9.18}$$

$$b = \frac{\sqrt{2}}{2} - \frac{\sqrt{3}}{3} + \frac{\sqrt{6}}{6}, \tag{9.19}$$

$$c = -\frac{\sqrt{2}}{2} + \frac{2\sqrt{3}}{3} - \frac{\sqrt{6}}{2} + \frac{2}{3}, \tag{9.20}$$

$$d = \frac{3\sqrt{2}}{2} - \sqrt{3} + \frac{\sqrt{6}}{2} - 1. \tag{9.21}$$

A numerical approximation of these irrational values corresponds to the values given by *AGX* in the conjecture.

Let T be a tree with maximum degree $\Delta \leq 3$. We have that

$$m = x_{12} + x_{13} + x_{22} + x_{23} + x_{33}, \tag{9.22}$$

and

$$n = x_{12} + x_{13} + x_{22} + x_{23} + x_{33} + 1. \tag{9.23}$$

Moreover, by definition of the irregularity

$$irr(T) = x_{12} + 2x_{13} + x_{23}, \tag{9.24}$$

and by definition of the Randic index

$$Ra(T) = \frac{x_{12}}{\sqrt{2}} + \frac{x_{13}}{\sqrt{3}} + \frac{x_{22}}{2} + \frac{x_{23}}{\sqrt{6}} + \frac{x_{33}}{3}. \tag{9.25}$$

By Theorem 14, if $n(\text{mod } 3) = 1$,

$$x_{13} = (n+5)/3, \tag{9.26}$$

and

$$x_{12} = x_{22} = x_{33} = 0. \tag{9.27}$$

Substituting (9.27) in (9.23) and (9.23) in (9.26) gives

$$x_{23} = 2x_{13} - 6. \tag{9.28}$$

By (9.27) and (9.28), Eqs. (9.22), (9.24) and (9.25) become

$$m = 3x_{13} - 6, \tag{9.29}$$

$$irr(T) = 4x_{13} - 6, \tag{9.30}$$

and

$$Ra(T) = x_{13}\frac{\sqrt{3}+\sqrt{6}}{3} - \sqrt{6}, \tag{9.31}$$

respectively. Moreover, Eq. (9.2) gives

$$n_1 = x_{13} \tag{9.32}$$

Replace irr by (9.30), m by (9.29), n_1 by (9.32) and a, b, c, d by Eqs. (9.18) – (9.21) in the right-hand-side of (9.13) and simplify. This leads to

$$x_{13}\frac{\sqrt{3}+\sqrt{6}}{3} - \sqrt{6},$$

which is equal to the Randic index of T given by (9.32).

The other cases are similar.

If $n(\text{mod } 3) = 0$, we start with $x_{13} = (n+6)/3$, $x_{33} = 1$ and $x_{12} = x_{22} = 0$ and modify the remainder of the proof in consequence.

If $n(\text{mod } 3) = 2$ we start with the three different solutions given in Theorem 14 and apply the same ideas in each case.

Fractals from genomes – exact solutions of a biology-inspired problem

Bai-Lin Hao[a,b,*]

[a] *Institute of Theoretical Physics, P.O. Box 2735, Beijing 100080, People's Republic of China*
[b] *International Centre for Theoretical Physics, Trieste 34100, Italy*

Received 1 February 2000

Abstract

This is a review of a few recent papers with some new results added. After a brief biological introduction a visualization scheme of the string composition of long DNA sequences, in particular, of bacterial complete genomes, will be described. This scheme leads to a class of self-similar and self-overlapping fractals in the limit of infinitely long constituent strings. The calculation of their exact dimensions and the counting of true and redundant avoided strings at different string lengths turn out to be one and the same problem. We give exact solution of the problem using two independent methods: the Goulden–Jackson cluster method in combinatorics and the method of formal language theory.

PACS: 87.14; 87.23

Keywords: DNA; Fractal; Goulden–Jackson cluster method; Language theory

1. Introduction

The genetic information of all organisms except for the so-called RNA viruses is encoded in thier DNA sequences. A DNA sequence is a long unbranched polymer made of four different kinds of monomers – nucleotides. As far as the encoded information is concerned we can ignore the fact that DNA exists as a double helix of two "conjugated" strands and treat it as a one-dimensional symbolic sequence made of four letters *a*, *c*, *g*, and *t*, representing the nucleotides *adenine*, *cytosine*, *guanine*, and *thymine*, respectively. Since the first complete genome of a free-living organism, *Mycoplasma genitalium*, was sequenced in 1995 the number of available complete

genomes has been growing steadily. As of 15 December 1999 there were in total 5 354 511 sequences containing 4 653 932 745 letters in the *GenBank*.[1] Among these sequences there are more and more complete genomes, including more than 20 bacteria and a few eukaryotes.

The availability of complete genomes of organisms allows one to ask many questions of global nature. Perhaps the simplest global question one can imagine consists in whether there exist short strings made of the four letters that do not appear in a genome. First of all, this is a question that can be asked only nowadays when complete genomes are at our disposal, as it does not make sense when dealing with small pieces of DNA segments. Secondly, as it will become clearer when we introduce some notions from language theory, there is a deeper reason to ask this question since in a sense a complete genome defines a language which is entirely specified by a minimal set of "forbidden words".

The visualization scheme of the string composition of long DNA sequences described in Ref. [1] inspires a few neat mathematical problems which can be solved precisely by using at least two different approaches. Brief accounts of these solutions will appear only in conference proceedings, e.g., Ref. [2]. The data collected in Tables 1 and 2

[1] All bacterial genomes mentioned in this paper are fetched by anonymous `ftp` from `http://ncbi.nlm.nih.gov`. The abbreviations of bacterial names are those of the corresponding subdirectory names in GenBank.

are presented for the first time. As language theory approach and the combinatorial technique used in the work may be quite instructive for other problems we think it appropriate to present them in some details.

2. The visualization scheme and self-overlapping fractals

Given a bacterial complete genome of length N, i.e., a linear or circular DNA sequence made of N letters from the alphabet $\Sigma = \{a, c, g, t\}$, we are interested in the frequency of appearance of various strings of length K. There are 4^K possible different K-strings so we need that many counters to do the counting. We display the counters in a fixed-size square frame on a computer screen.

If we present the $K=1$ frame as a 2×2 matrix

$$M=\begin{bmatrix} g & c \\ a & t \end{bmatrix},$$

then the $K=2$ frame is just a direct product of two copies of M:

$$M^{(2)}=M\otimes M=\begin{bmatrix} gg & gc & cg & cc \\ ga & gt & \text{ca} & ct \\ ag & ac & ta & tc \\ aa & at & ta & tt \end{bmatrix}.$$

In general, a K-frame is given by

$$M^{(K)}=M\otimes M\otimes\cdots\otimes M,$$

whose element is expressed via the elements of the 2×2 matrices as

$$M^{(K)}_{(i_1i_2\cdots i_K),(j_1j_2\cdots j_K)}=M_{i_1j_1}M_{i_2j_2}\cdots M_{i_Kj_K}.$$

In order to facilitate the computation, it is better to use binary indices for the matrix M, i.e., let

$$M_{00}=g,\quad M_{01}=c,\quad M_{10}=a,\quad M_{11}=t.$$

The indices $(i_1j_1)\cdots(i_Kj_K)$ follow from the input sequences $s_1s_2s_3\cdots s_Ks_{K+1}\cdots$.

By sliding a window of width K along the genome we get N or $N-K+1$ total counts for a circular or linear sequence. Every segment of length K in the input sequence, taken as a number in base 4, points to the array element of its own counter. In order to implement this we introduce a mapping

$$\alpha:\{g,c,a,t\}\mapsto\{00,01,10,11\}$$

for each letter in the input sequence. For the first K-string $s_1s_2\cdots s_K$ of the input sequence we get a number

$$\text{index}=\sum_{i=0}^{K-1}4^{K-i-1}\alpha(s_i),$$

which is nothing but the index used to locate its counter. In order to get the new index for the next K-string, it is enough to discard the contribution of the first letter in the previous string and take into account the next new letter. This is easily done by using binary operations.

We display the 4^K counters as a $2^K\times 2^K$ square on the screen. The counter for the first K-string is centered at (x,y):

$$x=\sum_{i=0}^{K-1}2^{K-i-1}(\alpha(s_i)\&E),$$

$$y=\sum_{i=0}^{K-1}2^{K-i-1}(\alpha(s_i)\gg 1),$$

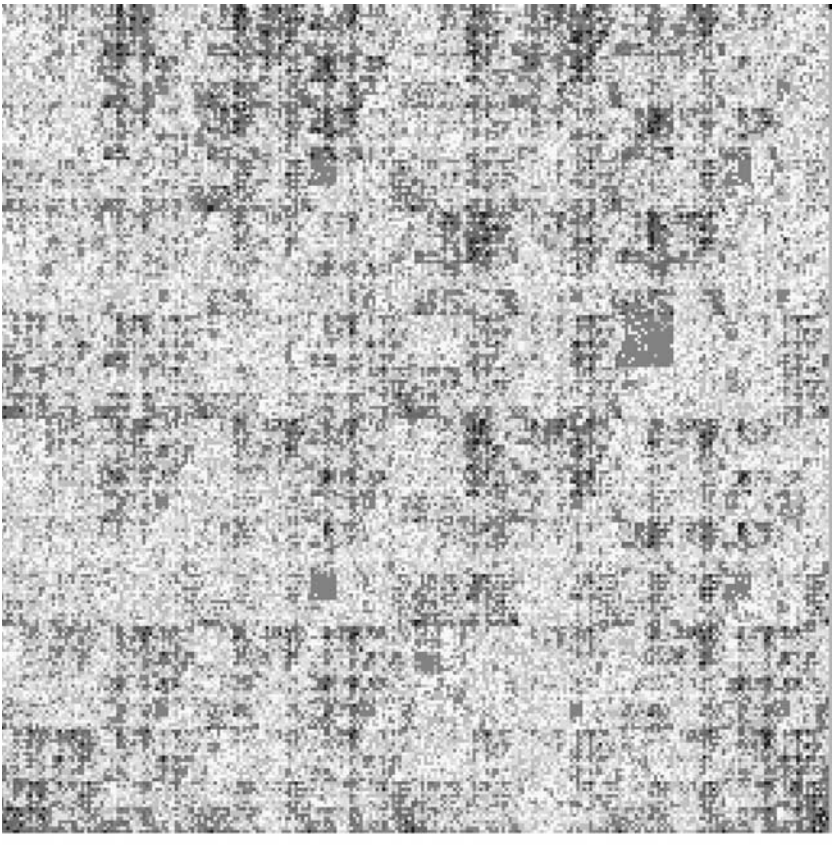

Fig. 1. Frequency of 8 strings in the complete genome of *E. coli*. The characteristic patterns are caused primarily by the under-representation of *ctag*-tagged strings.

where $\&E$ means logical and with the base-4 unit $E = 01$ and $\gg 1$ means left shift by one. Again, for the location of the next K-string one needs only to correct for the new input letter. This leads to a counting algorithm that depends only on the total length N of the genome but not on the string length K. It saves computer time when K gets large.

Applying the above algorithm to the $K=8$ strings in the 4 693 221 letter long genome of *E. coli*, we get the picture shown in Fig. 1

We have used a very crude color code of 16 colors, including black and white. As our attention is concentrated on those strings that do not appear or that are under-represented, we allocate most of the bright colors to small counts with white color representing avoided strings. This is a kind of coarse-graining which makes some features of the figure more prominent. In particular, the presence of some seemingly regular patterns in Fig. 1 may be understood as caused by under-representation of strings that contain *ctag* as a substring. In Fig. 2 we show the counting frames for $K = 6, 7, 8$, and 9 in

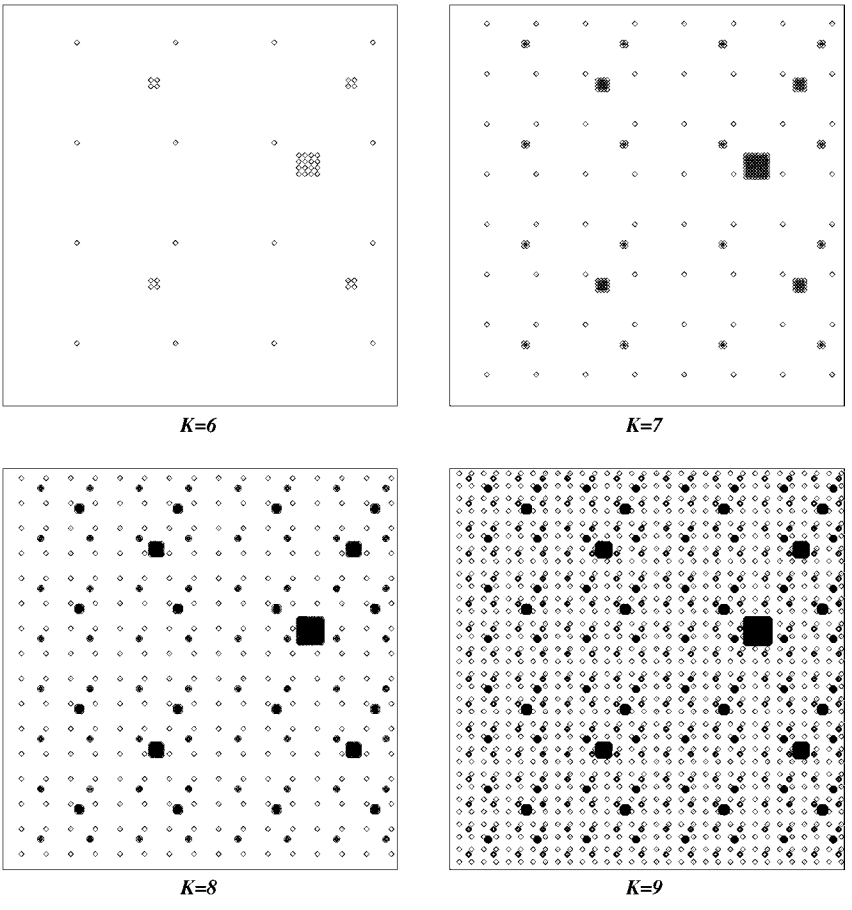

Fig. 2. Templates of *ctag*-tagged strings in the $K = 6, 7, 8,$ and 9 frames.

which the locations of strings that contain *ctag*, or in short, *ctag*-tagged strings, are marked with a small rhombic. We see that the basic features remain unchanged while more and more fine patterns appear with K increasing. The most clearly seen patterns in the *E. coli* portrait are indeed given by these *ctag*-tagged strings.

Fig. 1 is to be compared with the "portrait" of a sequence (not shown), obtained by randomizing the *E. coli* genome, i.e., a sequence with the same number of nucleotides of each kind but with their positions shuffled at random. In such a figure all the characteristic patterns disappear, only some hardly perceptible contrast due to the $c+g$ to $a+t$ ratio not being equal may be noticed under a careful scrutiny.

E. coli is not the only bacterium that does not like the *ctag* substring. Now 10 bacteria are known to have a tendency of having under-represented *ctag*-tagged strings. Other bacteria may avoid some other substrings and some may not show any apparent patterns of avoided substrings. For example, Fig. 3 shows the "portrait" of *Methanococcus jannaschii*. Using templates of various tetranucletides similar to those shown in

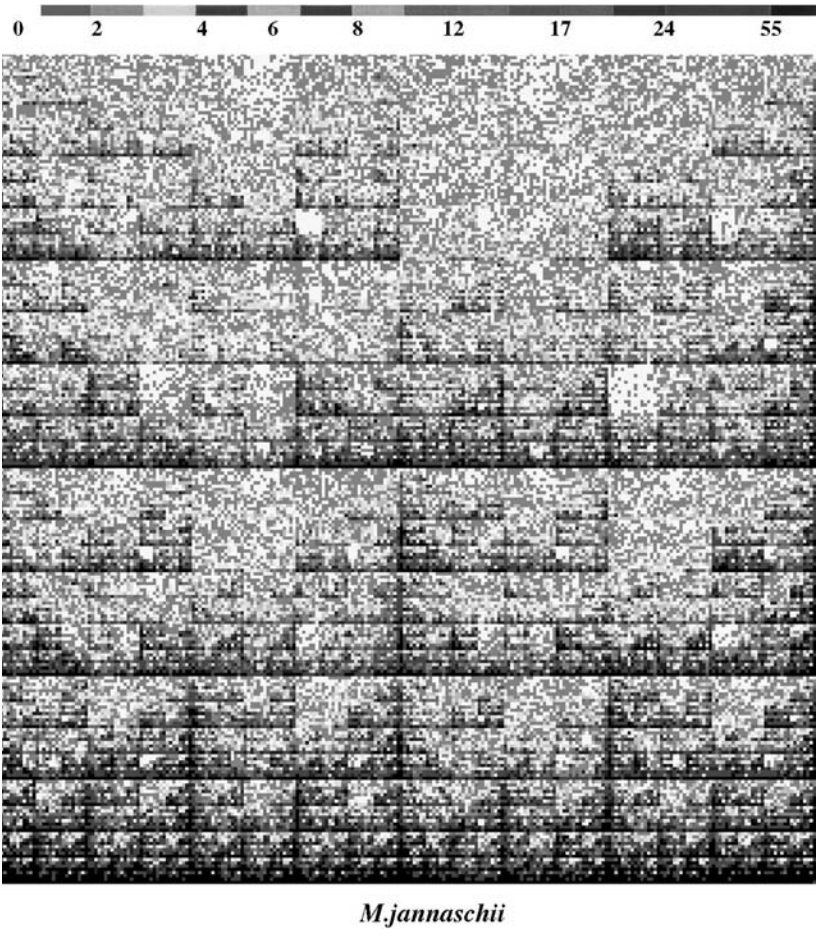

Fig. 3. Frequency of 8 strings in the complete genome of *Methanococcus jannaschii*. One can identify at least five sets of under-represented strings tagged by *ctag*, *cgcg*, *gcgc*, *gtac*, and *gatc*.

Fig. 2, one can identify at least five sets of under-represented strings tagged by *ctag*, *cgcg*, *gcgc*, *gtac*, and *gatc*.

A summary of what has been seen in "portraits" of all available bacterial complete genomes is given in Table 1. The fact that most of the under-represented tetranucleotides are palindromes, i.e., words that happen to be the same when read in both direct and reversed directions with the Watson–Crick conjugation being performed at reverse reading, may hint on their relation with the recognition sites of some restriction enzymes. This has been known to the biologists for some time, see, e.g., Ref. [3]. Our observation shows it is a quite common phenomenon in many bacterial complete genomes.

It is appropriate to mention the relation of the above visualization scheme to the "chaos game representation" (CGR [4]) of DNA sequences. In CGR the final picture

can only be drawn in black/white and may look quite similar to what one would obtain in the above visualization scheme after xeroxing the color figures on a black/white copying machine. There are, however, several essential differences. First, the resolution is not entirely under control in CGR, as different neighboring nucleotides may be resolved to a different precision, depending, say, on the direction of the line joining the nucleotides. Our method works at a fixed resolution – the string length. Second, the algorithm of CGR looks a bit more complicated: put a, c, g, and t at the four corners of a square; starting from the center of the square plot the middle point of the straight line connecting two consecutive nucleotides one by one. The results turn out to be much the same as simple counting with fixed string length. Third, if one wish to introduce color in order to add more information one should calculate the density of points in CGR – an operation that requires big memory and that cannot be realized in a single pass. Therefore, it seems to us that the proposed visualization scheme makes CGR obsolete.

3. Fractals derived from bacterial "portraits"

In genomes of organisms there are no fractals in the rigorous mathematical sense. However, in our visualization scheme fractals may be well defined in the non-biological $K \to \infty$ limit. These fractals may have some suggestion in the portraits of genomes of real organisms. Looking at the templates shown in Fig. 2, one naturally sees that what is left in the original framework after deleting all small squares at finer and finer scales that represent all possible *ctag*-tagged strings does lead to a fractal. What is the fractal dimension of the complementary pattern defined by one or more given tags? This is not a trivial question as besides obvious self-similarity one has to deal with self-overlappings of the excluded patterns at different levels.

Let us look at two simple examples.

The first example is the case of a one-letter tag, e.g., g-tagged strings. Denote by a_K the number of strings of length K that do not contain the letter g. At the zeroth level the linear size is $\delta_0 = 1$, that is the size of the whole square. Since there is only one empty string which by definition does not contain g we have $a_0 = 1$. At the next $K = 1$ level, the linear size is $\delta_1 = 1/2$ and among the four squares of that size three do not contain g. Therefore, we have $a_1 = 3$. In general, we have $\delta_K = 1/2^K$ and $a_K = 3^K$. The fractal dimension is

$$D = -\lim_{K\to\infty} \frac{\log a_K}{\log \delta_K} = \frac{\log 3}{\log 2}\,. \tag{1}$$

In this simple example, we might have defined a trivial recursion relation for a_K, namely,

$$a_0 = 1\,,$$

$$a_K = 3a_{K-1}\,.$$

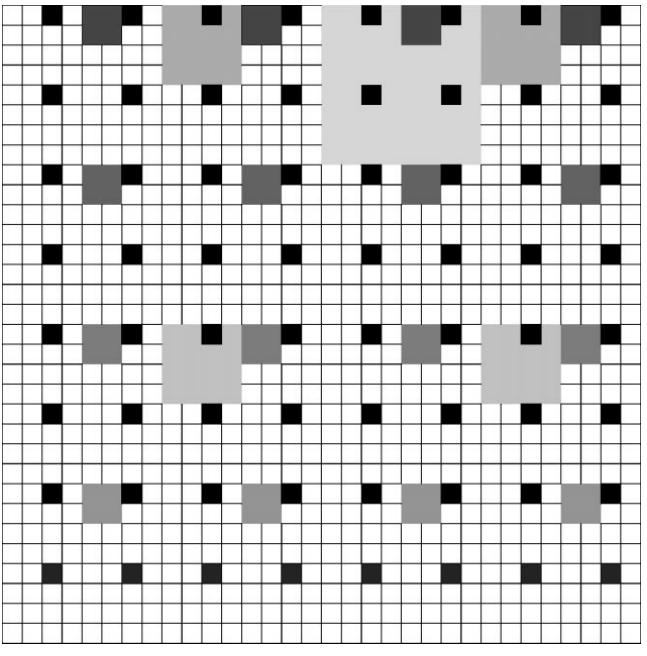

Fig. 4. A template for *gc*-tagged strings showing the overlaps at different levels.

Using the recursion relation one may derive a generating function $f(s)$ for all a_K:

$$f(s)=\sum_{K=0}^{\infty} a_K s^K=\frac{1}{1-3s}\,,$$

where s is an auxiliary variable. In fact, one-letter-tagged strings exclude the largest number of K-strings, leaving a set of strings over an alphabet of three letters. This is the meaning of $a_K=3^K$ and this tells us that for any possible tags the dimensions are included in between the limits:

$$\frac{\log 3}{\log 2}\leqslant D_{\text{tag}}\leqslant 2\,.$$

Next, look at *cg*-tagged strings. We first note that it is a known fact that in many human genes the dinucleotide *cg* is less represented than, e.g., the dinucleotide *gc*. This leads to a characteristic pattern in the portrait of the DNA sequence that contains the gene. As seen from the template for the *cg* tag, shown in Fig. 4, the exclusion starts at the level $K=2$: among the 16 possible dinucleotides only *cg* is avoided. At $K=3$ level, among the 64 trinucleotides the four combinations xcg, $x=\{a,c,g,t\}$ are excluded in addition to the four $cgx, x=\{a,c,g,t\}$ which have already been excluded at the $K=2$ level. So far, no overlap of exclusions has taken place. However, at the next $K=4$ level, one of the 16 $xycg$ type squares, where $x,y=\{a,c,g,t\}$, namely, $cgcg$, is immersed in the $K=2$ excluded square and should not be doubly counted.

There are eight such overlaps at $K=5$, 47 at $K=6$ (not shown in Fig. 4), etc. The question is how to take into account these overlaps automatically. Suppose we know

Table 3
Generating function and dimension for some single tags

Tag	$f(s)$	D	Tag	$f(s)$	D
g	$\frac{1}{1-3s}$	$\frac{\log 3}{\log 2}$	ggg	$\frac{1+s+s^2}{1-3s-3s^2-3s^3}$	1.98235
gc	$\frac{1}{1-4s+s^2}$	1.89997	$ctag$	$\frac{1}{1-4s+s^4}$	1.99429
gg	$\frac{1+s}{1-3s-3s^2}$	1.92269	$ggcg$	$\frac{1+s^3}{1-4s+s^3-3s^4}$	1.99438
gct	$\frac{1}{1-4s+s^3}$	1.97652	$gcgc$	$\frac{1+s^2}{1-4s+s^2-4s^3+s^4}$	1.99463
gcg	$\frac{1+s^2}{1-4s+s^2-3s^3}$	1.978	$gggg$	$\frac{1+s+s^2+s^3}{1-3s-3s^2-3s^3-3s^4}$	1.99572

how to calculate the generating function

$$f(s)=\sum_{K=0}^{\infty} a_K s^K\,, \tag{2}$$

then the fractal dimension is given by

$$D=-\lim_{K\to\infty}\frac{\log a_K}{\log \delta_K}=\lim_{K\to\infty}\frac{\log a_K^{1/K}}{\log 2}\,, \tag{3}$$

where we have used the fact that $\delta_K=1/2^K$. According to the Cauchy criterion the radius of convergence of the series (2) defining the generating function is determined by

$$\lim_{K\to\infty} a_K^{1/K}=\frac{1}{s_0}\,,$$

s_0 being the minimal module zero of $f^{-1}(s)$. Thus if we know the generating function, the fractal dimension is given by

$$D=-\frac{\log|s_0|}{\log 2}\,. \tag{4}$$

Therefore, the problem of calculating the fractal dimensions reduces to that of finding the generating functions. This will be treated in Sections 5 and 6 by using two different methods.

We shall see that for the cg-tagged strings the generating function is

$$f(s)=\frac{1}{1-4s+s^2}\,,$$

see Table 3. Consequently, $s_0=1/2-\sqrt{3}$ and $D=1.8999686$.

4. Number of true and redundant avoided strings by direct counting

Once we know that there might be avoided and under-represented strings from the visualization scheme, we can perform a direct identification of avoided strings.

The direct counting has the merit that the string length K is not seriously limited by the screen resolution. While the maximal K is 9 without scrolling the figure behind the screen, in direct counting one can go to longer K. In addition, direct counting does not miss any avoided strings while naked-eyes could only notice the most prominent ones. We show some of the results of direct counting in Table 2. In Table 2 K_0 is the minimal string length at which the first avoided strings are identified. N_{K_0} is the number of avoided strings at length K_0. In the list of avoided strings palindromic substrings are capitalized.

It is a remarkable fact that the first avoided strings appear at length $K_0 = 6$, 7, or 8 in all bacterial genomes, while statistically significant avoidance can only occur at much longer length in a random sequence.

The direct counting poses another question, namely, how to count the number of true and redundant avoided strings. For example, in the genome of *E. coli* the first avoided string *gcctagg* is identified at $K = 7$ in contrast to a random sequence of same length and nucleotide composition which would have each type of 7 strings appearing about 283 times. At the next length $K = 8$ a total of 173 strings are found absent. However, among these 173 strings 8 must be the consequence of the lack of *gcctagg*. Thus there are 165 true avoided strings at $K = 8$. Among the 5595 avoided 9 strings 48 are the consequence of *gcctagg* being absent, 1166 are redundant being the consequence of the 165 true avoided 8 strings, only 4381 are true avoided ones at $K = 9$. Among these 4381 strings 2041 do contain the palindromic tetranulcleotide *ctag*. At $K = 10$ there are 114 808 true avoided strings among a total of 150 409, while 256, 6531, and 28 814 are redundant strings caused by the absence of true avoided strings at length 7, 8, and 9. How to count the number of redundant strings at each K? A simple-minded estimate shows that a true avoided K-string takes away

$$E(i) = 4^i(i+1) \tag{5}$$

$(K+i)$-strings. We list the first $E(i)$ below for later comparison:

i	0	1	2	3	4	5	6	7
$E(i)$	1	8	48	256	1280	6144	28 672	131 072

This is obtained as follows. At the $K+1$ level one can add one letter from the alphabet either in front or at the end of the avoided K-string, thus there are $4+4$ redundant avoided strings at length $K+1$. At the next length $K+2$ there are three ways to add 2 letters to the avoided K-string to get avoided $(K+2)$-strings, each way having 4×4 combinations of letters. Continuation of the argument leads to Eq. (5). However, this is usually an over-estimation, as it does not take into account the overlaps of letters at the begining and the end of a string. A simple counter-example being the 4-string *gggg*: there are only 7 new 5 strings as adding a *g* to the head or the tail yields the same string *ggggg*.

A little reflection shows that the calculation of the generating function for given tags and the counting of the true and redundant avoided strings are one and the same

problem. Indeed, both problems need to take into account the overlap of substrings in making longer strings. The fractals provide a geometric representation of the problem as each small square corresponds to a well-defined type of K-string.

5. Combinatorial solution

We first formulate the problem in terms of combinatorics. Let Σ be an alphabet, e.g., $\Sigma = \{a, c, g, t\}$. Denote by Σ^* the set of all possible finite strings made of letters from the alphabet Σ, including the empty string. Given a set $B \in \Sigma^*$ of "bad" words that we wish to avoid in all words we are going to use. Let $A \in \Sigma^*$ be the set of all "clean" words that do not contain any member of B as substrings. Denote by a_K the number of clean words of length K.

Problem. Given Σ^*, B, calculate a_K or even better calculate the generating function (2) that gives a_K for all K.

5.1. The Goulden–Jackson cluster method

In combinatorics there exists a powerful method to deal with this kind of problems – the Goulden–Jackson cluster method [5]. This method has been well described by Noonan an Zeilberger [6]. However, we explain its basic idea and derivation in our specific context. First, we assign a weight to each word ω: it is an auxiliary variable s raised to the power $|\omega|$ where $|\omega|$ is the length of the word ω:

$$\text{weight}(\omega) = s^{|\omega|} .$$

If we can calculate the sum of weights over all clean words and reorder the terms according to the word length:

$$f(s) = \sum_{\omega \in A} \text{weight}(\omega) = \sum_{K=0}^{\infty} a_K s^K ,$$

our task would be accomplished. Let us extend the summation over clean words to that over all words

$$\sum_{\omega \in A} \Rightarrow \sum_{\omega \in \Sigma^*}$$

and at the same time multiply each weight(ω) by a zero raised to the power of the number of "bad" factors in ω:

$$\text{weight}(\omega) \Rightarrow \text{weight}(\omega) \times 0^{\text{number of factors of } \omega \text{ that } \in B} ,$$

where by definition

$$0^0 = 1 ,$$
$$0^m = 0, \quad m \geqslant 1 .$$

Now let us manipulate the power of zero. Suppose we have a set of 3 objects, say, $S=\{a_1,a_2,a_3\}$ and we multiply three zeros $\prod_{a_i\in S}0$. We reorganize the elements of S into subsets:

$$\{\sigma_i\}=\{\varepsilon;a_1,a_2,a_3;a_1a_2,a_2a_3,a_3a_1;a_1a_2a_3\}\,,$$

where ε denotes an empty subset. There are $2^3=8$ subsets. The product of three zeros may be rewritten as a sum over these 8 subsets:

$$\prod_{a_i\in S}0=\prod_{a_i\in S}[1+(-1)]=\sum_{\{\sigma_i\}}(-1)^{|\sigma|}\,,$$

where $|\sigma|$ is the cardinality of the subset σ_i, i.e., the number of elements in σ_i. This is a particular case of so-called Sylvester principle of inclusion–exclusion.

Now we can write

$$f(s)=\sum_{\omega\in\Sigma^*}\sum_{\sigma\in\mathrm{Bad}(\omega)}(-1)^{|\sigma|}s^{|\omega|}\,,$$

where $Bad(\omega)$ denotes the set of bad factors of ω. In fact, we have got a new counting problem for a collection of new subjects (ω,σ) with a new weight function $(-1)^{|\sigma|}s^{|\omega|}$. These (ω,σ) may be called *tagged words*, i.e., a word ω tagged by a factor $\sigma\in Bad(\omega)$. Note that a tag σ may be a combination of none or several bad factors of ω. When the tag is empty, $\sigma=\varepsilon$, the word is clean.

Denote the set of all tagged words as $\mathscr{M}=\{(\omega,\sigma)\}$. The weight of set $\mathscr{M}$ remains $f(s)$. Without loss of generality, we can examine all words in $\mathscr{M}$ starting from their right end. The set $\mathscr{M}$ contains an empty word. There are words in $\mathscr{M}$ that contain a single letter from the alphabet that does not form a part of any member of B. There are words in $\mathscr{M}$ that contain a cluster of bad members from B. Thus in set-theoretical notation we may write

$$\mathscr{M}=\{\text{empty word}\}\cap\mathscr{M}\Sigma\cap\mathscr{M}\mathscr{C}\,,$$

where $\mathscr{C}$ denotes clusters of bad words.

Written in terms of weight functions, we have

$$f(s)=1+f(s)ds+f(s)\mathrm{weight}(\mathscr{C})\,.$$

Therefore, we have

$$f(s)=\frac{1}{q-ds-\mathrm{weight}(\mathscr{C})}\,. \tag{6}$$

In the above formulas $d=|\Sigma|$ is the cardinality of the alphabet Σ. In our case of nucleotides $d=4$. When the set B is empty, i.e., no bad words at all, we have the trivial result

$$f(s)=\frac{1}{1-4s}\,. \tag{7}$$

This is just a pedantic way to say that there are 4^K words of length K.

When the set B contains only one word u that cannot make clusters with itself, e.g., $u = gct$, one simply has weight($\mathscr{C}$) $= s^{|u|}$ and the problem is solved:

$$f(s) = \frac{1}{1 - 4s - s^{|u|}} \,. \tag{8}$$

When the bad word can make clusters with itself, e.g., $u = gcg$ and a cluster being $gcgcg$, the situation is more complex and requires the technique described in the next subsection. Anticipating a few such results, we list all possible single-tag generating functions in Table 3 up to tag length $K = 4$.

A related question is the number $G(n)$ of different types of generating functions for a given tag length n. These numbers turn out to be independent of the size of the alphabet Σ as long as there are more than two letters in Σ [7]:

n	1	2	3	4	5	6	7	8	9	10	11	12	13	14
$G(n)$	1	2	3	4	6	8	10	13	17	21	27	30	37	47

In fact, these $G(n)$ are so-called correlations of n as given by the integer sequence $M0555$ in Ref. [8], see also Ref. [7].

Applying the Goulden–Jackson cluster method to the case of only one "bad word" $gcctagg$ in the case of *E. coli* leads to the following generating function:

$$f(s) = \frac{1 + s^6}{1 - 4s + s^6 - 3s^7} \,.$$

The number of redundant avoided strings is obtained by subtracting the above $f(s)$ from that of the "no-bad-words" case (7):

$$\frac{1}{1 - 4s} - f(s) = s^7 + 8s^8 + 48s^9 + 256s^{10} + 1280s^{11} + 6144s^{12} + 28671s^{13} + 131063s^{14} + \cdots \,.$$

These coefficients are to be compared with the naive estimates given below Eq. (5). As expected, the deviation appears from the term s^{13}.

5.2. Weight function for clusters

In order to continue with the full representation of the Goulden–Jackson method we take the newly published complete genome of the hyperthermophilic bacterium *Aquifex aeolicus* [9] as a non-trivial example. For this 1 551 335-letter sequence four avoided strings are identified at string length $K = 7$:

$$B = \{gcgcgcg, gcgcgca, cgcgcgc, tgcgcgc\} \,. \tag{9}$$

Since there are significant overlaps among the avoided strings, the naive estimate of redundant avoided words can hardly work. To treat clusters of bad words we introduce

a few notations. Suppose that there are two bad words $u, v \in B$. Define

$$Head[v] = \{\text{proper prefixes of } v\} ,$$

$$Tail[u] = \{\text{proper suffixes of } u\} ,$$

$$Overlap(u, v) = Tail[u] \cap Head[v] .$$

Note that the definition of $Overlap(u, v)$ is not symmetric. Take for example, $u = gcgcgcg$ and $v = gcgcgca$, we have

$$Head[u] = Head[v] = \{g, gc, gcg, gcgc, gcgcg, gcgcgc\} ,$$

$$Tail[u] = \{g, cg, gcg, cgcg, gcgcg, cgcgcg\} ,$$

$$Tail[v] = \{a, ca, gca, cgca, gcgca, cgcgca\} ,$$

$$Overlap(u, u) = \{g, gcg, gcgcg\} ,$$

$$Overlap(u, v) = \{g, gcg, gcgcg\} ,$$

$$Overlap(v, u) = \{\ \} = \Phi ,$$

$$Overlap(v, v) = \{\ \} = \Phi ,$$

where Φ denotes an empty set. If $v = xx'$ we write $v/x = x'$. Thus $v/gcg = cgca$. The weight of $Overlap(u, v)$ is denoted as

$$(u : v) = \sum_{x \in \text{Overlap}(u,v)} \text{weight}(v/x) .$$

Using the two above u, v as example, we have

$$\begin{aligned}(u : v) &= \sum_{x \in \{g,gcg,gcgcg\}} \text{weight}(gcgcgca/x) \\ &= \text{weight}(cgcgca) + \text{weight}(cgca) + \text{weight}(ca) \\ &= s^6 + s^4 + s^2 .\end{aligned}$$

In general, we may have $B = \{u_1, u_2, \ldots, u_L\}$. A cluster $\mathscr{C}$ may contain a different bad word at the rightmost end. We write

$$\mathscr{C} = \sum_{u_i \in B} C[u_i] ,$$

where $C[u]$ is a cluster with u being the rightmost part.

As $C[v]$ may consist of either a single v or several entangled bad words, we again have a set-theoretical relation:

$$C[v] \Leftrightarrow \{v\} \bigcup_{u \in B} C[u]\text{Overlap}(u, v) .$$

In terms of weight functions we have

$$\text{weight}(C[v]) = -\text{weight}(v) - \sum_{u \in B} (u : v)\text{weight}(C[u]) .$$

This is a system of L linear equations, L being the cardinality of the set B, i.e., $L=|B|$. The minus sign in the equation comes from the weight $(-1)^{|\sigma|}$ as $|\sigma|=1$.

In the case of *Aquifex aeolicus* $L=4$, see (9). The *Overlap* matrix is

$$\mathrm{Overlap}(u_i,u_j)=\begin{vmatrix} \begin{Bmatrix} g \\ gcg \\ gcgcg \end{Bmatrix} & \begin{Bmatrix} g \\ gcg \\ gcgcg \end{Bmatrix} & \begin{Bmatrix} cg \\ cgcg \\ cgcgcg \end{Bmatrix} & \Phi \\ \Phi & \Phi & \Phi & \Phi \\ \begin{Bmatrix} g \\ gcg \\ gcgcg \end{Bmatrix} & \begin{Bmatrix} g \\ gcg \\ gcgcg \end{Bmatrix} & \begin{Bmatrix} c \\ cgc \\ cgcgc \end{Bmatrix} & \Phi \\ \begin{Bmatrix} g \\ gcg \\ gcgcg \end{Bmatrix} & \begin{Bmatrix} g \\ gcg \\ gcgcg \end{Bmatrix} & \begin{Bmatrix} c \\ cgc \\ cgcgc \end{Bmatrix} & \Phi \end{vmatrix}.$$

We have further

$$(u_i:u_j)=\begin{vmatrix} p & p & q & 0 \\ 0 & 0 & 0 & 0 \\ q & q & p & 0 \\ q & q & p & 0 \end{vmatrix},$$

where

$$p=s^2+s^4+s^6,$$
$$q=s+s^3+s^5.$$

Therefore, the application of the Goulden–Jackson cluster method requires the solution of a system of four linear equations and leads to the following generating function:

$$f(s)=\frac{1+s^2+s^4+s^6+s^8+s^{10}+s^{12}}{1-4s+s^2-4s^3+s^4-4s^5+s^6-4s^8-4s^{10}-4s^{12}}.$$

The numbers of redundant avoided strings are given by

$$\frac{1}{1-4s}-f(s)=4s^7+27s^8+152s^9+784s^{10}+3840s^{11}+18176s^{12}+83968s^{13}+\cdots. \tag{10}$$

The coefficients coincide with the negative numbers in the last row of Table 5.

6. Language theory solution

Language theory is not just a formal object. Properly applied to the right problem it may provide computational frameworks and useful constructions to yield quite practical

results. We will make use of a special class of languages, namely, so-called factorizable language. However, we start with a brief summary of language theory in general.

6.1. Elements of language theory

One again begins with a finite *alphabet*, e.g., $\Sigma = \{a, c, g, t\}$ and collects all possible strings made of these letters into an infinite set Σ^*, including the empty string ε, i.e., a string that does not contain any letter.

Any subset $L \in \Sigma^*$ is said to be a *language* over the alphabet Σ. With such a general definition one cannot get very far. One has to specify how the subset L is formed. This may be done in many ways. For example,

(i) If the subset L is finite, one can simply enumerate its elements.

(ii) One can devise some production rules and by applying these rules repetitively to some initial letters one generates the language. This is by far the most important and well-studied way of defining languages. If the rules are to be applied sequentially it leads to the generative grammar of N. Chomsky. If applied in parallel this leads to the Lindenmayer or L-systems. Referring the interested readers to Ref. [10] and literature cited therein, we will not go into details of these generative grammars.

(iii) For a special class of languages, namely, the factorizable languages, one can define a language by indicating its set of *forbidden words*. This is the approach we are going to follow in this paper.

However, before turning to the factorizable language we formulate a few more notions which will be needed later.

According to the Chomsky classification the simplest language is called *regular language* which may be accepted or recognized by a finite automaton without any memory. A finite automaton has a finite number of states and it makes transition from one state to another by looking at an input symbol and a table of transition rules. In fact, the table of rules defines a discrete *transfer function*. For finite automata the set of input symbols is also finite. There are two kinds of finite automata: deterministic and non-deterministic. In a deterministic automaton there is a starting state and the transition rule from one state to another upon seeing a certain input symbol is unique. In a non-deterministic automaton one has the freedom to choose the start state and to decide which rule to use at a transition as there might be more than one rule for one and the same input symbol. To avoid any confusion we emphasize that deterministic and non-deterministic automata are entirely equivalent in their capability to define a regular language. There may be more than one automata that define one and the same language. Among deterministic automata defining a language there is a minimal one, namely, one with a minimal number of states. This is called a minimal deterministic finite automaton of the language and is denoted as $\min DFA(L)$.

To determine whether a language is regular or not, sometimes the following *Equivalence Relation* is quite helpful. Any language $L \in \Sigma^*$ introduces an equivalence relation R_L in Σ^* with respect to L: any two elements $x, y \in \Sigma^*$ are equivalent and denoted

as $xR_L y$ if and only if for every $z \in \Sigma^*$ both xz and yz either belong to L or not belong to L. As usual, the index of R_L is the number of equivalence classes in Σ^* with respect to L. An equivalence class may be represented by any element of that class, say, $x \in L$, we will denote its equivalence class by $[x]$.

So far we have used only general notions of language theory. The importance of the equivalence relation R_L is due to the following *Myhill-Nerode Theorem* (see references in Ref. [10]):

(i) The language L is regular if and only if the index of R_L is finite.
(ii) The language L being regular implies that min$DFA(L)$ is unique up to an isomorphism, namely, renaming of the states.
(iii) The number of states of min$DFA(L)$ is given by the index of R_L.

6.2. Factorizable language

Once a language $L \in \Sigma^*$ has been defined, its complementary set $L' = \Sigma^* - L$ contains all words that do not appear in L. A language L is called *factorizable* if any substring of a word $x \in L$ also belongs to L. In this case the complementary set L' contains a minimal core L'' such that although any word $x \in L''$ is forbidden in L, any proper substring of x belongs to L. Sometime we simply call L'' the set of forbidden words. It is nothing but what Wolfram called *Distinct Excluded Blocks* (DEBs) in the grammatical analysis of cellular automata [11]. Owing to the factorizability we can express the complementary set as $L' = \Sigma^* L'' \Sigma^*$. This means that L is entirely determined by the minimal set of forbidden words or DEBs. Written in set theory terms we have

$$L = \Sigma^* - \Sigma^* L'' \Sigma^* .$$

There are at least two important classes of factorizable language: dynamical language and the language defined by a complete genome.

It is a natural consequence of dynamical-evolution that symbolic sequences encountered in symbolic dynamics of dynamical systems come under the definition of factorizable language, as any small part of a trajectory is also produced by the same dynamics. Furthermore, these languages are *prolongable* as one can always append at least one letter from the alphabet to make an admissible word longer. Factorizability and prolongability together make the class of dynamical languages [10]. However, we will not make use of prolongability in the context of this work.

A second class of factorizable language may be defined from a complete genome: given a complete genome G of an organism, consisting of one or more linear or circular DNA sequences. One cuts the DNA sequences into all possible subsequences and forms a language $L = sub(G)$ by collecting these subsequences, including the empty string. This language is factorizable by definition. It is almost prolongable if one does not extend it beyond the total length of the genome. The factorizability alone is enough for our purpose.

6.3. Minimal deterministic automaton accepting the Aquifex aeolicus genome

Now we show how language theory works on our familiar example of the *Aquifex aeolicus* complete genome. Although there are longer avoided strings we take the set B given by Eq. (9) to be its set L'' of forbidden words for the time being. Since B is finite, the factorizable language defined by B is regular. In order to construct the automaton we have to know all the equivalence classes of Σ^* with respect to L. We make use of the following mathematical result [10].

Let L be a factorizable language and L'' be its set of all DEBs. Define

$$V = \{v, v \text{ is a proper prefix of some } y \in L''\} .$$

Then for each word $x \in L$ there exists a string $v \in V$ such that is equivalent to x, or, in our notations, $xR_L v$. In other words, all equivalence classes of Σ^* with respect to L are represented in the set V. Therefore, in order to find all equivalence classes of Σ^* with respect to L it is enough to work with L''. We note in passing that $[\varepsilon]$ is always an equivalence class, and the complementary set L' makes another equivalence class.

From the proper suffixes of the avoided strings in B we get the set

$$V = \{g, gc, gcg, gcgc, gcgcg, gcgcgc, c, cg, cgc, cgcg ,$$
$$cgcgc, cgcgcg, t, tg, tgc, tgcg, tgcgc, tgcgcg\} .$$

By checking the equivalence relations among these strings only 13 out of 18 are kept as representatives of each class. Adding the class $[L'] \subset \Sigma^*$ we get the following 14 equivalence classes of Σ^*:

$$[\varepsilon]\ [g]\ \ [gc]\ \ [gcg]\ \ [gcgc]\ \ [gcgcg]\ \ [gcgcgc]$$
$$[c]\ [cg]\ [cgc]\ [cgcg]\ [cgcgc]\ [cgcgcg]\ [L'] .$$

We note that the task of "checking the equivalence relations" may seem formidable as the requirement "for every $z \in \Sigma^*$" concerns an infinite set. However, a little practice shows that this may be done effectively without too much work.

The transfer function is defined by

$$\delta([x_i], s) = [x_i s] \quad \text{for } x_i \in V \text{ and } s \in \Sigma .$$

Therefore, our task is to attribute each $[x_i s]$ to one of the existing equivalence classes. The discrete transfer function is listed in Table 4. The particular function relation $\delta([x_i], s) = [L']$ leads to a "dead end".

One can draw the minimal deterministic automaton according to the above transfer function. As it is no longer a planar graph we do not show it here. By counting

Table 4
The transfer function for the minimal deterministic automaton for *Aquifex aeolicus*

$[x_i] \setminus s$	a	c	g	t
$[\varepsilon]$	$[\varepsilon]$	$[c]$	$[g]$	$[c]$
$[g]$	$[\varepsilon]$	$[gc]$	$[g]$	$[c]$
$[gc]$	$[\varepsilon]$	$[c]$	$[gcg]$	$[c]$
$[gcg]$	$[\varepsilon]$	$[gcgc]$	$[g]$	$[c]$
$[gcgc]$	$[\varepsilon]$	$[c]$	$[gcgcg]$	$[c]$
$[gcgcg]$	$[\varepsilon]$	$[gcgcgc]$	$[g]$	$[c]$
$[gcgcgc]$	$[L']$	$[c]$	$[L']$	$[c]$
$[c]$	$[\varepsilon]$	$[c]$	$[cg]$	$[c]$
$[cg]$	$[\varepsilon]$	$[cgc]$	$[g]$	$[c]$
$[cgc]$	$[\varepsilon]$	$[c]$	$[cgcg]$	$[c]$
$[cgcg]$	$[\varepsilon]$	$[cgcgc]$	$[g]$	$[c]$
$[cgcgc]$	$[\varepsilon]$	$[c]$	$[cgcgcg]$	$[c]$
$[cgcgcg]$	$[\varepsilon]$	$[L']$	$[g]$	$[c]$

the number of lines leading from one state to another, we write down an *incidence matrix*:

$$M = \begin{bmatrix}
1 & 1 & & & & & & 2 & & & & & \\
1 & 1 & 1 & & & & & 1 & & & & & \\
1 & & & 1 & & & & 2 & & & & & \\
1 & 1 & & & 1 & & & 1 & & & & & \\
1 & & & & & 1 & & 2 & & & & & \\
1 & 1 & & & & & 1 & 1 & & & & & \\
 & & & & & & & 2 & & & & & \\
1 & & & & & & & 2 & 1 & & & & \\
1 & 1 & & & & & & 1 & & 1 & & & \\
1 & & & & & & & 2 & & & 1 & & \\
1 & 1 & & & & & & 1 & & & & 1 & \\
1 & & & & & & & 2 & & & & & 1 \\
1 & 1 & & & & & & 1 & & & & &
\end{bmatrix} .$$

The columns and rows of the matrix M are ordered as elements in the first column in Table 4 of the transfer function.

To make connection with the generating function (2) we note that the characteristic polynomial of M is related to $f(1/\lambda)$:

$$\det(\lambda I - M) = \lambda^{13} f\left(\frac{1}{\lambda}\right) .$$

Moreover, the sum of elements in the first row of the Kth power of M is nothing but a_K [11]:

$$a_K = \sum_{j=1}^{13} (M^K)_{1j} .$$

Table 5
Elements of the first row of M_K (shown as columns) and their sum. The negative numbers in the last row are the difference between a_K and 4^K

K	1	2	3	4	5	6	7	8	9	10	11
	1	4	16	64	256	1024	4095	16 378	65 501	261 960	1 047 664
	1	2	8	32	128	512	2048	8190	32 756	131 002	523 920
	0	1	2	8	32	128	512	2048	8190	32 756	131 002
	0	0	1	2	8	32	128	512	2048	8190	32 756
	0	0	0	1	2	8	32	128	512	2048	8190
	0	0	0	0	1	2	8	32	128	512	2048
	0	0	0	0	0	1	2	8	32	128	512
	2	7	28	112	448	1792	7168	28 665	114 640	458 483	1 833 624
	0	2	7	28	112	448	1792	7168	28 665	114 640	458 483
	0	0	2	7	28	112	448	1792	7168	28 665	114 640
	0	0	0	2	7	28	112	448	1792	7168	28 665
	0	0	0	0	2	7	28	112	448	1792	7168
	0	0	0	0	0	2	7	28	112	448	1792
Sum	4	16	64	256	1024	4096	16 380	65 509	261 992	1 047 792	4 190 464
							−4	−27	−152	−784	−3840

The summation runs over all equivalence classes except for L'. We list the elements of the first row of M^K in columns of Table 5.

The negative numbers in the last row of Table 5 show the difference between a_K and 4^K. They are precisely the coefficients in the expansion (10) of $1/(1-4s)-f(s)$, shown at the end of Section 5.2. We see that the transfer function and the incidence matrix contain more detailed information on the combinatorial problem than the generating function alone. The implication of this approach needs to be further elucidated.

In order to avoid any confusion we emphasize that the minimal deterministic automaton defined by the transfer function given in Table 4 accepts a regular language determined by the set B of four forbidden words. This language is larger than the language $sub(G)$ obtained from the complete genome of *Aquifex aeolicus*. By including more and more avoided strings into the set B the minimal automaton gets larger but the language it accepts approaches $sub(G)$ gradually. However, the calculation becomes tedious.

Acknowledgements

The author would like to thank Hoong-Chien Lee, Shu-yu Zhang, Hui-min Xie, Zu-guo Yu, and Guo-yi Chen, with whom one or another part of this research was carried out. He also thanks D. Zeilberger for calling his attention to the Goulden–Jackson cluster method. The hospitality and support of the Abdus Salam International Centre for Theoretical Physics, Trieste, where a substantial part of this review was

written, is also gratefully acknowledged. This work was supported in part by the China Natural Science Fondation and the State Project on Nonlinear Science.

AMS Subject Classification: 05A15, 92C40

Abstract. The visualization of avoided and under-represented strings in some bacterial complete genomes raises a combinatorical problem which may be solved either by using the Goulden–Jackson cluster method or by construction of the minimal finite automaton defined by the set of forbidden words of the corresponding language.

Keywords: complete genomes, avoided strings, language, enumeration, fractal

1. Introduction

The heredity information of organisms (except for so-called RNA-viruses) is encoded in their DNA sequence which is a one-dimensional unbranched polymer made of four different kinds of monomers (nucleotides): adenine (a), cytosine (c), guanine (g), and thymine (t). As far as the encoded information is concerned, we can ignore the fact that DNA exists as a double helix of two "conjugated" strands and only treat it as a one-dimensional symbolic sequence made of the four letters from the *alphabet* $\Sigma = \{a, c, g, t\}$. Since the first complete genome of a free-living bacterium *Mycoplasma genitalium* was sequenced in 1995, an ever-growing number of complete genomes has been deposited in public databases. The availability of complete genomes opens the possibility to ask some global questions on these sequences. One of the simplest conceivable questions consists of checking whether there are short strings of letters that are absent or under-represented in a complete genome. The answer is in the affirmative and the fact may have some biological meaning [4].

The reason why we are interested in absent or under-represented strings is twofold. First of all, this is a question that can only be asked in the present day when complete genomes are at our disposal. Second, the question makes sense as one can derive a *factorizable* language from a complete genome which would be entirely defined by the set of forbidden words.

We start by considering how to visualize the avoided and under-represented strings in a bacterial genome whose length is usually the order of a million letters.

* Partially Supported by the CNSF. † On leave from the Department of Mathematics, Suzhou University, Jiangsu 215006, China.

2. Visualization of Under-Represented Strings

There are 4^K different strings of length K made of four letters. In order to check whether all these strings appear in a genome we use 4^K counters to be visualized as a $2^K \times 2^K$ square array on a computer screen. These can be realized as a direct product of K identical 2×2 matrices:

$$M^{(K)} = M \otimes M \otimes \cdots \otimes M,$$

where

$$M = \begin{pmatrix} g & c \\ a & t \end{pmatrix}.$$

We call this $2^K \times 2^K$ square a K-frame. In practice it is convenient to use binary subscripts for this 2×2 matrix and it is easy to develop an algorithm that depends only on the total length of the genome but not on the string length K. Put in a frame of fixed K and described by a color code biased towards small counts, each bacterial genome shows a distinctive pattern which indicates on absent or under-represented strings of certain types [4]. For example, many bacteria avoid strings containing the string *ctag*. Any string that contains *ctag* as a substring will be called a *ctag*-tagged string. If we mark all *ctag*-tagged strings in frames of different K, we get pictures as shown in

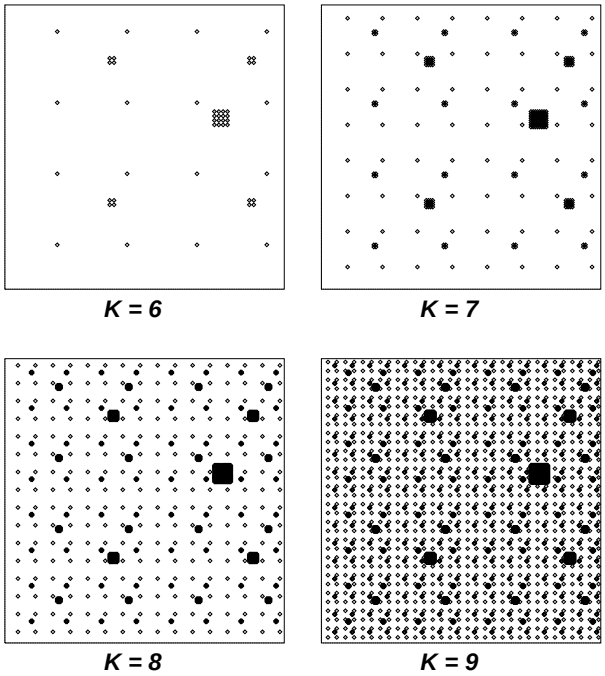

Figure 1: *Ctag*-tagged strings in $K = 6$ to 9 frames.

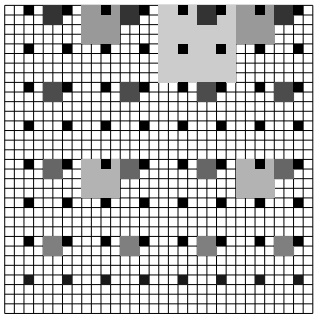

Figure 2: The pattern of *cg*-tagged strings showing the overlaps.

Figure 1. The large scale structure of these pictures persists but more details appear with growing K. Excluding the area occupied by these tagged strings, one gets a fractal in the $K \to \infty$ limit. It is natural to ask what is the dimension of this fractal for a given tag.

In fact, this is the dimension of the complementary set of the tagged strings. The simplest case is that of *g*-tagged strings. As the pattern has an apparently self-similar structure, the dimension is easily calculated to be

$$D = \frac{\log 3}{\log 2}.$$

Moreover, the dimension of all other cases must lie in between $\log 3/\log 2$ and 2. However, the calculation of these dimensions is somewhat tricky as one must take into account the overlap of patterns precisely (see, for example the case of *cg*-tagged strings shown in Figure 2).

Now let a_K be the number of all strings of length K that do not contain the given tag. As the linear size δ_K in the K-frame is $1/2^K$, the dimension may be calculated as:

$$D = \lim_{K\to\infty} \frac{\log a_K}{-\log \delta_K} = \lim_{K\to\infty} \frac{\log {a_K}^{1/K}}{\log 2}.$$

Suppose the generating function of a_K is known:

$$f(s) = \sum_{K=0}^{\infty} a_K s^K.$$

Then, according to the Cauchy criterion of convergence, we have

$$\lim_{K\to\infty} a_K^{1/K} = |\lambda| = \frac{1}{|s_0|},$$

where λ is the radius of convergence of series expansion of $f(s)$ and s_0 is the minimal module zero of $f^{-1}(s)$. This finally determines the dimension

$$D = -\frac{\log |s_0|}{\log 2}.$$

Table 1: Generating function and dimension for some single tags.

Tag	$f(s)$	D	Tag	$f(s)$	D
g	$\frac{1}{1-3s}$	$\frac{\log 3}{\log 2}$	ggg	$\frac{1+s+s^2}{1-3s-3s^2-3s^3}$	1.98235
gc	$\frac{1}{1-4s+s^2}$	1.89997	$ctag$	$\frac{1}{1-4s+s^4}$	1.99429
gg	$\frac{1+s}{1-3s-3s^2}$	1.92266	$ggcg$	$\frac{1+s^3}{1-4s+s^3-3s^4}$	1.99438
gct	$\frac{1}{1-4s+s^3}$	1.97652	$gcgc$	$\frac{1+s^2}{1-4s+s2-4s^3+s^4}$	1.99463
gcg	$\frac{1+s^2}{1-4s+s^2-3s^3}$	1.978	$gggg$	$\frac{1+s+s^2+s^3}{1-3s-3s^2-3s^3-3s^4}$	1.99572

The generating function for the numbers of strings of various length made of the four letters that do not contain certain designated strings ("bad words" as called in [6]) may be calculated by using the Goulden–Jackson cluster method [2], well-described by Noonan and Zeilberger [6]. In particular, the case of a single tag—one "bad word" only—is easily treated and some of the results are shown in Table 1.

A related question is the number $G(n)$ of different types of generating functions for a given tag length n. These numbers turn out to be independent upon the size of the alphabet Σ as long as there are more than two letters in Σ [3]:

n	1	2	3	4	5	6	7	8	9	10	11
$G(n)$	1	2	3	4	6	8	10	13	17	21	27

In fact, these $G(n)$ are so-called correlations of n as given by the integer sequence $M0555$ in [7] (see also [3]).

3. Redundant and True Avoided Strings

Once we know that there are avoided strings in the complete genomes from the visualization scheme, one can perform a direct search for these strings. The direct search has the merit not being significantly limited by the string length K. However, another combinatorical problem arises which is closely related to the problem discussed in the previous section. Take, for example, the complete genome of *E. coli*. At $K = 7$, the first avoided string *gcctagg* is discovered. At the next $K = 8$ level, a total of 173 avoided strings are identified. However, these 173 strings are not all true avoided strings as some must be the consequence of the absence of the $K = 7$ string *gcctagg*. A naive estimate of the redundant avoided strings without taking into account any possible overlap of substrings would lead to $4^i(i+1)$: If there is only one avoided string at the $K+0$ level, it would take away 8, 48, 256, 1280, ... strings at the next $K+i$ levels. This estimate works well for *E. coli* until $K = 13$ when the overlap of the first and the last letter g in the true avoided string *gcctagg* would show off. Applying the Goulden–Jackson cluster

method to the case of only one "bad word" *gcctagg* leads to the following generating function:

$$f(s) = \frac{1+s^6}{1-4s+s^6-3s^7}.$$

The number of redundant avoided strings are given by

$$\frac{1}{1-4s} - f(s) = s^7 + 8s^8 + 48s^9 + 256s^{10} + 1280s^{11} + 6144s^{12} + 28671s^{13} + 131063s^{14} + \cdots.$$

The deviation from the naive estimate appears from s^{13}.

For a non-trivial example, we consider the newly published complete genome of the hyperthermophilic bacterium *Aquifex aeolicus* [1]. For this, 155 1335-letter sequence four avoided strings are identified at $K = 7$. They form the set B of "bad words":

$$B = \{gcgcgcg,\ gcgcgca,\ cgcgcgc,\ tgcgcgc\}.$$

As there are significant overlaps among these strings, the naive estimate of redundant avoided words can hardly work. The application of the Goulden–Jackson cluster method requires the solution of a system of four linear equations and leads to the following generating function:

$$f(s) = \frac{1+s^2+s^4+s^6+s^8+s^{10}+s^{12}}{1-4s+s^2-4s^3+s^4-4s^5+s^6-4s^8-4s^{10}-4s^{12}}.$$

The numbers of redundant avoided strings are given by:

$$\frac{1}{1-4s} - f(s) = 4s^7 + 27s^8 + 152s^9 + 784s^{10} + 3840s^{11} + \cdots.$$

In what follows we show that these results may be obtained by an entirely different method, namely, by making use of formal language theory. For convenience of presentation, we first collect a few notions from language theory without proofs. The details may be found, e.g., in [9] and references therein.

4. Some Notions from Formal Language Theory

In formal language theory one starts with an alphabet, e.g., $\Sigma = \{a, c, g, t\}$. Let Σ^* denote the collection of all possible strings made of letters from Σ, including the empty string ε. Any subset $L \subset \Sigma^*$ is called a *language* over the alphabet Σ. The set $L' = \Sigma^* - L$ defines the complementary language. A language L is a factorizable language if any substring of a word $x \in L$ also belongs to L. A factorizable language has a minimal set of forbidden words or *Distinctive Excluded Blocks* [8] (DEBs) L'' such that, if $x \in L''$, then any proper substring of x belongs to L. A factorizable language is completely determined by its set of DEBs:

$$L = \Sigma^* - \Sigma^* L'' \Sigma^*.$$

A prominent example of factorizable language is given by the admissible symbolic sequences in the symbolic dynamics of a dynamical system (see, e.g., [5, 9]). Another class of factorizable languages may be obtained from a complete genome as follows. Let G be a complete genome of an organism; it may consist of one or more linear or circular sequences. All possible substrings of G, including the empty string ε and G itself, obviously form a subset of Σ^* and thus define a language which is factorizable by construction.

Any language $L \subset \Sigma^*$ introduces an equivalence relation R_L in Σ^* with respect to L. For any pair $x, y \in \Sigma^*$ xR_Ly if and only if for each $z \in \Sigma^*$, either both $xz, yz \in L$ or both $xz, yz \notin L$. The number of equivalence classes in Σ^* with respect to L defines the *index* of R_L, denoted by index(R_L).

An important theorem (Myhill–Nerode) says that L is a regular language if and only if index(R_L) is finite and L being regular implies that the minimal deterministic automaton corresponding to L, minDFA(L), is unique up to an isomorphism, i.e., to renaming of the states. Moreover, the number of states in minDFA(L) equals to index(R_L).

Let L be a factorizable language and L'' its set of all DEB's. Define a set

$$V = \{v | v \text{ is a proper prefix of some } y \in L''\}.$$

For each word $x \in L$, there exists a string $v \in V$ such that xR_Lv. In other words, all equivalence classes of L are represented in the set V. In order to find all equivalence classes of Σ^* with respect to L, it is enough to start from L''. In addition, L' is an equivalence class of Σ^*. For two given strings $u, v \in V$, uR_Lv if and only if for each $z \in \Sigma^*$ uz contains a DEB as its suffix $\Leftrightarrow$ $vz \in L'$ and *vice versa*. This statement sets the computation rule to identify all equivalence classes. Each equivalence class may be named after a member $x_i \in L$ and be denoted as $[x_i]$. The transfer function between states of minDFA(L) is defined as $\delta([x_i], s) = [x_is]$ for $x_i \in L$ and $s \in \Sigma$.

5. Finite Automaton and Incidence Matrix

Now we apply what has just been said to the complete genome of *Aquifex aeolicus* with its set B of four avoided strings at length $K = 7$. Although there are longer avoided strings we take B to be its L'' for the time being. From the proper suffixes of these strings, we get the set

$$\begin{aligned} V = \{&g, gc, gcg, gcgc, gcgcg, gcgcgc, c, cg, cgc, cgcg,\\ &cgcgc, cgcgcg, t, tg, tgc, tgcg, tgcgc, tgcgcg\}. \end{aligned}$$

By checking the equivalence class of these strings, only 13 out of these 18 strings are kept as representatives of each class. Adding the class $[L'] \subset \Sigma^*$, we get the following 14 equivalence classes of Σ^*:

$$\begin{aligned} &[\varepsilon]\ [g]\ \ [gc]\ \ [gcg]\ \ [gcgc]\ \ [gcgcg]\ \ [gcgcgc]\\ &[c]\ [cg]\ [cgc]\ [cgcg]\ [cgcgc]\ [cgcgcg]\ [L']. \end{aligned}$$

The transfer function $\delta([x_i], s) = [x_is]$, $x_i \in V$ and $s \in \Sigma$, is determined by attributing

Table 2: The transfer function for the minimal deterministic automaton for *Aquifex aeolicus*.

$[x_i]\backslash s$	a	c	g	t

$[gcg]$	$[\varepsilon]$	$[gcgc]$	$[g]$	$[c]$
$[gcgc]$	$[\varepsilon]$	$[c]$	$[gcgcg]$	$[c]$
$[gcgcg]$	$[\varepsilon]$	$[gcgcgc]$	$[g]$	$[c]$
$[gcgcgc]$	$[L']$	$[c]$	$[L']$	$[c]$
$[c]$	$[\varepsilon]$	$[c]$	$[cg]$	$[c]$
$[cg]$	$[\varepsilon]$	$[cgc]$	$[g]$	$[c]$
$[cgc]$	$[\varepsilon]$	$[c]$	$[cgcg]$	$[c]$
$[cgcg]$	$[\varepsilon]$	$[cgcgc]$	$[g]$	$[c]$
$[cgcgc]$	$[\varepsilon]$	$[c]$	$[cgcgcg]$	$[c]$
$[cgcgcg]$	$[\varepsilon]$	$[L']$	$[g]$	$[c]$

$[x_i s]$ to the existing equivalence classes. It is listed in Table 2. The particular transfer function $\delta([x_i], s) = [L']$ leads to a "dead end".

By counting the number of lines leading from one state to another, we write down an *incidence matrix*:

$$M = \begin{bmatrix}
1 & 1 & & & & & 2 & & & & \\
1 & 1 & 1 & & & & 1 & & & & \\
1 & & & 1 & & & 2 & & & & \\
1 & 1 & & & 1 & & 1 & & & & \\
1 & & & & & 1 & 2 & & & & \\
1 & 1 & & & & 1 & 1 & & & & \\
 & & & & & 2 & & & & & \\
1 & & & & & & 2 & 1 & & & \\
1 & 1 & & & & & 1 & & 1 & & \\
1 & & & & & & 2 & & & 1 & \\
1 & 1 & & & & & 1 & & & & 1 \\
1 & & & & & & 2 & & & & \\
1 & 1 & & & & & 1 & & & &
\end{bmatrix}.$$

One draws the minimal deterministic automaton according to the above transfer function. As it is no longer a planar graph, we do not show it here. The columns and rows of the matrix M are ordered as elements in the first column in Table 2 of the transfer function.

To make connection with the generating function

$$f(s) = \sum_{0}^{\infty} a_K s^K,$$

obtained by using the Goulden–Jackson cluster method, we note that the sum of elements in the first row of the Kth power of M is nothing but a^K [8]:

$$a_K = \sum_{j=1}^{13} (M^K)_{1j}.$$

The summation runs over all equivalence classes except for L'. We list the elements of the first row of M^K in columns of Table 3.

The negative numbers in the last row of Table 3 show the difference of a_K and 4^K. They are precisely the coefficients in the expansion of $1/(1-4s) - f(s)$ as shown at the end of Section 3. We see that the transfer function and the incidence matrix contain more detailed information on the combinatorical problem than the generating function alone. The consequence of this approach has to be further elucidated in the future.

Table 3: Elements of the first rows of M_K and their sum.

Abstract

Symbolic sequences generated by symbolic dynamics of a dynamical system belong to a special class of language in which any admissible word is factorisable as well as prolongable. From a complete genome sequence of an organism, one may also define a factorizable language. A factorizable language enjoys the nice property that it is entirely determined by the set of minimal fobidden words or distinct excluded blocks (DEBs). We use this property to calculate the fractal dimension of patterns related to a visualisation scheme of under-represented strings in bacterial complete genomes within the limit of infinitely long strings. The same problem may be solved by using a purely combinatorial approach. The methods described in this paper may be applied to other regular fractals with self-similar and self-overlapping structure.

Keywords: Language; Symbolic dynamics; Genome

1. Introduction

We start from the following observation.

For those studying high-energy particle physics the six letters

u d c s b t

denote different types of quarks. They are associated with certain fractional charge, mass, flavour, charm, and other quantum numbers. However, many more people deal

with the three letters

p n e

as names of proton, neutron, and electron with definite mass, charge, spin, magnetic momentum, etc. There is no need to know from which three quarks a proton or a neutron is made. Chemists know well the symbols

H C N O P S ···

representing different atoms. They are concerned with the atomic number, ion radius, chemical valence and affinity, of the corresponding element. Using these atomic symbols chemists write molecular formulas such as H_2O, NO, or CO_2. However, when it comes to biochemistry it is usually not necessary and convenient to write down explicitly all the 30 odd atoms forming the phosphate, sugar and base parts of a nucleotide. Suffice it to denote the nucleotides adenine, cytosine, guanine, and thymine by the four letters **a, c, g, t** and to remember that when forming a double helix of DNA a **a** is associated with a **t** by two hydrogen bonds ("weak coupling") while a **c** conjugates with a **g** with three hydrogen bonds ("strong coupling"). A long sequence of DNA made of millions of **a, c, g** and **t** may be denoted by a single symbol in a "higher"-level analysis.

What is the moral of the observation? In describing Nature, we can only concentrate on one or another level by ignoring the detailed structure and dynamics in smaller scales. This is nothing but *coarse-graining*. Coarse-graining is inevitably associated with the use of symbols and in many lucky cases these symbols make one-dimensional sequences. (By the way, "high"-dimensional strings may be treated as one-dimensional with farther than nearest-neighbor interactions if one confines to strings of finite length.) These symbolic sequences fit well into the scheme of formal languages where a wealth of knowledge has been accumulated. In fact, formal languages are not just formal. They may provide a definite framework for comparison or a computation scheme to solve practical problems.

We will touch on two.

2. Some notions from language theory

In formal language theory, one starts with an alphabet, e.g., $\Sigma=\{R,L\}$ in the symbolic dynamics of unimodal maps or $\Sigma=\{a,c,g,t\}$ for DNA sequences of an organism.[3] Let Σ^* denote the collection of all possible strings made of letters from Σ, including the empty string ε. Any subset $L\subset\Sigma^*$ is called a *language* over the alphabet Σ. This general definition of language cannot lead us very far. One must specify how the subset is formed. To this end, one may devise a generative grammar, i.e., a set of production rules to generate words in the language by applying the rules to some starting symbols.

[3] All genome sequences mentioned in this paper are fetched by anonymous FTP from GenBank maintained by the National Center for Biotechnology Information at `http://ncbi.nlm.nih.gov`

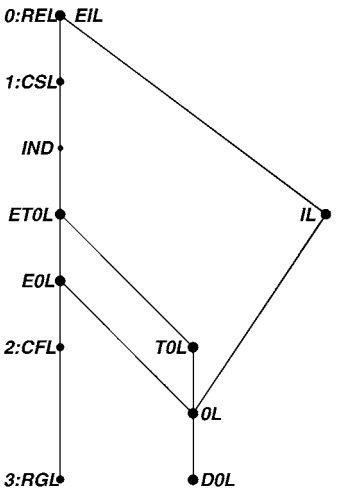

Fig. 1. Relationship of various classes of languages.

Two generative schemes are well-developed: the sequential production of Chomsky and the parallel production of Lindenmayer. We show their relationship in Fig. 1.

The set $L' = \Sigma^* - L$ defines the complementary language. A language L is a factorizable language if any substring of a word $x \in L$ also belongs to L. A factorizable language has a minimal set of forbidden words or *Distinctive Excluded Blocks* [1] (DEBs) L'' such that if $x \in L''$, then any proper substring of x belongs to L. A factorizable language is completely determined by its set of DEBs:

$$L = \Sigma^* - \Sigma^* L'' \Sigma^* .$$

A prominent example of factorizable language is given by the admissible symbolic sequences in the symbolic dynamics of a dynamical system, see, e.g., Refs. [2,3]. Another class of factorizable languages may be obtained from a complete genome as follows. Let G be a complete genome of an organism; it may consist of one or more linear or circular sequences. All possible substrings of G, including the empty string ε and G itself, obviously form a subset of Σ^* and, thus, define a language which is factorizable by construction.

Any language $L \subset \Sigma^*$ introduces an equivalence relation R_L in Σ^* with respect to L. For any pair $x, y \in \Sigma^*$ $xR_L y$ iff for each $z \in \Sigma^*$ either both $xz, yz \in L$ or both $xz, yz \notin L$. The number of equivalence classes in Σ^* with respect to L defines the *index* of R_L, denoted by index (R_L).

An important theorem (Myhill–Nerode) says that L is a regular language iff index (R_L) is finite and L being regular implies that the minimal deterministic automaton corresponding to L, $\min \mathrm{DFA}(L)$, is unique up to an isomorphism, i.e., to renaming of the states. Moreover, the number of states in the $\min \mathrm{DFA}(L)$ equals to index (R_L).

Let L be a factorizable language and L'' be its set of all DEBs. Define a set

$$V = \{v \mid v \text{ is a proper prefix of some } y \in L''\} .$$

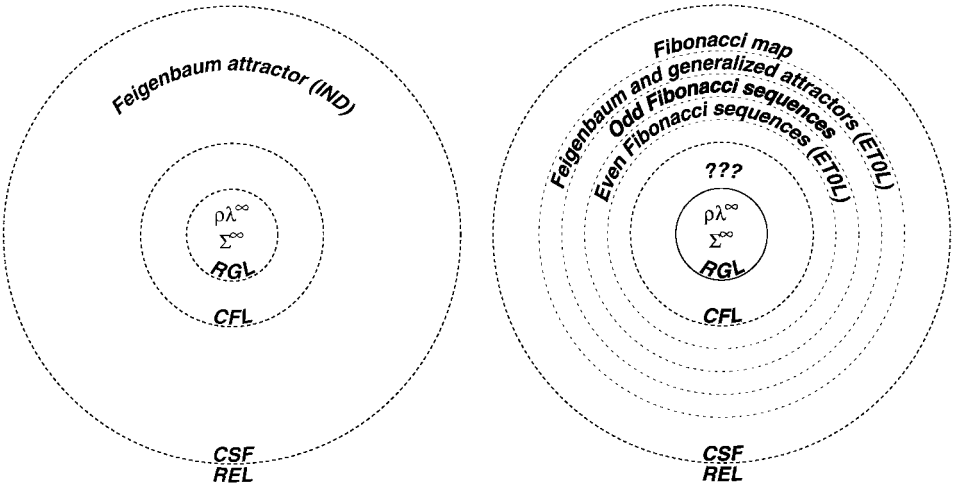

Fig. 2. Grammatical complexity of symbolic sequences in unimodal maps: left: what was known in 1991; right: what is known now.

For each word $x \in L$ there exists a string $v \in V$ such that xR_Lv. In other words, all equivalence classes of L are represented in the set V. In order to find all equivalence classes of Σ^* with respect to L it is enough to start from L''. In addition, L' is an equivalence class of Σ^*. For two given strings $u, v \in V$, uR_Lv iff for each $z \in \Sigma^*$ uz contains a DEB as its suffix $\Leftrightarrow vz \in L'$ and vice versa. This statement sets the computation rule to identify all equivalence classes. Each equivalence class may be named after a member $x_i \in L$ and be denoted as $[x_i]$. The transfer function between states of $\min \mathrm{DFA}(L)$ is defined as $\delta([x_i], s) = [x_i s]$ for $x_i \in L$ and $s \in \Sigma$.

3. Complexity of symbolic sequences in unimodal maps

Grammatical complexity of symbolic sequences in unimodal maps is shown in Fig. 2.

4. Visualization of under-represented strings

We start by considering on how to visualize the avoided and under-represented strings in a bacterial genome whose length is usually the order of a few million letters.

There are 4^K different strings of length K made of four letters. In order to check whether all these strings appear in a genome, we use 4^K counters to be visualized as a $2^K \times 2^K$ square array on a computer screen. These can be realized as a direct product of K identical 2×2 matrices:

$$M^{(K)} = M \otimes M \otimes \cdots \otimes M \,,$$

where

$$M = \begin{pmatrix} g & c \\ a & t \end{pmatrix}.$$

We call this $2^K \times 2^K$ square a K-frame. In practice, it is convenient to use binary subscripts for this 2×2 matrix and it is easy to develop an algorithm that depends only on the total length of the genome but not on the string length K. Put in a frame of fixed K and described by a color code biased towards small counts, each bacterial genome shows a distinctive pattern which indicates on absent or under-represented strings of certain types [4]. For example, many bacteria avoid strings containing the string *ctag*. Any string that contains *ctag* as a substring will be called a *ctag*-tagged string. If we mark all *ctag*-tagged strings in frames of different K, we get pictures as shown in Fig. 3. The large-scale structure of these pictures persists but more details appear with growing K. Excluding the area occupied by these tagged strings, one gets a fractal in the $K \to \infty$ limit. It is natural to ask as what is the dimension of this fractal for a given tag or for a given set of tags.

In fact, this is the fractal dimension of the complementary set of the tagged strings. The simplest case is that of *g*-tagged strings. As the pattern has an apparently self-similar structure the fractal dimension is easily calculated to be

$$D = \frac{\log 3}{\log 2}.$$

Moreover, the fractal dimension of all other cases must lie in between $\log 3/\log 2$ and 2. However, the calculation of these dimensions is somewhat tricky as one must take into account the overlap of patterns precisely. For example the $K = \infty$ frame with all *cg*-tagged strings marked is shown in Fig. 4. There is one big shaded square representing all possible strings with the two leading letters being *cg*. There are four middle-size squares coming from strings starting from *g*, *c*, *a*, or *t* with the next two letters being *gc*. There are 16 small squares, 64 tiny squares, etc., whose meaning may be read off in a similar manner. However, one of the 16 small squares is contained in the big square; eight of the tiny squares are contained in the larger ones. At the next level (not shown), 47 of 256 even tinier squares are located in larger ones. Without taking into account these overlaps precisely, the fractal dimension of the limiting complementary set cannot be calculated.

Now, let a_K be the number of all strings of length K that do not contain the given tag. As the linear size δ_K in the K-frame is $1/2^K$, the fractal dimension may be calculated as

$$D = \lim_{K\to\infty} \frac{\log a_K}{-\log \delta_K} = \lim_{K\to\infty} \frac{\log a_K^{1/K}}{\log 2}.$$

Suppose the generating function of a_K is known:

$$f(s) = \sum_{K=0}^{\infty} a_K s^K,$$

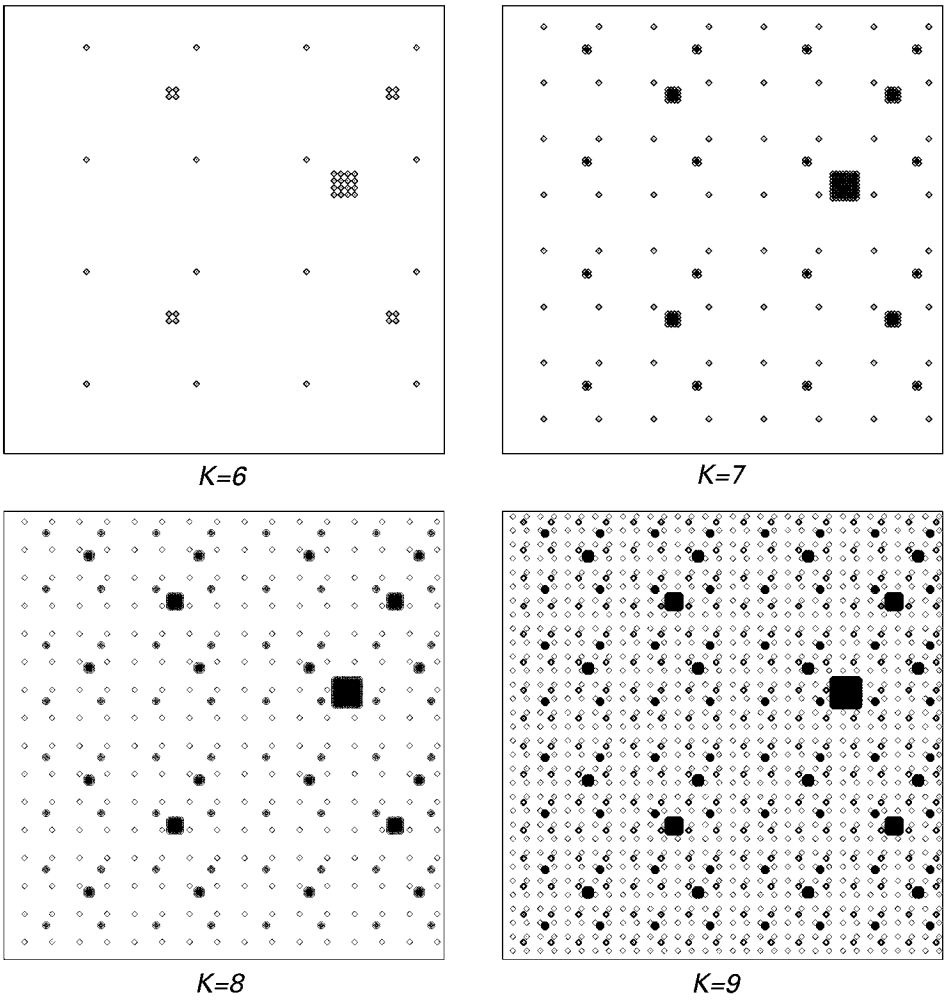

Fig. 3. *ctag*-tagged strings in $K = 6$–9 frames.

where s is a complex auxiliary variable, then according to the Cauchy criterion of convergence we have

$$\lim_{K\to\infty} a_K^{1/K} = \frac{1}{|s_0|} ,$$

where s_0 is the minimal positive zero of $f^{-1}(s)$. This finally determines the fractal dimension

$$D = -\frac{\log|s_0|}{\log 2} .$$

Before undertaking to calculate the generating function $f(s)$ for various tags we indicate another related problem, namely, the problem of *redundant* and *true* avoided strings.

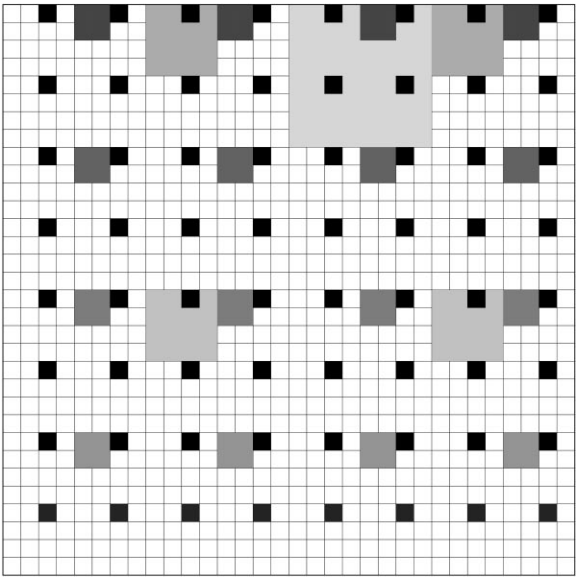

Fig. 4. The pattern of *cg*-tagged strings showing the overlaps.

Once we know that there are avoided strings in the complete genomes from the visualization scheme, one can perform a direct search for these strings. The direct search has the merit of not being significantly limited by the string length K. Take, for example, the complete genome of *E. coli*. At $K=7$ the first avoided string *gcctagg* is discovered. At the next $K=8$ level a total of 173 avoided strings are identified. However, these 173 strings are not all true avoided strings as some must be the consequence of the absence of the $K=7$ string *gcctagg*. A naive estimate of the redundant avoided strings without taking into account any possible overlap of substrings would lead to $4^i(i+1)$: if there is only one avoided string at the Kth level, it would take away 8, 48, 256, 1280, 6144, 28 672, ..., strings at the next $K+i$ levels. This estimate works well for *E. coli* until $K=13$ when the overlap of the first and the last letter g in the true avoided string *gcctagg* would show off. Applying the Goulden–Jackson cluster method to the case of only one "bad word" *gcctagg* leads to the following generating function:

$$f(s)=\frac{1+s^6}{1-4s+s^6-3s^7}\,.$$

The number of redundant avoided strings are given by

$$\frac{1}{1-4s}-f(s)=s^7+8s^8+48s^9+256s^{10}+1280s^{11}$$
$$+6144s^{12}+28671s^{13}+131063s^{14}+\cdots\,.$$

The deviation from the naive estimate appears from the term s^{13}.

For a non-trivial example, we consider the newly published complete genome of the hyperthermophilic bacterium *Aquifex aeolicus* [5]. For this 155 1335-letter sequence

four avoided strings are identified at $K = 7$. They form the set B of "bad words":

$$B = \{gcgcgcg, gcgcgca, cgcgcgc, tgcgcgc\} .$$

As there are significant overlaps among these strings, the naive estimate of redundant avoided words can hardly work. The application of the Goulden–Jackson cluster method requires the solution of a system of four linear equations and leads to the following generating function:

$$f(s) = \frac{1 + s^2 + s^4 + s^6 + s^8 + s^{10} + s^{12}}{1 - 4s + s^2 - 4s^3 + s^4 - 4s^5 + s^6 - 4s^8 - 4s^{10} - 4s^{12}} .$$

The numbers of redundant avoided strings are given by

$$\frac{1}{1-4s} - f(s) = 4s^7 + 27s^8 + 152s^9 + 784s^{10} + 3840s^{11} + 18176s^{12} + 83968s^{13} + \cdots .$$

In what follows, we show that these results may be obtained by an entirely different method, namely, by making use of formal language theory. For convenience of presentation, we first collect a few notions from language theory without proofs. The details may be found, e.g., in Ref. [2] and references therein.

5. Language theory solution

Now we apply what has just been said to the complete genome of *Aquifex aeolicus* with its set B of four avoided strings at length $K=7$. Although there are longer avoided strings we take B to be its L'' for the time being. From the proper suffixes of these strings we get the set

$$V = \{g, gc, gcg, gcgc, gcgcg, gcgcgc, c, cg, cgc, cgcg, cgcgc, cgcgcg, t, tg, tgc, tgcg, tgcgc, tgcgcg\} .$$

By checking the equivalence class of these strings only 13 out of these 18 strings are kept as representatives of each class. Adding the class $[L'] \subset \Sigma^*$ we get the following 14 equivalence classes of Σ^*:

$$[\varepsilon]\ [g]\ \ [gc]\ \ [gcg]\ \ [gcgc]\ \ [gcgcg]\ \ [gcgcgc]$$
$$[c]\ [cg]\ [cgc]\ [cgcg]\ [cgcgc]\ [cgcgcg]\ [L'] .$$

The transfer function $\delta([x_i], s) = [x_i s]$, $x_i \in V$ and $s \in \Sigma$, is determined by attributing $[x_i s]$ to the existing equivalence classes. They are listed in Table 1. The particular transfer function $\delta([x_i], s) = [L']$ leads to a "dead end".

One draws the minimal deterministic automaton according to the above transfer function. As it is no longer a planar graph we do not show it here. By counting the

number of lines leading from one state to another, we write down an *incidence matrix*:

$$M = \begin{bmatrix}
1 & 1 & & & & & & 2 & & & & & \\
1 & 1 & 1 & & & & & 1 & & & & & \\
1 & & & 1 & & & & 2 & & & & & \\
1 & 1 & & & 1 & & & 1 & & & & & \\
1 & & & & & 1 & & 2 & & & & & \\
1 & 1 & & & & & 1 & 1 & & & & & \\
 & & & & & & & 2 & & & & & \\
1 & & & & & & & 2 & 1 & & & & \\
1 & 1 & & & & & & 1 & & 1 & & & \\
1 & & & & & & & 2 & & & 1 & & \\
1 & 1 & & & & & & 1 & & & & 1 & \\
1 & & & & & & & 2 & & & & & 1 \\
1 & 1 & & & & & & 1 & & & & &
\end{bmatrix}.$$

The columns and rows of the matrix M are ordered as elements in the first column in Table 1 of the transfer function.

To make connection with the generating function

$$f(s) = \sum_{0}^{\infty} a_K s^K ,$$

obtained by using the Goulden–Jackson cluster method, we note that the characteristic polynomial of M is related to $f(1/\lambda)$:

$$\det(\lambda I - M) = \lambda^{13} f\left(\frac{1}{\lambda}\right) .$$

Table 2

							−4	−27	−152	−784	−3840

Moreover, the sum of elements in the first row of the Kth power of M is nothing but a_K [1]:

$$a_K = \sum_{j=1}^{13} (M^K)_{1j} .$$

The summation runs over all equivalence classes except for L'. We list the elements of the first row of M^K in columns of Table 2.

The negative numbers in the last row of Table 2 show the difference of a_K and 4^K. They are precisely the coefficients in the expansion of $1/(1-4s) - f(s)$, shown at the end of Section 6. We see that the transfer function and the incidence matrix contain more detailed information on the combinatorial problem than the generating function alone. The consequence of this approach has to be further elucidated in the future.

6. Combinatorial solution

The generating function for the numbers of strings of various length made of the four letters that do not contain certain designated strings ("bad words" as called in Ref. [6]) may be calculated by using the Goulden–Jackson cluster method [7], well-described by Noonan and Zeilberger [6]. In particular, the case of a single tag – one "bad word" only – is easily treated and some of the results are shown in Table 3.

A related question is the number $G(n)$ of different types of generating functions for a given tag length n. These numbers turn out to be independent of the size of the alphabet Σ as long as there are more than two letters in Σ [8]:

n	1	2	3	4	5	6	7	8	9	10	11	12	13	14
$G(n)$	1	2	3	4	6	8	10	13	17	21	27	30	37	47 .

Table 3
Generating function and dimension for some single tags

Tag	$f(s)$	D	Tag	$f(s)$	D
g	$\frac{1}{1-3s}$	$\frac{\log 3}{\log 2}$	ggg	$\frac{1+s+s^2}{1-3s-3s^2-3s^3}$	1.98235
gc	$\frac{1}{1-4s+s^2}$	1.89997	$ctag$	$\frac{1}{1-4s+s^4}$	1.99429
gg	$\frac{1+s}{1-3s-3s^2}$	1.92269	$ggcg$	$\frac{1+s^3}{1-4s+s^3-3s^4}$	1.99438
gct	$\frac{1}{1-4s+s^3}$	1.97652	$gcgc$	$\frac{1+s^2}{1-4s+s^2-4s^3+s^4}$	1.99463
gcg	$\frac{1+s^2}{1-4s+s^2-3s^3}$	1.978	$gggg$	$\frac{1+s+s^2+s^3}{1-3s-3s^2-3s^3-3s^4}$	1.99572

In fact, these $G(n)$ are the so-called correlations of n as given by the integer sequence $M0555$ in Ref. [9], see also Ref. [8].

Abstract

Recursive equations are derived for the exact number t_h of nonisomorphic free trees which have some rooting as a binary tree of height *h*. Numerical results are calculated using these formulae.

1. Introduction

A **binary tree** *T* can be defined as a rooted tree in which each node has degree at most 3, except that the root has degree at most 2. The **height** of *T* is the maximum distance from the root node to an endnode. Binary trees are much used in theoretical computer science, with height often being a key parameter directly related to the efficiency of associated algorithms. A **free binary tree** *F* is an unrooted tree which has a node *u* (not necessarily unique) such that *F* is a binary tree when rooted at *u*. Our purpose is to derive formulae for the number of unlabeled free binary trees which have a rooting that produces a binary tree of height *h*; we say that such a tree **admits height** *h*. In general our terminology follows [3]. Unlabeled counting does not distinguish between versions of a tree which differ only in the assignment of labels to the nodes.

A **3-tree** has maximum degree at most 3. It is convenient for our purpose of counting free binary trees by admissible height to consider 3-trees first. Obviously every free binary tree is a 3-tree, and conversely since any node of degree 1 or 2 could serve as the root. Figure 1 shows a free binary tree *F* which has four distinct binary rootings. Rooting *F* at node 5 or 6 gives one binary tree of height 5; at 7 gives height 4; at 3 gives height 3; finally, rooting *F* at 8 or 9 gives a second binary tree of height 5. Thus *F* admits height 3, 4, and 5. In the total of free binary trees of order a admitting height 5, for

instance, *F* will be counted just once.

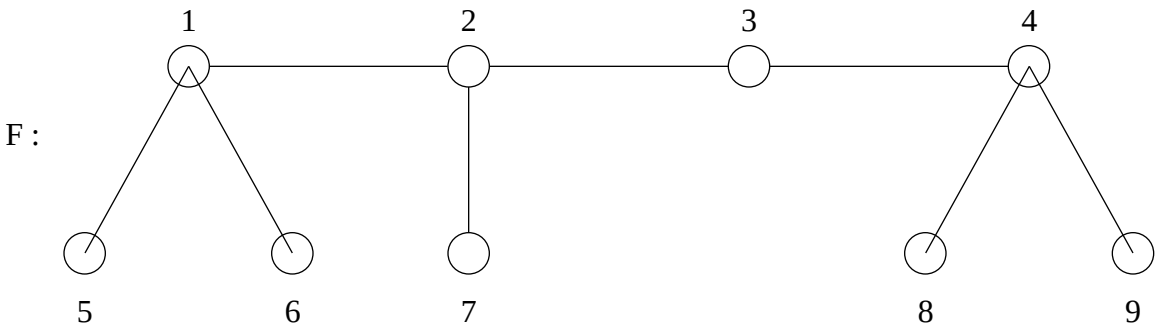

FIGURE 1. A free binary tree which has four binary rootings

Both rooted and unrooted 3-trees have been counted by Cayley and Otter; see [4] for a modern exposition.

2. Planted 3-trees of given height

In a **planted tree**, the root is an endnode. Let p_h be the number of planted 3-trees of height *h*, and let q_h be the number of height less than *h*, including for convenience the empty one with no nodes and no edges.

Then $p_1 = q_1 = 1$, while for all $h \geq 1$,

$$q_{h+1} = q_h + p_h \tag{1}$$

$$p_{h+1} = \binom{1+p_h}{2} + p_h q_h \tag{2}$$

Note that the numbers p_h were known to Etherington [2]; they are sequence number 718 in Sloane's book, [6].

To justify (2), we observe that a planted tree of height $h+1$ has two major subtrees, one of height *h* and the other of height *h* or less. For both to have height *h*, there are $\binom{1+p_h}{2}$ possibilities since we need to select two trees (which may be isomorphic) from among the p_h of height *h*, and their order is immaterial. For the case when one major subtree has height *h* and the other less, the possibilities are enumerated by $p_h q_h$ since the two branches cannot be confused with one another. The empty case admitted by $q_1 = 1$ corresponds to the possibility that the node adjacent to the root has degree 2, so that there is really only one major subtree.

In order to allow for the analysis of free 3-trees, it will be necessary to determine the number $d_{h,i}$ of planted 3-trees of height *h* which have no nodes of degree 1 or 2 at level *i* (distance *i* from the root). Of course all 3-trees of height *h* have one or more nodes of

degree 1 at level *h* and no nodes at any level greater than *h*, so $d_{h,h} = 0$ and $d_{h,i} = p_h$ for all $i > h$. In fact, our interest will be in the number $(p_h - d_{h,i})$ of 3-trees of height *h* which do have a node of degree 1 or 2 at level *i*, for $1 \le i < h$. However the defining equations are more direct when written in terms of $d_{h,i}$. It will also be convenient to identify the quantity

$$e_{h,i} = 1 + \sum_{1 \le j < h} d_{j,i} \quad , \tag{3}$$

which bears the same relation to $d_{h,i}$ that q_h bears to p_h. One can then write the recursively defining equations as

$$d_{h+1,i+1} = \binom{1+d_{h,i}}{2} + d_{h,i}\, e_{h,i} \tag{4}$$

$$e_{h+1,i} = e_{h,i} + d_{h,i} \tag{5}$$

for $h > i \ge 1$. These parallel precisely equations (1) and (2). For boundary conditions we have

$$\begin{aligned} d_{h+1,1} &= p_{h+1} - p_h \quad , \\ e_{h+1,1} &= p_h \end{aligned} \tag{6}$$

for all $h \ge 1$. This is because if a planted tree of height $h + 1$ has a node of degree 1 or 2 adjacent to the root, that node must have degree 2 since $h \ge 1$. By suppressing this node, one obtains a tree of height h in a 1-1 fashion, so that

$$p_{n+1} - d_{h+1,1} = p_h \quad .$$

Now

$$e_{h+1,1} = 1 + \sum_{1 \le k \le h} d_{k,1} = 1 + d_{1,1} + \sum_{2 \le k \le h} (p_k - p_{k-1})$$

$$= 1 + d_{1,1} + p_h - p_1$$

$$= p_h$$

since $p_1 = 1$ and $d_{1,1} = 0$.

3. Free 3-trees by admissible height

It does not appear possible to apply the principle of Otter's dissimilarity characteristic [4, p.56] to obtain the number t_h of free 3-trees which have some rooting as a binary tree of height *h*. Instead, we will make use of the fact that every tree has a unique center consisting of a single node or two adjacent nodes. The possibilities for binary rootings of various heights are enumerated separately for these two cases. This approach was used by Cayley [1] when he first counted trees.

Case 1 The center is a single node.

Assuming a nontrivial tree *T*, the diameter is $2h$ for some $h \ge 1$. Then some two branches at the center must have height *h* and the third branch (if there is one) must have height at most *h*. The number of ways to choose these branches is

$$a_h = \binom{2+p_h}{3} + \binom{1+p_h}{2} q_h \quad . \tag{7}$$

The first term counts the number of ways to choose all three branches to have height *h*, and the second gives the number with two branches of height *h* and either no third branch or else a third branch having some height *k*, $1 \le k < h$.

Suppose now that one of the branches at the center of *T* has a node of degree 1 or 2 at level *i*, $i \geq 1$. Then *T* would have height $h + i$ if rooted at such a node, since any path of maximum length must pass through the center. The number of ways that *T* could fail to contain such a node is exactly

$$\left\{ \begin{matrix} 2+d_{h,i} \\ 3 \end{matrix} \right\} + \left\{ \begin{matrix} 1+d_{h,i} \\ 2 \end{matrix} \right\} e_{h,i} \quad . \tag{8}$$

This is just as for (7) except that every branch must fail to have a node of degree 1 or 2 at level *i*. Subtracting (8) from (7) will then give the number of 3-trees of diameter $2h$ which have a binary rooting of height $h + i$, $1 \leq i \leq h$.

There remains the possibility of rooting at the central node. The center has degree at most 2 exactly when there are just two branches. In that case the tree has height *h* when rooted at the center, so we have exactly

$$\left\{ \begin{matrix} 1+p_h \\ 2 \end{matrix} \right\} \tag{9}$$

3-trees of diameter $2h$ which have a binary rooting of height *h*.

Case 2 The center consists of two adjacent nodes.

The diameter is $2h - 1$ for some $h \geq 1$, and we can obtain any such tree in a unique fashion by joining two trees of height *h* at the root, then smoothing out the root node. We refer to these two trees as the branches at the bicenter. Of course their order is unimportant, and they may be isomorphic. Hence there are exactly

$$b_h = \left\{ \begin{matrix} 1+p_h \\ 2 \end{matrix} \right\} \tag{10}$$

3-trees of diameter $2h - 1$.

In this case a node of level *i* on one of the branches at the bicenter gives a rooting of height $h + i - 1$. The number of 3-trees of diameter $2h - 1$ having no node of level *i* of degree 1 or 2 on either branch at the center is just

$$\left\lceil \frac{1+d_{h,i}}{2} \right\rceil . \tag{11}$$

Subtracting (11) from (10) then gives the number of 3-trees of diameter $2h - 1$ which have a binary rooting of height $h + i - 1$.

The total number t_h of free 3-trees with a binary rooting is just the sum of the numbers obtained in Cases 1 and 2, for the appropriate values of *h* and *i*. More explicitly, for $h \geq 1$ we have

$$t_h = \left\lceil \frac{1+p_h}{2} \right\rceil + \sum_{i=1}^{\lfloor h/2 \rfloor} \left\{ a_{h-i} - \left\lceil \frac{2+d_{h-i,i}}{3} \right\rceil - \left\lceil \frac{1+d_{h-i,i}}{2} \right\rceil e_{h-i,i} \right\}$$
$$+ \sum_{i=1}^{\lfloor (h+1)/2 \rfloor} \left\{ b_{h-i+1} - \left\lceil \frac{1+d_{h-i+1,i}}{2} \right\rceil \right\} . \tag{12}$$

4. Numerical results.

Table I lists p_h for $h \leq 11$. Equations (1) and (2) enable us to calculate the sequence $p_1, p_2, \ldots, p_n$ in *O*(n) time.

Table II gives the values of t_h for $h \leq 10$. Note that $p_{h+1} \geq t_h$. This is because any tree with a binary rooting of height *h* corresponds to a planted 3-tree of height $h + 1$. This correspondence is obtained by adding a new root of degree one adjacent to the original root node. In general there are trees with more than one binary rooting of

height *h*, so that equality does not hold. (An example is provided by the tree *F* of Figure 1, which has two different binary rootings of height 5.) However, it is apparent that $p_{h+1} - t_h$ is small compared to t_h as *h* increases, so that multiple rootings of the same height are relatively rare.

In general, the method employed enables one to compute the values $t_1,t_2,...,t_n$ with $O(n^2)$ integer arithmetic operations and storage of *O(n)* integers. This analysis of complexity takes no account of the rapid increase in the size of the numbers involved. It is clear that log t_n = $O(n^2)$, so this has a significant effect.

First, (1) and (2) are applied to compute p_h and q_h for $h \le n$. Simultaneously (7) and (10) are applied to determine a_h and b_h for $h \le n$, and these values are stored. At the same time, (5) and (6) are used to find $d_{h,1}$ and $e_{h,1}$ for $h \le n$, and these too are stored. The calculation proceeds by induction on *i*, $i = 1, \cdots, \lfloor (n+1)/2 \rfloor$. As the numbers $d_{h,i}$ and $e_{h,i}$ are computed and stored, their contributions to $t_1,...,t_n$ as given in (12) are accummulated. First $d_{h,i+1}$ for $h \le n$ is given by (3), and then $e_{h,i+1}$ for

$h \leq n$ is determined from (4).

By computing the values of $d_{h,i}$ in descending order of *h*, one can overwrite the $d_{h,i}$ array by the $d_{h,i+1}$. Using (4) one calculates the $e_{h,i+1}$ in ascending order, but the $e_{h,i}$ are not needed and so can be overwritten too. In order to avoid separately storing the values $e_{i+1,i}$ needed to start with (4), note that for $i \geq 2$ we have

$$e_{i+1,i} = e_{i,i-1} + p_{i-1},$$

and

$$p_{i-1} = d_{i,i-1}.$$

Now $d_{i,i-1}$ should still be available due to the fact that $d_{h,i}$ only needed computing for $h > i$. This is because $d_{i,i} = 0$ (so can be handled separately) and $d_{h,i}$ for $h < i$ is not called for in (12). For the same reasons $e_{i,i-1}$ should also still be available. Finally, the trees counted by $d_{i,i-1}$ can be obtained in a 1-1 fashion from those of height $i - 1$ by joining two new endnodes to each old endnode. Each new tree then has height *i* but has only nodes of degree 3 at level $i - 1$. Hence $p_{i-1} = d_{i,i-1}$ as claimed above.

Abstract.

Bernoulli numbers and similar arithmetic objects have long been of interest in mathematics. Historically, people have been interested in different recursion formulae that can be derived for the Bernoulli numbers, and the use of these recursion formulae for the calculation of Bernoulli numbers. Some of these methods, which in the past have only been of theoretical interest, are now practical with the availability of high-powered computation.

This thesis explores some of these techniques of deriving new recursion formulae, and expands upon these methods. The main technique that is explored is that of "*multisectioning*". Typically, the calculation of a Bernoulli number requires the calculation of all previous Bernoulli numbers. The method of multisectioning is such that only a fraction of the previous Bernoulli numbers are needed. In exchange, a more complicated recursion formula, called a "*lacunary recursion formula*", must be derived and used.

Dedication.

I would like to dedicate this thesis to my parents, who always supported me with my interest in mathematics.

Acknowledgments.

I would like to thank my supervisor, Jon Borwein, for all his help and insight with respect to this area of research. Also, I would like to thank Marni Mishna, Cindy Loten and Jeff Graham for their proof reading of my thesis, Greg Fee for all of his suggestions on how to improve my Maple code, and numerous other people both within the CECM, and at SFU who made my time here enjoyable.

Chapter 1

Introduction and preliminaries.

1.1 Introduction.

Bernoulli numbers and similar arithmetic objects have long been of interest in mathematics. Historically, people have been interested in different recursion formulae that can be derived for the Bernoulli numbers, and the use of these recursion formulae for the calculation of Bernoulli numbers. Some of these methods, which in the past have only been of theoretical interest, are now practical with the availability of high-powered computation.

This thesis explores some of these techniques of deriving new recursion formulae, and expands upon these methods. The main technique that is explored is that of "*multisectioning*". Typically, the calculation of a Bernoulli number requires the calculation of all previous Bernoulli numbers. The method of multisectioning is such that only a fraction of the previous Bernoulli numbers are needed. In exchange, a more complicated recursion formula, called a "*lacunary recursion formula*", must be derived and used.

There is a simple formula for $\zeta(n)$, the "*Riemann zeta function*" evaluated at n, for positive even integers n and for negative odd integers n in terms of the Bernoulli numbers. Also, there are numerous constants, (π^{2n}, $\log 2$, γ - the Euler gamma function, τ - the golden mean, G - Catalan's constant) that admit identities of infinite sums of zeta values. Thus the calculations of Bernoulli numbers can be used for certain high precision evaluations of other constants [6].

Bernoulli numbers were first introduced by Jacques Bernoulli (1654-1705), in the second part of his treatise published in 1713, *Ars conjectandi* ("Art of Conjecturing"). At the time, Bernoulli numbers were used for writing the infinite series expansions of hyperbolic and trigonometric functions [7].

Von Staudt and Clausen independently discovered a rapid means of determining the denominator of the Bernoulli numbers [17]. This is very useful for testing to see if the calculation was done without errors. (Any error will most likely return a result for which the Clausen - von Staudt theorem does not hold.)

Van den Berg was the first to discuss finding recurrence formulae for the Bernoulli numbers with arbitrary sized gaps (1881) [19]. (Gaps of size m implies that only $\frac{1}{m}$-th of the information is required, and is the result of multisectioning by m.) Haussner worked on this again, 12 years later (1893) giving the results in terms of hypergeometric functions [19]. Ramanujan, in 1911, is given credit for first giving the formulae for small gaps explicitly. Ramanujan showed how gaps of size 7 could be found, and explicitly wrote out the recursion for gaps of size 6 [4, 19, 22]. These methods were extended to the Euler numbers in 1914 by Glaisher, who used these to compute the first 27 non-zero Euler numbers [14].

Nielsen in 1922, gave an improved notation from a computational point of view to deal with gaps of large sizes [19].

Lehmer in 1934 extended these methods to Euler numbers, Genocchi numbers, and Lucas numbers (1934) [19], and calculated the 196-th Bernoulli number.

The goal in this thesis is to expand these techniques to much more than just Bernoulli and Euler numbers. In general anything that is in the form $\frac{\sum_{i=1}^{n} p_i(x)e^{\lambda_i x}}{\sum_{j=1}^{m} q_j(x)e^{\mu_j x}}$ for polynomials $p_i(x)$, $q_j(x) \in \mathbb{C}[x]$ and constants λ_i, $\mu_j \in \mathbb{C}$ can have the terms of its exponential generating function calculated quickly via multisectioning. This type of function is called a "*rational poly-exponential function*".

This thesis will be looking at examples that are derived from Bernoulli numbers, such as Euler numbers, Genocchi numbers and Lucas numbers. But there are a large variety of other situations where rational poly-exponential functions occur. Some are listed below:

- $(1 + x)(\tan(x) + \sec(x))$ - Boustrophedon transform of sequence 1,1,0,0,0,0,... [21]. Reference number A000756 [25, 26].
- $e^{2x}(\tan(x)+\sec(x))$ - Boustrophedon transform of powers of 2 [21]. Reference number A000752 [25, 26].
- $e^x(\tan(x) + \sec(x))$ - Boustrophedon transform of all-1's sequence [21]. Reference number A000667 [25, 26].
- $(1 + x)e^x(\tan(x) + \sec(x))$ - Boustrophedon transform of natural numbers [21]. Reference number A000737 [25, 26].
- $\frac{e^{-x}}{(1-x)^3}$ - $a(n) = na(n-1) + (n-2)a(n-2)$ [23]. Reference numbers A000153, M1791, N0706 [25, 26].

- $\frac{e^{-x}}{(1-x)^2}$ - $a(n) = na(n-1) + (n-1)a(n-2)$ [11, 23]. Reference numbers A000255, M2905, N1166 [25, 26].
- $\frac{e^{x}}{(1-x)^2}$ - $\sum_{k=0}^{n}(k+1)!\binom{n}{k}$ [3, 29]. Reference numbers A001339, M2901, N1164 [25, 26].
- $\frac{e^{-x}}{(1-x)^4}$ - $a(n) = na(n-1) + (n-3)a(n-2)$ [23]. Reference numbers A000261, M2949, N1189 [25, 26].
- $\frac{1-e^{x}}{1-2e^{-x}}$ - Simplices in barycentric subdivisions of n-simplex. Reference numbers A002050, M3939, N1622 [25, 26].
- $\frac{1}{2+x-e^{x}}$ - Partition n labeled elements into sets of sizes of at least 2 and order the sets. Reference number A032032 [25, 26].
- The tangent numbers T_n where $\tan z = \sum_{i=0}^{\infty}(-1)^{n+1}\frac{T_{2n+1}z^{2n+1}}{(2n+1)!}$ [5].

These examples, with the exception of the last one, were all found with the help of *The Encyclopedia of Integer Sequences* and its online counterpart [25, 26]. The reference number is the number associated with the sequence within *The Encyclopedia of Integer Sequences*.

Also, although most of the techniques discussed in this thesis are for rational poly-exponential functions in one variable, it is possible to perform multisectioning in a more general setting, such as for the Bernoulli polynomials, or Euler polynomials (the exponential generating function with respect to x of $\frac{xe^{tx}}{e^{x}-1}$ and $\frac{2e^{xt}}{e^{x}+1}$ give the Bernoulli and Euler polynomials respectively as polynomials in t) [2].

The goal of multisectioning by m is to calculate a lacunary recursion formula so that to calculate a term of the exponential generating function of the rational poly-exponential function requires only $\frac{1}{m}$-th of the time and an $\frac{1}{m}$-th of the information when compared with the standard recursion formula. This allows the calculation on m different machines to achieve a theoretical speed up of a factor of m. (In actual fact, experience shows that the speed up will be greater than this, as the reduction in memory requirements will delay thrashing, and the system can better utilize memory management.) Unfortunately for large m it becomes impractical to determine what these lacunary recursion formulae are as the time to determine the recursion formulae and the complexity of these recursion formulae far exceeds the time to calculate these values with smaller gaps.

Hence multisectioning is a method to compute the Bernoulli numbers that does not require any shared memory. This method is limited by the growth in the cost of determining the lacunary recursion formulae. Conversely there are methods which make use of shared memory (or limited message passing) that are not limited by any increase in the complexity of the lacunary recursion formulae. These methods are limited by the effectiveness of the communication between processes. These techniques are called "*recycling methods*" [6].

Included with this thesis are are a description of the computer programs to determine the lacunary recurrence relations for multisectioned poly-exponential functions, programs to determine the lacunary recursion formulae for multisectioned rational poly-exponential function, as well as algorithms to perform these calculations by recycling. For space consideration the actual code was not included within the thesis. These programs can be found on the web at [1]. This is all written in Maple [13].

1.2 Outline.

Chapter 2 defines and explores poly-exponential functions. This chapter examines some closure properties and metrics upon these functions. As well, this chapter looks at some examples of multisectioning functions of this type.

Rational poly-exponential functions are defined and explored in Chapter 3. Again some closure properties, and metrics upon these functions are examined. As well, examples of how to calculate the coefficients of the exponential generating functions of rational poly-exponential functions and multisectioned rational poly-exponential functions via their lacunary recursion formulae are looked at.

Chapter 4 examines different techniques of calculating lacunary recursion formulae for multisectioned poly-exponential functions.

Different techniques of calculating lacunary recursion formulae for multisectioned rational poly-exponential functions are examined at in Chapter 5.

Chapter 6 looks at different methods to perform the calculation of the coefficients of the exponential generating functions of rational poly-exponential functions, after the lacunary recursion formulae are determined. These different techniques take advantage of multi-processor computers, and distributed computer networks.

The last chapter, Chapter 7 discusses some of the results of this thesis, and makes some conclusions as to what has been learned as a result of these investigations.

Appendix A is an outline of the code. Appendix B lists the common notation and page references. Appendix C contains a list of definitions along with the page reference where the definition is first made. Appendix D is for the bugs reports of bugs found in Maple during the course of these investigations. The last appendix, Appendix E is the code.

Chapter 2

Poly-exponential functions.

2.1 Poly-exponential functions.

The study of rational poly-exponential functions is begun with the exploration of a simpler model; that of poly-exponential functions. To that end define:

Definition 2.1 (Poly-exponential function.) *Let* λ_1, ..., $\lambda_n \in \mathbb{C}$ *be constants and* $p_1(x)$, ..., $p_n(x) \in \mathbb{C}[x]$ *be polynomials. Then*

$$\sum_{i=1}^{n} p_i(x) e^{\lambda_i x},$$

*is a "*poly-exponential function*". Denote the set of all such functions by* $\mathcal{P}$.

This definition along with Lemma 2.1 and Theorem 2.1 are generalization of examples found in Wilf's *Generating Functionology* [30].

Many results for poly-exponential functions can be extended to ratios of poly-exponential functions, thus allowing a simpler setting for developing techniques for the calculations that are the goal of this thesis. Section 2.2 examines the relationship between exponential generating functions and poly-exponential functions. In Section 2.3 the recurrence polynomial corresponding to a linear recurrence relation is defined and explored. Section 2.4 examines in detail the structure and some of the substructure of $\mathcal{P}$, defining both $\mathcal{P}^{R_1,R_2}$ and $\mathcal{P}_{R_1,R_2}$ ($\mathcal{P}^{R_1,R_2}$ and $\mathcal{P}_{R_1,R_2}$ being subrings of $\mathcal{P}$ where the certain coefficients lie within R_1 or R_2). The relationship between two subrings of $\mathcal{P}$, $\mathcal{P}^{R_1,R_2}$ and $\mathcal{P}_{R_1,R_2}$, and showing that these subrings are distinct are shown in Section 2.5. (The subrings are defined by restricting the coefficients to certain rings.) In Section 2.6 some metrics of complexity are introduced for the functions in $\mathcal{P}$, and the relationships between these metrics, with

each other and with standard operations such as addition or multiplication are explored. Section 2.7 contains three detailed examples. The last section, Section 2.8, summarizes the main points of this chapter into a final theorem.

2.2 Exponential generating functions.

The main result of this section is the detailing of the relationship between poly-exponential functions and exponential generating functions.

Lemma 2.1 *Let $s(x)$ be a complex valued function. Then $s(x)$ can be written as an exponential generating function $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$, where the b_i satisfies an N-term linear recurrence relation with constant terms if and only if $s(x)$ can be written as $\sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$ for polynomials $p_i(x) \in \mathbb{C}[x]$ and non-zero constants $\lambda_i \in \mathbb{C}$.*

Proof: Let $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$ where the b_i satisfy the linear recurrence relation $b_i = \beta_1 b_{i-1} + ... + \beta_N b_{i-N}$, $\beta_N \neq 0$ for $i \geq N$. Let λ_1, ..., λ_N be roots of the polynomial $x^N - \beta_1 x^{N-1} - ... - \beta_N$ (not necessarily distinct). It is worth noting here that $\lambda_i \neq 0$ for all i. From a standard result on linear recurrence relations [16], it follows that $b_j = \sum_{i=1}^{N} \alpha_i j^{(r_i)} \lambda_i^{j-r_i}$ for some $r_i \in \mathbb{Z}$, and some $\alpha_i \in \mathbb{C}$. Here the notation of Comtet [10] is used, where $j^{(r)} = j(j-1)(j-2)...(j-r+1)$ and $j^{(0)} = 1$. Thus:

$$\begin{aligned} s(x) &= \sum_{j=0}^{\infty} b_j \frac{x^j}{j!} = \sum_{j=0}^{\infty} \sum_{i=1}^{N} \frac{\alpha_i j^{(r_i)} \lambda_i^{j-r_i} x^j}{j!} = \sum_{i=1}^{N} \sum_{j=0}^{\infty} \alpha_i x^{r_i} (\frac{j^{(r_i)} \lambda_i^{j-r_i} x^{j-r_i}}{j!}) \\ &= \sum_{i=1}^{N} \alpha_i x^{r_i} \sum_{j=0}^{\infty} (\frac{j^{(r_i)} \lambda_i^{j-r_i} x^{j-r_i}}{j!}) = \sum_{i=1}^{N} \alpha_i x^{r_i} \sum_{j=r_i}^{\infty} (\frac{\lambda_i^{j-r_i} x^{j-r_i}}{(j-r_i)!}) = \sum_{i=1}^{N} \alpha_i x^{r_i} e^{\lambda_i x}. \end{aligned}$$

Now combine the $\alpha_i x^{r_i}$ which have the same λ_i, and relabel to get $s(x) = \sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$, where the λ_i are distinct and non-zero.

To prove the other direction, let $t(x) = \sum_{j=1}^{m} q_j(x)e^{\mu_j x}$, where $\mu_j \neq 0$, $\mu_j \in \mathbb{C}$ and $q_j(x) \in \mathbb{C}[x]$ are polynomials. Consider the polynomial:

$$P(x) = \prod_{j=1}^{n} (x - \mu_j)^{\deg(q_j(x))} = x^n - \alpha_1 x^{n-1} - ... - \alpha_n.$$

Then $t(x) = \sum_{j=0}^{\infty} d_j \frac{x^j}{j!}$ where the d_j satisfies the n term linear recurrence relation $d_j = \alpha_1 d_{j-1} + ... + \alpha_n d_{j-n}$. Later, in Section 2.3 it will be shown that $P(x)$ is the recurrence polynomial of $t(x)$.

■

Theorem 2.1 *Let $s(x)$ be a complex valued function. Then $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$ where there exists an m, such that for $i > m$ the b_i satisfy an N-term linear recurrence relation with constant terms if and only if $s(x) \in \mathcal{P}$.*

Proof: First consider $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$ where after some m, the b_i satisfy an N-term linear recurrence relation. A degree m polynomial can be extracted, say $p_0(x)$ $(= \sum_{i=0}^{m} \beta_i \frac{x^i}{i!})$ such that the resulting $\bar{b}_i$ $(= b_i - \beta_i)$ satisfy an N-term linear recurrence relation. Then by Lemma 2.1 $s(x)$ can be written as:

$$s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} = \sum_{i=0}^{\infty} \bar{b}_i \frac{x^i}{i!} + p_0(x) = \sum_{i=1}^{n} p_i(x) e^{\lambda_i x} + p_0(x) e^{0x},$$

for some polynomials $p_i(x)$ and constants λ_i.

Similarly, if $t(x) = \sum_{j=1}^{m} q_j(x) e^{\mu_j x} + p_0(x)$, for polynomials $p_0(x)$, $q_j(x)$, and non-zero constants μ_j, by Lemma 2.1, $t(x)$ can be rewritten as:

$$t(x) = \sum_{j=0}^{\infty} d_j \frac{x^j}{j!} + p_0(x) = \sum_{j=0}^{\infty} \bar{d}_j \frac{x^j}{j!},$$

where the d_j satisfy an N-term linear recurrence relation and where the $\bar{d}_j$ (which are derived by adding the d_j to the coefficients of the polynomial $p_0(x)$) satisfy an N-term linear recurrence relation for $j \geq N + \deg(p_0(x))$.

■

Example 1 *Consider the following example in Maple. For more information about the Maple code, see Appendix A. For the Maple code see Appendix E. The Maple code and help files (including information about syntax) are available on the web at [1].*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the function $s_1(x) = x + x\,e^x$. Converting this to an exponential generating function gives:

```
> \mapleinline{active}{1d}{s[1] := x + x * exp(x):}{%
> }
```

```
> \mapleinline{active}{1d}{convert_egf(s[1], b, x);}{%
> }
```

$$\mathrm{b}(x) = 2\,\mathrm{b}(x-1) - \mathrm{b}(x-2),\ b,\ x,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 2,\ \mathrm{b}(2) = 2,\ \mathrm{b}(3) = 3]$$

So $s_1(x)$ *can be written as* $\sum_{i=0}^{\infty} \frac{b_i\, x^i}{i!}$ *where* $b_i = 2\, b_{i-1} - b_{i-2}$, *with* $b_0 = 0$, $b_1 = 2$, $b_2 = 2$ *and* $b_3 = 3$.

Example 2 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the function $s_2(x) = \sum_{i=0}^{\infty} \frac{b_i\, x^i}{i!}$, *where* $b_i = b_{i-1} + b_{i-2}$ *with* $b_0 = 0$ *and* $b_1 = 1$. *These* b_i *are the "*Fibonacci numbers*" [2]. Converting this to a poly-exponential function gives.*

```
> \mapleinline{active}{1d}{s[2] := b(x) = b(x-1) + b(x-2), b, x,
> [b(0) = 0, b(1) = 1];}{%
> }
```

$$s_2 := \mathrm{b}(x) = \mathrm{b}(x-1) + \mathrm{b}(x-2),\, b,\, x,\, [\mathrm{b}(0) = 0,\, \mathrm{b}(1) = 1]$$

```
> \mapleinline{active}{1d}{convert_pe(s[2]);}{%
> }
```

$$-\frac{1}{5}\sqrt{5}\, e^{(x\,(1/2-1/2\sqrt{5}))} + \frac{1}{5}\sqrt{5}\, e^{(x\,(1/2+1/2\sqrt{5}))},\, x$$

So this can be written as a poly-exponential function, as demonstrated above.

2.3 The recurrence polynomial.

Identifying linear recurrence relations with polynomials will be useful for the further exploration of poly-exponential functions and rational poly-exponential functions. To this end define:

Definition 2.2 (Recurrence polynomial $P^s(x)$**.)** *Let* $s(x) \in \mathcal{P}$, *where* $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$, *where the* b_i *satisfy an* N*-term linear recurrence relation for all* b_i, $i \geq m+N$, *say* $b_i = \alpha_1 b_{i-1} + ... + \alpha_N b_{i-N}$. *For* $m \geq 1$ *assume that for* $i = m + N - 1$, *that* $b_i \neq \alpha_1 b_{i-1} + ... + \alpha_N b_{i-N}$. *Define the "*recurrence polynomial*"* $P^s(x)$ *by:*

$$P^s(x) = x^m(x^N - \alpha_1 x^{N-1} - ... - \alpha_{N-1}x - \alpha_N).$$

Example 3 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Again consider $s_1(x) = x + e^x\, x$ *from Example 1. This example determines what* $s_1(x)$*'s recurrence polynomial is.*

```
> \mapleinline{active}{1d}{s[1] := x + exp(x)*x;}{%
> }
```

$$s_1 := x + x\,e^x$$

```
> \mapleinline{active}{1d}{egf := convert_egf(s[1], b, x);}{%
> }
```

$$egf := \mathrm{b}(x) = 2\,\mathrm{b}(x-1) - \mathrm{b}(x-2),\ b,\ x,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 2,\ \mathrm{b}(2) = 2,\ \mathrm{b}(3) = 3]$$

```
> \mapleinline{active}{1d}{convert_poly(egf);}{%
> }
```

$$x^4 - 2\,x^3 + x^2$$

In contrast consider a random polynomial, and determine what its linear recurrence relation would be.

```
> \mapleinline{active}{1d}{poly := randpoly(x);}{%
> }
```

$$poly := -55\,x^5 - 37\,x^4 - 35\,x^3 + 97\,x^2 + 50\,x + 79$$

```
> \mapleinline{active}{1d}{convert_rec(poly,b,x);}{%
> }
```

$$\mathrm{b}(x) = -\frac{37}{55}\,\mathrm{b}(x-1) - \frac{7}{11}\,\mathrm{b}(x-2) + \frac{97}{55}\,\mathrm{b}(x-3) + \frac{10}{11}\,\mathrm{b}(x-4) + \frac{79}{55}\,\mathrm{b}(x-5)$$

The recurrence polynomial $P^s(x)$ is defined in this way so that it will contain information about when a linear recurrence relation is valid. This construction was suggested by my supervisor, Jon Borwein partly because a useful corollary follows from this definition as a result.

Corollary 1 *If $s(x) \in \mathcal{P}$, $s(x) = \sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$, with n distinct λ_i, then:*

$$\deg(P^s(x)) = \sum_{i=1}^{n}(\deg(p_i(x)) + 1).$$

Later, it will be show that this corollary also follows from Lemma 2.5 and is related to the definition of $deg^P(s(x))$ as given in Definition 2.7.

Let $s(x) \in \mathcal{P}$, $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$. It is possible to find more than one linear recurrence relation for the b_i. For example $b_i = b_{i-1} + b_{i-2}$ and $b_i = 2b_{i-2} + b_{i-3}$ are both valid linear recurrence relations for the Fibonacci numbers. Next it is shown how to avoid the ambiguity of which recurrence polynomial or linear recurrence relation to use.

Define the "*length*" of a linear recurrence relation to be the degree of the recurrence polynomial associated with it. (Later it is shown that this is equivalent to the metric deg^P.) Consider the

minimal integer $n \geq 0$ such that there is a linear recurrence relation of length n; this gives a unique lower bound to the length of a linear recurrence relation. From this it can be shown that this minimal linear recurrence relation is unique, for if there were two different linear recurrence relations of length N,

$$\begin{aligned} b_i &= \alpha_1 b_{i-1} + ... + \alpha_N b_{i-N} \\ \text{and } b_i &= \beta_1 b_{i-1} + ... + \beta_N b_{i-N}, \end{aligned}$$

then

$$0 = (\alpha_1 - \beta_1) b_{i-1} + ... + (\alpha_N - \beta_N) b_{i-N},$$

which has non-zero terms, hence is a smaller linear recurrence relation, which is a contradiction.

Therefore from the comments above, and the results of Corollary 1, assume that $P^s(x)$ is the unique smallest polynomial associated with the unique linear recurrence relation of minimal length associated with $s(x) \in \mathcal{P}$.

If $P(x)$ and $Q(x)$ are two recurrence polynomials associated with the linear recurrence relation of $s(x) \in \mathcal{P}$ (not necessarily minimal) then $\gcd(P(x), Q(x))$ is also associated with $s(x)$. In fact, any polynomial $P(x)$ such that $P^s(x) | P(x)$ will yield a linear recurrence relation for $s(x)$, albeit not one of minimal length.

2.4 The structure of $\mathcal{P}$.

As yet, $\mathcal{P}$ has only been looked at as a collection of functions. However $\mathcal{P}$ has an internal structure. The main result of this section is to show that $\mathcal{P}$ is a ring. As well, some subrings of $\mathcal{P}$ are examined. Some of the consequences of this are re-examined in Section 4.6 in which calculations over different subrings of $\mathcal{P}$ and $\mathcal{R}$ (to be defined in Chapter 3) are made.

To the best of my knowledge, the subrings of $\mathcal{P}$ in this section have never been examined before, and the results in this section are new.

Definition 2.3 ($\mathcal{P}_{R_1,R_2}$.) *Let R_1 and R_2 be subrings of $\mathbb{C}$. Define*

$$\mathcal{P}_{R_1,R_2} = \{s(x) \in \mathcal{P} : s(x) = \sum_{i=1}^{n} p_i(x) e^{\lambda_i x}, \lambda_i \in R_1, p_i(x) \in R_2[x]\}.$$

Definition 2.4 ($\mathcal{P}^{R_1,R_2}$.) *Let R_1 and R_2 be subrings of $\mathbb{C}$. Define*

$$\mathcal{P}^{R_1,R_2} = \{s(x) \in \mathcal{P} : s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}, P^s(x) \text{ factors in } R_1[x], b_i \in R_2\}.$$

The main result of this section is to show that $\mathcal{P}_{R_1,R_2}$ and $\mathcal{P}^{R_1,R_2}$ are both rings. First some preliminary definitions are made to help discuss multisectioning. The process of multisectioning has had a long history, including Ramanujan, Lehmer, Glaisher [14, 19, 22]. For a more detailed describe of the history, see Section 1.1.

Definition 2.5 *Define* $\omega_m = e^{\frac{2\pi i}{m}}$.

Definition 2.6 (Multisectioning.) *Let* $f(x)$ *be a function acting on a subset of* $\mathbb{C}$. *Define* $f_m^q(x) = \frac{1}{m}\sum_{i=0}^{m-1} \omega_m^{-iq}\ f(\omega_m^i x)$.

The term "*multisectioning*" is used to describe this process [24]. To say a function $s(x)$ is "*multisectioned by* m" means that $s_m^q(x)$ is being discussed for some q. To say a function $s(x)$ is "*multisectioned by* m *at* q" means that the function $s_m^q(x)$ is being discussed. The term "*lacunary recurrence relation*" is used to describe the linear recurrence relation of a poly-exponential function that has been multisectioned [24].

If $s(x) \in \mathcal{P}$, then it follows that $s_m^q(x) \in \mathcal{P}$. Let $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$, then:

$$\begin{aligned} s_m^q(x) &= \frac{1}{m}\sum_{k=0}^{m-1} \omega_m^{-kq} s(\omega_m^k x) = \frac{1}{m}\sum_{k=0}^{m-1} \omega_m^{-kq} \sum_{i=0}^{\infty} b_i \frac{x^i \omega_m^{ki}}{i!} = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} \frac{1}{m}\sum_{k=0}^{m-1} \omega_m^{-kq}\omega_m^{ki} \\ &= \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} \frac{1}{m}\sum_{k=0}^{m-1} \omega_m^{-kq+ki}. \end{aligned}$$

By noticing that $\frac{1}{m}\sum_{k=0}^{m-1} \omega_m^{-kq+ki}$ is equal to 1 if and only if $q \equiv i \pmod m$ and 0 otherwise, this simplifies to

$$s_m^q(x) = \sum_{i=0}^{\infty} b_{mi+q} \frac{x^{mi+q}}{(mi+q)!}.$$

So the process of multisectioning will isolate certain terms within the power series.

Consider a poly-exponential functions, say $t(x) = \sum_{i=1}^{n} p_i(x) e^{\lambda_i x}$, then a simple calculation shows that $t_m^q(x)$ has the form:

$$t_m^q(x) = \frac{1}{m}\sum_{j=0}^{m-1}\sum_{i=0}^{n} \omega_m^{-jq} p_i(x\omega_m^{-j}) e^{\lambda_i x \omega_m^{-j}}.$$

Rewriting this as $t_m^q(x) = \sum_{j=1}^{\bar{n}} \bar{p}_j(x) e^{\mu_j x}$, shows that, the recurrence polynomial of $t_m^q(x)$ is:

$$P^{t_m^q(x)}(x) = \prod_{j=1}^{\bar{n}} (x-\mu_j)^{\deg(\bar{p}_j(x))}.$$

The set $\{u_j : j = 1...n\}$ is independant of q, (they will run through $\lambda_i \omega_m^j$). By multisectioning, it is possible that the roots will be of a different multiplicity, hence giving a different recurrence polynomial

(as shown in the example below). But to do this, a sub-component of the poly-exponential function needs to have a symmetry when shifting by ω_m around the origin, which would result in a different degree for some $\bar{p}_i(x)$. (For example $e^x - e^{-x}$ has a symmetry which shifting by $\omega_2 = -1$ about the origin, as $e^x - e^{-x} = -1(e^{-1x} - e^{-1\times -x})$. For a more detailed discussions of symmetries, see Section 5.4.) For example when multisectioning by two, then the function would need to have an even component or an odd component. The probability of this happening is not very great (measure zero) so, as long as something is known about $s(x)$, then the fact that the recurrence for $s^q_m(x)$ is likely the same as $s^{\bar{q}}_m(x)$ can be taken advantage of; by simplifying the calculation of the lacunary recurrence relation of $s^{\bar{q}}_m(x)$ to checking if the lacunary recurrence relation of $s^q_m(x)$ is valid for the first few initial values.

Example 4 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

This is an example of a poly-exponential function, which when multisectioned by 2 will give a different linear recurrence relation if it is multisectioned at 0 or at 1. Consider the function $\mathrm{s}(x) = e^x + e^{(-x)} + e^{(2\,x)} - e^{(-2\,x)}$.

```
> \mapleinline{active}{1d}{s := exp(x)+exp(-x)+exp(2*x)-exp(-2*x);}{%
> }
```

$$\mathrm{s} := e^x + e^{(-x)} + e^{(2\,x)} - e^{(-2\,x)}$$

```
> \mapleinline{active}{1d}{`pe/ms`(s, f, x, 2, 0);}{%
> }
```

$$\mathrm{f}(x) = \mathrm{f}(x-2),\ f,\ x,\ [\mathrm{f}(0) = 2,\ \mathrm{f}(1) = 0]$$

```
> \mapleinline{active}{1d}{`pe/ms`(s, f, x, 2, 1);}{%
> }
```

$$\mathrm{f}(x) = 4\,\mathrm{f}(x-2),\ f,\ x,\ [\mathrm{f}(0) = 0,\ \mathrm{f}(1) = 4]$$

In the first case the linear recurrence relation is $\mathrm{f}(x) = \mathrm{f}(x-2)$ *and in the second* $\mathrm{f}(x) = 4\,\mathrm{f}(x-2)$.

The notation of Herstein [18] is used with respect to rings and subrings. Let A be a subset of $\mathbb{C}$. Then $\langle A\rangle$ is the smallest subring of $\mathbb{C}$ that contains A. Denote $A^{-1} = \{a^{-1} : a \in A\}$. Let R_1 and R_2 be subrings of $\mathbb{C}$. Denote $R_1R_2 = \{a_1a_2 : a_1 \in R_1 \text{ and } a_2 \in R_2\}$.

Next some closure properties for $\mathcal{P}^{R_1,R_2}$ and $\mathcal{P}_{R_1,R_2}$ are collected.

Lemma 2.2 *Let R_1, R_2, R_3, R_4 and R_5 be subrings of $\mathbb{C}$. If $s(x) \in \mathcal{P}_{R_1,R_2}$, $t(x) \in \mathcal{P}_{R_3,R_4}$ and $\alpha \in R_5$, then:*

1. $s(x)t(x) \in \mathcal{P}_{\langle R1,R3\rangle,R_2R_4}$,
2. $s(x)+t(x) \in \mathcal{P}_{\langle R_1,R_3\rangle,\langle R_2,R_4\rangle}$,
3. $s'(x) \in \mathcal{P}_{R_1,\langle R_1,R_2\rangle}$,
4. $\int_0^x s(y)dy \in \mathcal{P}_{R_1,\langle \mathbb{Q}R_2,R_1^{-1}R_2\rangle}$,
5. $s(\alpha x) \in \mathcal{P}_{R_1R_5,\langle R_2,R_2R_5\rangle}$,
6. $s_m^q(x) \in \mathcal{P}_{\langle\omega_m\rangle R_1,\langle\frac{1}{m}\rangle\langle\omega_m\rangle R_2}$.

Proof: Assume that $s(x)=\sum_{i=1}^n p_i(x)e^{\lambda_i x}$, and $t(x)=\sum_{j=1}^m q_j(x)e^{\mu_j x}$ throughout this proof.

1. Observe that:
$$s(x)t(x) \quad = \quad \sum_{i=1}^n p_i(x)e^{\lambda_i x}\sum_{j=1}^m q_j(x)e^{\mu_j x} = \sum_{i=1,j=1}^{i=n,j=m} p_i(x)q_j(x)e^{(\lambda_i+\mu_j)x}.$$
Then $p_i(x)q_j(x) \in R_2R_4[x]$, and $\lambda_i+\mu_j \in \langle R_1,R_3\rangle$. So $s(x)t(x) \in \mathcal{P}_{\langle R_1,R_3\rangle,R_2R_4}$.

2. Observe that:
$$s(x)+t(x) = \sum_{i=1}^n p_i(x)e^{\lambda_i x} + \sum_{j=1}^m q_j(x)e^{\mu_j x}.$$
Both $p_i(x)$ and $q_j(x)$ are in $\langle R_2,R_4\rangle[x]$ and further $\lambda_i,\mu_j \in \langle R_1,R_3\rangle$. Thus $s(x)+t(x) \in \mathcal{P}_{\langle R_1,R_3\rangle,\langle R_2,R_4\rangle}$.

3. Observe that:
$$s'(x) = \sum_{i=1}^n \lambda_i p_i(x)e^{\lambda_i x} + \sum_{i=1}^n p_i'(x)e^{\lambda_i x}.$$
Consequently $p_i'(x), \lambda_i p_i(x) \in \langle R_2, R_1R_2\rangle[x]$ and that $\lambda_i \in R_1$. Thus $s'(x) \in \mathcal{P}_{R_1,\langle R_2,R_1R_2\rangle}$.

4. Re-index the function $s(x)$ so that $s(x)=\sum_{i=1,\lambda_i\neq 0}^n \alpha_i x^{r_i}e^{\lambda_i x} + \sum_{i=0}^m \beta_i x^i$, where $\lambda_i \in R_1$, α_i, $\beta_i \in R_2$ and $r_i \in \mathbb{Z}$, $r_i \geq 0$. Then:
$$\begin{aligned}
\int_0^x s(y)dy &= \int_0^x \sum_{i=1,\lambda_i\neq 0}^n \alpha_i y^{r_i}e^{\lambda_i y} + \sum_{i=0}^m \beta_i y^i dy \\
&= \sum_{i=1,\lambda_i\neq 0}^n \int_0^x \alpha_i y^{r_i}e^{\lambda_i y}dy + \sum_{i=0}^m \int_0^x \beta_i y^i dy \\
&= \sum_{i=1,\lambda_i\neq 0}^n \alpha_i \sum_{j=0}^{r_i} \frac{r_i! x^{r_i-j}e^{\lambda_i x}(-1)^j}{\lambda_i^{j+1}(j-1)!} + \sum_{i=0}^m \frac{\beta_i x^{i+1}}{i+1} \\
&= \sum_{i=1,\lambda_i\neq 0}^n \alpha_i e^{\lambda_i x}\sum_{j=0}^{r_i} \frac{r_i! x^{r_i-j}(-1)^j}{\lambda_i^{j+1}(j-1)!} + \sum_{i=0}^m \frac{\beta_i x^{i+1}}{i+1}.
\end{aligned}$$

The case $\lambda_i \neq 0$ gives that the coefficients are contained in the subring $\langle R_2 R_1^{-1} \rangle$. In the case $\lambda_i = 0$, the coefficients are contained in $\mathbb{Q}R_2$. The λ_i are still in R_1. Therefore $\int_0^x s(y)dy \in \mathcal{P}_{R_1, \langle \mathbb{Q}R_2, R_2 R_1^{-1} \rangle}$.

5. Notice that $s(\alpha x) = \sum_{i=1}^n p_i(\alpha x) e^{\alpha \lambda_i x}$. So $p_i(\alpha x) \in \langle R_2, R_2 R_5 \rangle$. Further $\alpha \lambda_i \in R_1 R_5$, so $s(\alpha x) \in \mathcal{P}_{R_1 R_5, \langle R_2, R_2 R_5 \rangle}$.

6. By combining part 2 and part 5 of this lemma $s_m^q(x)$ can be written as:

$$\frac{1}{m} \sum_{i=1}^m \omega_m^{-iq} s(\omega_m^i x) \in \mathcal{P}_{\langle \langle \omega_m \rangle R_1, \langle \omega_m^2 \rangle R_1, \ldots \langle \omega_m^m \rangle R_1 \rangle, \langle \langle \frac{1}{m} \omega_m \rangle R_2, \langle \frac{1}{m} \omega_m^2 \rangle R_2, \ldots \langle \frac{1}{m} \omega_m^m \rangle R_2 \rangle}.$$

This simplifies to $\mathcal{P}_{\langle \omega_m \rangle R_1, \langle \frac{1}{m} \rangle \langle \omega_m \rangle R_2}$.

■

Lemma 2.3 *Let R_1, R_2, R_3, R_4 and R_5 be subrings of $\mathbb{C}$. If $s(x) \in \mathcal{P}^{R_1, R_2}$, $t(x) \in \mathcal{P}^{R_3, R_4}$, and $\alpha \in R_5$ then:*

1. $s(x)t(x) \in \mathcal{P}^{\langle R_1, R_3 \rangle, R_2 R_4}$,
2. $s(x) + t(x) \in \mathcal{P}^{\langle R_1, R_3 \rangle, \langle R_2, R_4 \rangle}$,
3. $s'(x) \in \mathcal{P}^{R_1, R_2}$,
4. $\int_0^x s(y)dy \in \mathcal{P}^{R_1, R_2}$,
5. $s(\alpha x) \in \mathcal{P}^{R_1 R3, \langle R_2, R_2 R_3 \rangle}$,
6. $s_m^q(x) \in \mathcal{P}^{R_1 \langle \omega_m \rangle, R_2}$.

Proof: Again, assume that $s(x) = \sum_{i=0}^\infty b_i \frac{x^i}{i!} = \sum_{i=1}^n p_i(x) e^{\lambda_i x}$, and $t(x) = \sum_{j=0}^\infty d_j \frac{x^j}{j!} = \sum_{j=1}^m q_j(x) e^{\mu_j x}$ throughout this proof.

1. Consider:

$$s(x)t(x) = \sum_{i=1}^n p_i(x) e^{\lambda_i x} \sum_{j=1}^m q_j(x) e^{\mu_j x} = \sum_{i=1 j=1}^{i=n, j=m} p_i(x) q_j(x) e^{(\lambda_i + \mu_j)x}.$$

From this $\prod_{i=1,j=1}^{i=n,j=m} (x - \lambda_i - \mu_j)^{\deg(p_i(x)) + \deg(q_i(x))}$ is a recurrence polynomial (not necessarily minimal) for $s(x)t(x)$. Hence:

$$P^{st}(x) | \prod_{i=1,j=1}^{i=n,j=m} (x - \lambda_i - \mu_j)^{\deg(p_i(x)) + \deg(q_i(x))}.$$

This splits in $\langle R_1, R_3\rangle$. Further,

$$s(x)t(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} \sum_{j=0}^{\infty} d_j \frac{x^j}{j!} = \sum_{j=0}^{\infty} \sum_{i=0}^{j} \frac{b_{j-i} d_i}{(j-i)!i!} x^j = \sum_{j=0}^{\infty} \sum_{i=0}^{j} b_{j-i} d_i \binom{j}{i} \frac{x^j}{j!}.$$

Therefore the coefficients are in $R_2 R_4$. Thus $s(x)t(x) \in \mathcal{P}^{\langle R_1, R_3\rangle, R_2 R_4}$.

2. Consider:

$$s(x) + t(x) = \sum_{i=1}^{n} p_i(x) e^{\lambda_i x} + \sum_{j=1}^{m} q_j(x) e^{\mu_j x}.$$

The polynomial $\prod_{i=1}^{n} (x - \lambda_i)^{\deg(p_i(x))} \prod_{j=1}^{m} (x - \mu)^{\deg(q_i(x))}$ is a recurrence polynomial for $s(x) + t(x)$ (not necessarily minimal). Hence $P^{s+t}(x) | P^s(x) P^t(x)$. Thus $P^{s+t}(x)$ will split in $\langle R_1, R_3\rangle$. Further,

$$s(x) + t(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} + \sum_{j=0}^{\infty} d_j \frac{x^j}{j!} = \sum_{i=0}^{\infty} (b_i + d_i) \frac{x^i}{i!}.$$

Where the $b_i + d_i$ are in $\langle R_2, R_4\rangle$. Hence $s(x) + t(x) \in \mathcal{P}^{\langle R_1, R_3\rangle, \langle R_2, R_4\rangle}$.

3. If $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$. then

$$s'(x) = \sum_{i=1}^{\infty} b_i \frac{x_{i-1}}{(i-1)!} = \sum_{i=0}^{\infty} b_{i+1} \frac{x_i}{i!}.$$

Hence the coefficients are in the same ring as before, hence in R_2.

Now consider $s(x) = \sum_{i=1}^{n} p_i(x) e^{\lambda_i x}$. This implies that:

$$s'(x) = \sum_{i=1}^{n} q_i(x) e^{\lambda_i x},$$

where $\deg(p_i(x)) = \deg(q_i(x))$ if $\lambda_i \neq 0$ and $\deg(p_i(x)) = \deg(q_i(x)) + 1$ if $\lambda_i = 0$. Thus $P^{s'}(x) = \prod_{i=1}^{n} (x - \lambda_i)^{\deg(q_i(x))}$. Therefore if there exists a λ_i that is equal to 0, then $P^{s'}(x) = P^s(x)x$, and otherwise $P^{s'}(x) = P^s(x)$. So $P^{s'}(x)$ splits over the same field as $P^s(x)$. Hence $s'(x) \in \mathcal{P}^{R_1, R_2}$.

4. By observing that

$$\int_0^x s(y)dy = \int_0^x \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} = \sum_{i=0}^{\infty} \int_0^x \frac{b_i}{i!} y^i dy = \sum_{i=0}^{\infty} \frac{b_i}{(i+1)!} y^{i+1} |_0^x = \sum_{i=1}^{\infty} \frac{b_{i-1}}{i!} x^i,$$

it follows that all the coefficients of $\int_0^x s(y)dy$ are in R_2

Now consider $s(x) = \sum_{i=1}^{n} p_i(x) e^{\lambda_i x}$. This implies that:

$$\int_0^x s(y)dy = \sum_{i=1}^{n} q_i(x) e^{\lambda_i x},$$

where $\deg(p_i(x)) = \deg(q_i(x))$ if $\lambda_i \neq 0$ and $\deg(p_i(x)) + 1 = \deg(q_i(x))$ if $\lambda_i = 0$. From this $P^{s'}(x) = \prod_{i=1}^{n}(x-\lambda_i)^{\deg(q_i(x))}$. Consequently if there exists a λ_i that is equal to 0, then $P^{\int_0^x s(y)dy}(x) = P^s(x)$, and otherwise $P^{\int_0^x s(y)dy}(x) = P^s(x)$. So $P^{\int_0^x s(y)dy}(x)$ splits over the same field as $P^s(x)$. Thus $\int_0^x s(y)dy \in \mathcal{P}^{R_1,R_2}$.

5. It can be seen that
$$s(\alpha x) = \sum_{i=0}^{\infty} b_i \frac{\alpha^i x^i}{i!},$$
Consequently all of the $b_i\alpha^i \in \langle R_2, R_2R_5\rangle$.

The next aim is to find a linear recurrence relation for the $b_i\alpha^i$. Now if:
$$P^s(x) = x^n - \beta_1 x^{n-1} - ... - \beta_n = \prod_{i=1}^{n}(x-\lambda_i)^{\deg(p_i(x))},$$
and letting $c_i = b_i\alpha^i$ then:
$$\frac{c_i}{\alpha^i} = \beta_1\frac{c_{i-1}}{\alpha^{i-1}} + ... + \beta_n\frac{c_{i-n}}{\alpha^{m-i}}.$$
Multiplying through by α^i gives:
$$c_i = \alpha\beta_1 c_{i-1} + ... + \alpha^n\beta_n c_{i-n},$$
which gives:
$$P^{s(\alpha x)}(x) = x^n - \beta_1\alpha x^{n-1} - ...\alpha^n\beta_n,$$
this factors as:
$$P^{s(\alpha x)}(x) = \prod_{i=1}^{n}(x-\lambda_i\alpha)^{\deg(p_i(x))}.$$
Therefore $P^{s(\alpha x)}(x)$ splits over R_1R_5. So $s(\alpha x) \in \mathcal{P}^{R_1R_5,\langle R_2,R_2R_5\rangle}$.

6. By combining part 2 and part 5 of this lemma $s_m^q(x)$ can be written as:
$$\frac{1}{m}\sum_{i=1}^{m}\omega_m^{-i*q}s(\omega_m^i x) \in \mathcal{P}^{\langle\langle\omega_m\rangle R_1,\langle\omega_m^2\rangle R_1,...\langle\omega_m^m\rangle R_1\rangle,\langle\frac{1}{m}\langle\omega_m\rangle R_2,\langle\frac{1}{m}\omega_m^2\rangle R_2,...\langle\frac{1}{m}\omega_m^m\rangle R_2\rangle}.$$
But this will simplify to $\mathcal{P}^{\langle\omega_m\rangle R_1,\langle\frac{1}{m}\rangle\langle\omega_m\rangle R_2}$.

An even tighter bound on the coefficients can be seen by noticing that:
$$s_m^q(x) = \sum_{i=0}^{\infty} b_{mi+q}\frac{x^{mi+q}}{(mi+q)!}.$$
From this all the coefficients in the resulting formula are still contained within the ring R_2. Hence $s_m^q(x) \in \mathcal{P}^{R_1\langle\omega_m\rangle,R_2}$.

■

In the proof of Lemma 2.3, some intermediate results were obtained, which are summarized below:

Corollary 2 *Let R_1, R_2 and R_3 be subrings of $\mathbb{C}$. If $s(x)$, $t(x) \in \mathcal{P}$ such that $P^s(x) \in R_1[x]$, $P^t(x) \in R_2[x]$ and $\alpha \in R_3$. Then:*

1. $P^{st}(x) \in R_1R_2[x]$,
2. $P^{s+t}(x) \in R_1R_2[x]$,
3. $P^{s'}(x) \in R_1[x]$ *(infact* $P^s(x) = P^{s'}(x)$ *or* $P^s(x) = xP^{s'}(x)$*)*,
4. $P^{\int_0^x s(y)dy}(x) \in R_1[x]$ *(infact* $P^{\int_0^x s(y)dy}(x) = P^s(x)$ *or* $P^{\int_0^x s(y)dy}(x) = xP^s(x)$*)*,
5. $P^{s(\alpha x)}(x) \in \langle R_1, R_3 \rangle[x]$,
6. $P^{s^q_m}(x) \in R_1[x]$.

These results will be useful later in Chapters 4 and 5. These results imply that the calculations can normally be assumed to be over "nice" rings such as the integers or rationals.

Corollary 3 *Let R_1 and R_2 be subrings of $\mathbb{C}$. Then $\mathcal{P}_{R_1,R_2}$ and $\mathcal{P}^{R_1,R_2}$ are both rings.*

Example 5 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the function $\mathrm{s}(x) = \sum_{i=0}^{\infty} \frac{b_i\, x^i}{i!}$*, where* $b_i = b_{i-1} + b_{i-2}$ *and* $b_0 = 2$, $b_1 = 1$*. These are the Lucas numbers as defined by Graham, Knuth and Patashnik, [16, 24]. To avoid confusion with the Lucas numbers as defined by Lehmer, call these the "*Lucas numbers, type I*" . Now multisection s(x) by 4 at 1.*

```
> \mapleinline{active}{1d}{s := b(x) = b(x-1) + b(x-2), b, x, [b(0) =
> 2, b(1) = 1];}{%
> }
```

$$\mathrm{s} := \mathrm{b}(x) = \mathrm{b}(x-1) + \mathrm{b}(x-2),\ b,\ x,\ [\mathrm{b}(0) = 2,\ \mathrm{b}(1) = 1]$$

First convert this to poly-exponential form:

```
> \mapleinline{active}{1d}{pe := convert_pe(s)[1];}{%
> }
```

$$pe := e^{(x\,(1/2-1/2\,\sqrt{5}))} + e^{(x\,(1/2+1/2\,\sqrt{5}))}$$

Now multisection the poly-exponential function using the formula as given in Definition 2.6.

```
> \mapleinline{active}{1d}{ms  := 1/4*sum(subs(x=x*exp(2*Pi*I/4*i),
> pe)*exp(-2*Pi*I/4*i), i=0..3);}{%
> }
```

$$ms := \frac{1}{4}\,e^{(x\,\%2)} + \frac{1}{4}\,e^{(x\,\%1)} - \frac{1}{4}\,I\,(e^{(I\,x\,\%2)} + e^{(I\,x\,\%1)}) - \frac{1}{4}\,e^{(-x\,\%2)} - \frac{1}{4}\,e^{(-x\,\%1)} + \frac{1}{4}\,I\,(e^{(-I\,x\,\%2)} + e^{(-I\,x\,\%1)})$$

$$\%1 := \frac{1}{2} + \frac{1}{2}\,\sqrt{5}$$

$$\%2 := \frac{1}{2} - \frac{1}{2}\,\sqrt{5}$$

Now convert this back into an exponential generating function.

```
> \mapleinline{active}{1d}{convert_egf(ms, b, x);}{%
> }
```

$$\mathrm{b}(x) = -\mathrm{b}(x-8) + 7\,\mathrm{b}(x-4),\ b,\ x,$$
$$[\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 1,\ \mathrm{b}(2) = 0,\ \mathrm{b}(3) = 0,\ \mathrm{b}(4) = 0,\ \mathrm{b}(5) = 11,\ \mathrm{b}(6) = 0,\ \mathrm{b}(7) = 0]$$

From this it follows that $s_4^1(x) = \sum_{i=0}^{\infty} \frac{b_i\,x^i}{i!}$, *where* $b_i = 7\,b_{i-4} - b_{i-8}$ *and* $b_1 = 1$, $b_5 = 11$ *and* $b_i = 0$ *if* $i \neq 1 \bmod 4$. *So* $s_4^1(x) = \sum_{i=0}^{\infty} \frac{b_{4\,i+1}\,x^{(4\,i+1)}}{(4\,i+1)!}$.

Alternatively there is automated code to achieve the same result, using this naive method.

```
> \mapleinline{active}{1d}{`egf/ms/naive`(s,4,1);}{%
> }
```

$$\mathrm{b}(x) = -\mathrm{b}(x-8) + 7\,\mathrm{b}(x-4),\ b,\ x,$$
$$[\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 1,\ \mathrm{b}(2) = 0,\ \mathrm{b}(3) = 0,\ \mathrm{b}(4) = 0,\ \mathrm{b}(5) = 11,\ \mathrm{b}(6) = 0,\ \mathrm{b}(7) = 0]$$

This is a relationship for the Lucas numbers, type I that is only concerned with $b_1, b_5, b_9, ...$

Automating the process of multisectioning is covered in Chapter 4.

2.5 Hierarchy of $\mathcal{P}$.

While many results for both $\mathcal{P}^{R_1,R_2}$ and $\mathcal{P}_{R_1,R_2}$ have been obtained, it is not yet clear as to how these two rings relate to each other. This section shows that they are in fact different sets of rings. Further an inclusion relationship between the rings is shown.

Theorem 2.2 *Let R_1 and R_2 be subrings of $\mathbb{C}$. Then the following inclusion relationships of the subrings of $\mathcal{P}$ hold.*

1. $\mathcal{P}_{R_1,R_2} \subseteq \mathcal{P}^{R_1,\langle R_1R_2,R_2\rangle}$,
2. $\mathcal{P}^{R_1,R_2} \subseteq \mathcal{P}_{R_1,R_2\langle R_1^{-1},R_1\rangle}$.

Proof:

1. Let $s(x) \in \mathcal{P}_{R_1,R_2}$, $s(x) = \sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$, $p_i(x) \in R_2[x]$, $\lambda_i \in R_1$. Noticing that $P^s(x) = \prod_i^n (x-\lambda_i)^{\deg(p_i(x))}$, demonstrates that $P^s(x)$ splits in $R_1[x]$. Now notice that $b_i = s^{(i)}(0)$, the i-th derivative of $s(x)$. But $s^{(i)}(x) \in \mathcal{P}_{R_1,\langle R_1R_2,R_2\rangle}$ by Lemma 2.2 part 3. Evaluating at 0 gives $b_i \in \langle R_1R_2, R_2\rangle$, hence $\mathcal{P}_{R_1,R_2} \subseteq \mathcal{P}^{R_1,\langle R_1R_2,R_2\rangle}$.

2. Let $s(x) \in \mathcal{P}^{R_1,R_2}$, $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$. By definition $P^s(x)$ splits in R_1. Lemma 2.1 implies that if $s(x) = \sum_i^n \alpha_i x^{(r_i)} e^{\lambda_i x}$ then all the λ_i are in R_1.

   Again from Lemma 2.1 it follows that:

$$b_j = \sum_{i=1}^{n} j^{(r_i)} \lambda_i^{j-r_i} \alpha_{r_i},$$

   where $\lambda_i \in R_1$, $j^{(r_i)} \in \mathbb{Z}$ and $b_j \in R_2$, and $j^{(r)} = (j)(j-1)...(j-r+1)$. A solution to these equations using Gaussian elimination requires only addition, subtraction, multiplication, and division of elements in R_1. Thus $\alpha_{r_i} \in R_2\langle R_1^{-1}, R_1\rangle$. Hence $\mathcal{P}^{R_1,R_2} \subseteq \mathcal{P}_{R_1,R_2\langle R_1^{-1},R_1\rangle}$.

■

Consider the following examples, which shows that the two rings are distinct.

Example 6 *Consider $s(x) = e^{\sqrt{2}x} \in \mathcal{P}_{\mathbb{Q}(\sqrt{2}),\mathbb{Z}}$. Now $s'(x) = \sqrt{2}e^{\sqrt{2}x}$, and $\sqrt{2} \notin \mathbb{Z}$ implies that $s'(x) \notin \mathcal{P}_{\mathbb{Q}(\sqrt{2}),\mathbb{Z}}$. But all rings of the form $\mathcal{P}^{R_1,R_2}$ are closed under differentiation (Lemma 2.3). Hence there do not exist rings R_1, R_2 such that $\mathcal{P}_{\mathbb{Q}(\sqrt{2}),\mathbb{Z}} = \mathcal{P}^{R_1,R_2}$.*

Example 7 *Consider $\mathcal{P}^{\mathbb{Z},\mathbb{Z}}$. The goal here is to show that there do not exist rings R_1, R_2 such that $\mathcal{P}^{\mathbb{Z},\mathbb{Z}} = \mathcal{P}_{R_1,R_2}$. Consider the exponential generating function $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$ with the linear relation $b_i = 3cb_{i-1} - 2c^2b_{i-2}$, for $c \in \mathbb{Z}$. If b_0, $b_1 \in \mathbb{Z}$, then $s(x) \in \mathcal{P}^{\mathbb{Z},\mathbb{Z}}$. But this is equivalent to $s(x) = \alpha_1 e^{cx} + \alpha_2 e^{2cx}$, where $\alpha_1 = 2b_0 - \frac{b_1}{c}$ and $\alpha_2 = -b_0 + \frac{b_1}{c}$. Hence α_1 can be any arbitrary rational in $\mathbb{Q}$, say $\frac{p}{q}$, by picking $b_0 = 0$, $b_1 = -p$ and $c = q$. Thus if $\mathcal{P}^{\mathbb{Z},\mathbb{Z}} \subseteq \mathcal{P}_{R_1,R_2}$, then $\mathbb{Z} \subseteq R_1$ (as R_1 must contain arbitrary c, where $c \in \mathbb{Z}$) and $\mathbb{Q} \subseteq R_2$. Now $\mathcal{P}^{\mathbb{Z},\mathbb{Z}}$ is a strict subset of $\mathcal{P}_{\mathbb{Z},\mathbb{Q}}$, as $\frac{1}{2} \in \mathcal{P}_{\mathbb{Z},\mathbb{Q}}$ and $\frac{1}{2} \notin \mathcal{P}^{\mathbb{Z},\mathbb{Z}}$. Hence there do not exist rings R_1 and R_2, such that $\mathcal{P}^{\mathbb{Z},\mathbb{Z}} = \mathcal{P}_{R_1,R_2}$.*

Corollary 4 *If F_1 is a subfield of $\mathbb{C}$, and $R_1 \subseteq F_1$ is a subring of $\mathbb{C}$ then $\mathcal{P}_{R_1,F_1} = \mathcal{P}^{R_1,F_1}$.*

2.6 Some complexity bounds.

Understanding the complexity of the functions being manipulated is useful for doing computations on $s(x) \in \mathcal{P}$. To this end some metrics of complexity are defined. These metrics have been looked at in the past but not in such a generalized fashion. Typically they would be applied to a particular problem, such as the Bernoulli numbers [9].

Definition 2.7 *Let $s(x) \in \mathcal{P}$, where $s(x) = \sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$. Define the following metrics:*

1. $deg^d(s(x)) = \max(\deg(p_i(x)))$,
2. $deg^P(s(x)) = \deg(P^s(x))$.

Example 8 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

This example determines what $deg^d(s(x))$ and $deg^P(s(x))$ are for various s(x). This example uses the automated code described in appendix A.

First consider the function from Example 1.

```
> \mapleinline{active}{1d}{s[1] := x + x * exp(x);}{%
> }
```

$$s_1 := x + x\,e^x$$

```
> \mapleinline{active}{1d}{`pe/metric/d`(s[1],x);}{%
> }
```

$$1$$

Recalls that $P^{s_1}(x) = x^4 - 2x^3 + x^2$.

```
> \mapleinline{active}{1d}{`pe/metric/P`(s[1],x);}{%
> }
```

$$4$$

Next, consider the Fibonacci numbers from Example 2.

```
> \mapleinline{active}{1d}{s[2] := b(x) = b(x-1)+b(x-2),b,x,
> [b(0)=0,b(1)=1];}{%
> }
```

$$s_2 := \mathrm{b}(x) = \mathrm{b}(x-1) + \mathrm{b}(x-2),\ b,\ x,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 1]$$

```
> \mapleinline{active}{1d}{`egf/metric/d`(s[2]);}{%
> }
```

$$0$$

```
> \mapleinline{active}{1d}{`egf/metric/P`(s[2]);}{%
> }
```

$$2$$

These metrics are of use later on in Chapter 4 and 5. In those two chapters, upper bounds for functions under different operations are required.

Lemma 2.4 *Let $s(x)$, $t(x) \in \mathcal{P}$, and $\alpha \neq 0$ a constant. Then:*

1. $deg^d(s(x)t(x)) = deg^d(s(x)) + deg^d(t(x))$,
2. $0 \leq deg^d(s(x) + t(x)) \leq \max(deg^d(s(x)), deg^d(t(x)))$,
3. $deg^d(s(x)) - 1 \leq deg^d(s'(x)) \leq deg^d(s(x))$,
4. $deg^d(s(x)) \leq deg^d(\int_0^x s(y)dy) = deg^d(s(x)) + 1$,
5. $deg^d(s(\alpha x)) = deg^d(s(x))$,
6. $0 \leq deg^d(s_m^q(x)) \leq deg^d(s(x))$.

Proof: Write $s(x) = \sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$ and $t(x) = \sum_{j=1}^{m} q_j(x)e^{\mu_j x}$ for the remainder of this proof.

1. Notice that:
$$deg^d(s(x)t(x)) = deg^d(\sum_{i=1,j=1}^{i=n,j=m} p_i(x)q_j(x)e^{(\lambda_i+\mu_j)x}).$$
Denote $I = \{i : \deg(p_i(x)) = deg^d(s(x))\}$ and $J = \{j : \deg(q_i(x)) = deg^d(t(x))\}$. Pick $\lambda = \max_{i\in I}(\lambda_i)$ and $\mu = \max_{j\in J}(\lambda_i)$. (The maximum is taken lexigraphically, for example, for two complex numbers α and β, α is greater than β if the real component of α is greater than that of β, or if the real component of α and β are equal, and the imaginary component of α is greater than that of β.)
Consequently the polynomial associated with $\lambda + \mu$ is of degree $deg^d(s(x)) + deg^d(t(x))$. Thus $deg^d(s(x)t(x)) = deg^d(s(x)) + deg^d(t(x))$.
2. The upper bound is clear, and taking $s(x) = -t(x)$ gives the lower bound.

3. Notice that:

$$deg^d(s'(x)) \quad = \quad deg^d(\frac{d}{dx}\sum_{i=1}^{n} p_i(x)e^{\lambda_i x}) = deg^d(\sum_{i=1}^{n}(\lambda_i p_i(x) + p_i'(x))e^{\lambda_i x}).$$

Notice that $\deg(p_i(x)\lambda_i + p_i'(x)) = \deg(p_i(x))$ if $\lambda_i \neq 0$, and is equal to $\deg(p_i(x)) - 1$ if $\lambda_i = 0$. Hence $deg^d(s'(x)) = deg^d(s(x))$ or $deg^d(s(x)) - 1$.

4. Part 4 of Lemma 2.2 shows that:

$$deg^d(\int_0^x s(y)dy) \quad = \quad deg^d(\int_0^x \sum_{i=1}^{n} p_i(y)e^{\lambda_i y}dy) = deg^d(\sum_{i=1}^{n} q_i(x)e^{\lambda_i x}).$$

Where $\deg(q_i(x)) = \deg(p_i(x))$ if $\lambda_i \neq 0$ and $\deg(q_i(x)) = \deg(p_i(x)) + 1$ if $\lambda_i = 0$. Thus $deg^d(\int_0^x s(y)dy) = deg^d(s(x))$ or $deg^d(s(x)) + 1$.

5. Observe that:

$$deg^d(s(\alpha x)) = deg^d(\sum_{i=1}^{n} p_i(\alpha x)e^{\lambda_i \alpha x}).$$

As $\deg(p_i(\alpha x)) = \deg(p_i)$ it follows that $deg^d(s(\alpha x)) = deg^d(s)$.

6. Part 2 and part 5 of this lemma, in combination shows that $deg^d(s_m^q(x)) \leq deg^d(s(x))$. If $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$ and $b_i = 0$ whenever $i \equiv q \pmod m$, then $s_m^q(x) = 0$. Hence $deg^d(s_m^q(x)) = 0$ in this case.

■

Lemma 2.5 *Let $s(x), t(x) \in \mathcal{P}$, and α a constant. Then:*

1. $deg^P(s(x)t(x)) \leq deg^P(s(x))deg^P(t(x))$,
2. $0 \leq deg^P(s(x) + t(x)) \leq deg^P(s(x)) + deg^P(t(x))$,
3. $deg^P(s(x)) - 1 \leq deg^P(s'(x)) = deg^P(s(x))$,
4. $deg^P(s(x)) \leq deg^P(\int_0^x s(y)dy) = deg^P(s(x)) + 1$,
5. $deg^P(s(\alpha x)) = deg^P(s(x))$,
6. $0 \leq deg^P(s_m^q(x)) \leq m \times deg^P(s(x))$.

Proof: Write $s(x) = \sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$ and $t(x) = \sum_{j=1}^{m} q_j(x)e^{\mu_j x}$ for the remainder of this proof.

1. Noticing that $P^{st}(x) | \prod_{i=1,j=1}^{i=n,j=m}(x - \lambda_i - \mu_j)^{\deg(p_i(x))+\deg(q_i(x))}$ as shown in Lemma 2.3 gives $deg^P(s(x)t(x)) \leq deg^P(s(x))deg^P(t(x))$.

2. Observing that $P^{s+t}(x)|P^s(x)P^t(x)$, as shown in Lemma 2.3 gives $deg^P(s(x)+t(x)) \leq deg^P(s(x))+deg^P(t(x))$. The lower bound comes from taking $s(x) = -t(x)$.

3. In Lemma 2.3 it was shown that $P^{s'}(x) = P^s(x)$ or $xP^{s'}(x) = P^s(x)$. Hence $deg^P(s'(x)) = deg^P(s(x))$ or $deg^P(s(x)) - 1$.

4. In Lemma 2.3 it was shown that $P^{\int_0^x s(y)dy}(x) = P^s(x)$ or $P^{\int_0^x s(y)dy}(x) = xP^s(x)$. Hence $deg^P(\int_0^x s(y)dy) = deg^P(s(x))$ or $deg^P(s(x)) + 1$.

5. If $P^s(x) = \prod_{i=1}^n (x-\lambda_i)^{\deg(p_i(x))}$ then $P^{s(\alpha x)}(x) = \prod_{i=1}^n (x-\alpha\lambda_i)^{\deg(p_i(x))}$, which has the same degree. Hence $deg^P(s(\alpha x)) = deg^P(s(x))$.

6. Part 2 and part 5 of this lemma, in combination shows that $deg^P(\sum_{k=1}^m s(\omega_m^k x)\omega_m^{-qk}) \leq \sum_{k=1}^m deg^P(s(\omega_m^k x)) = m \times deg^P(s(x))$. The lower bound follows by considering the same example as is found in Lemma 2.4 part 6.

■

Chapters 4 and 5 typically work with the recurrences instead of with the poly-exponential function directly. These results are useful as they give bounds for the linear recurrence relations. The bound given by the metric deg^P is obvious, and the metric deg^d gives a bound to the multiplicity of roots in the recurrence polynomial.

Now the relationship between the metrics is examined.

Lemma 2.6 *Let $s(x) \in \mathcal{P}$. Then $1 + deg^d(s(x)) \leq deg^P(s(x))$.*

Proof: Write $s(x) = \sum_{i=1}^n p_i(x)e^{\lambda_i x}$ for the remainder of this proof. By Corollary 1 it follows that:

$$1 + deg^d(s(x)) \quad = \quad \max_{i=1}^n(\deg(p_i(x)) + 1) \leq \sum_{i=1}^n (\deg(p_i(x)) + 1) = deg^P(s(x)).$$

Which gives the desired result.

■

2.7 Examples.

In this section, three detailed examples are worked out. That of $s(x) = \sum_{i=1}^n \alpha_i e^{\lambda_i(x)}$ and $t(x) = e^{\lambda x}p(x)$, and the Chebyshev T polynomials.

Example 9 *Consider* $s(x) = \sum_{i=1}^{n} \alpha_i \ e^{\lambda_i(x)}$. *Therefore the recurrence polynomial is* $P^s(x) = \prod_{i=1}^{n}(x-\lambda_i)$. *Denoting* $\beta_k = \sum_{J\subseteq\{\lambda_1,\ldots,\lambda_n\},|J|=k} \prod_{\lambda\in J} \lambda$ *to be the elementary symmetric polynomials of* N *variables gives* $P^s(x) = \sum_{k=0}^{N} x^{N-k}\beta_k(-1)^k$.

Writing $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$ *gives a linear recurrence relation for the* b_i *namely* $b_i = \sum_{k=1}^{N} \beta_k \ b_{i-k}(-1)^k$.

The first N *values of the* b_i *must be determined. Note that* $b_i = s^{(i)}(0)$, *the* i*-th derivative of* $s(x)$. *Also* $s(x) = \sum_{i=1}^{n} \alpha_i e^{\lambda_i x}$, *so* $b_i = \sum_{k=1}^{n} \alpha_k \lambda_k^i$.

Example 10 *Consider* $t(x) = e^{\lambda x}p(x)$. *So the recurrence polynomial satisfies* $P^t(x) = (x-\lambda)^{\deg(p(x))}$. *Let* $N = \deg(p(x))$ *for convenience. Consequently* $P^t(x) = \sum_{k=0}^{N} \binom{N}{k} x^{N-k}(-\lambda)^k$. *Thus linear recurrence relation is simply:* $b_i = -\sum_{k=0}^{N} \binom{N}{k} b_{i-k}(-\lambda)^k$.

Now determine the first N *values of the* b_i. *Observe that* $b_i = t^{(i)}(0)$, *the* i*-th derivative of* $t(x)$. *Further, observe that* $t(x) = e^{\lambda x}p(x)$. *So* $t^{(0)}(0)$ *is simply* $p(0)$. *Next* $t^{(1)}(0) = \lambda p(0) + p'(0)$. *Next* $t^{(2)}(0) = \lambda^2 p(0) + 2\lambda p'(0) + p''(0)$. *In general* $t^{(k)}(0) = \sum_{i=0}^{k} \binom{k}{i} \lambda^{k-i} p^{(i)}(0)$. *If* $p(x) = a_N x^N + \ldots + a_0$, *then this formula for the* b_i *will simplify to* $t^{(k)}(0) = \sum_{i=0}^{k} \binom{k}{i} \lambda^{k-i} i! a_i$.

Thus the linear recurrence relation is $b_i = -\sum_{k=0}^{N} b_{i-k}(-\lambda)^k$ *and where for* $k < N$, $b_i = \sum_{k=0}^{i} \binom{i}{k} \lambda^{i-k} k! a_k$.

Example 11 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

*This example will demonstrate that process of multisectioning can be used where the recurrence has symbolic values rather than simply numeric ones. Consider the "*Chebyshev T polynomials*", as polynomials in t, with the recurrence* $T_n = 2\,t\,T_{n-1} - T_{n-2}$ *with initial polynomials* $T_0 = 1$ *and* $T_1 = t$ *[2]. Consider multisectioning this by 5 at 1, to get a recurrence for* T_1, T_6, T_{11}, T_{16}, ...

```
> \mapleinline{active}{1d}{egf := f(x) = 2*t*f(x-1)-f(x-2),f,x,[f(0)=1,
> f(1)=t];}{%
> }
```

$$egf := \mathrm{f}(x) = 2\,t\,\mathrm{f}(x-1) - \mathrm{f}(x-2),\ f,\ x,\ [\mathrm{f}(0) = 1,\ \mathrm{f}(1) = t]$$

```
> \mapleinline{active}{1d}{`egf/ms`(egf,5,1);}{%
> }
```

$$\begin{aligned}\mathrm{f}(x) = {} & -\mathrm{f}(x-10) + (32\,t^5 - 40\,t^3 + 10\,t)\,\mathrm{f}(x-5),\ f,\ x, [\mathrm{f}(0) = 0,\ \mathrm{f}(1) = t,\ \mathrm{f}(2) = 0,\\ & \mathrm{f}(3) = 0,\ \mathrm{f}(4) = 0,\ \mathrm{f}(5) = 0, \mathrm{f}(6) = \\ & 2\,t\,(2\,t\,(2\,t\,(2\,t^2-1)-t) - 2\,t^2 + 1) - 2\,t\,(2\,t^2-1) + t)\\ & - 2\,t\,(2\,t\,(2\,t^2-1)-t) + 2\,t^2 - 1,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 0,\ \mathrm{f}(9) = 0]\end{aligned}$$

```
> \mapleinline{active}{1d}{expand([%]);}{%
> }
```

$$[\mathrm{f}(x) = -\mathrm{f}(x-10) + 32\,\mathrm{f}(x-5)\,t^5 - 40\,\mathrm{f}(x-5)\,t^3 + 10\,\mathrm{f}(x-5)\,t,\ f,\ x, [\mathrm{f}(0) = 0,\ \mathrm{f}(1) = t,$$
$$\mathrm{f}(2) = 0,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = 0,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 32\,t^6 - 48\,t^4 + 18\,t^2 - 1,\ \mathrm{f}(7) = 0,$$
$$\mathrm{f}(8) = 0,\ \mathrm{f}(9) = 0]]$$

This example is interesting in that it shows that the λ_i used in the definition of poly-exponential functions, (Definition 2.1) can be symbolic values in the complex numbers, as opposed to just the numeric values.

2.8 Conclusions.

By combining the results of Theorem 2.1, Lemmas 2.3, 2.5 and Corollary 2 the following results are true.

Theorem 2.3 *Let $s(x) \in \mathcal{P}$.*

1. *Then there exists a lacunary recurrence relation for the $mi+q$-th coefficient of $s(x)$'s exponential generating function in terms of the $mj+q$-th coefficient $j = i-N, ..., i-1$, where N is bounded above by $deg^P(s(x))$.*
2. *Moreover if the linear recurrence relation associated with $s(x)$ is such that the associated recurrence polynomial is in $R_1[x]$, then the recurrence polynomial of the new lacunary recurrence relation will also be in $R_1[x]$.*
3. *Furthermore if the linear recurrence relation associated with $s(x)$ is of length N, then the new lacunary recurrence relation will be of length less than or equal to mN, where only $\frac{1}{m}$-th of the terms are non-zero.*

The following corollory was know in [16], but its proof was specific to either the Fibonacci or Lucas type I numbers, and was not the consequence of a more general theorem.

Corollary 5 *The $mi+q$ term of the Fibonacci and Lucas type I numbers can be computed in terms of $mj+q$ term for $j = i-2, i-1$ via a lacunary recurrence relation. Moreover the lacunary recurrence relation will be over $\mathbb{Z}$. Lastly, the lacunary recurrence relation will be of length $2m$ with 2 non-zero terms.*

Chapter 3

Rational poly-exponential functions.

3.1 Rational poly-exponential function.

Some techniques for poly-exponential functions where developed in Chapter 2. This chapter expands the scope of the study to a more general setting; that of ratios of poly-exponential functions. To that end, define:

Definition 3.1 (Rational poly-exponential function.) *Let $s(x)$, $t(x) \in \mathcal{P}$ and $t(x) \neq 0$. Then*

$$\frac{s(x)}{t(x)},$$

*is a "*rational poly-exponential function*". Denote the set of all such functions by $\mathcal{R}$.*

This definition was suggested by my supervisor, Jon Borwein, as a generalization of the Bernoulli numbers. All of the methods Lehmer, or Glaisher [19, 14] to multisectioning the Bernoulli numbers relied only upon the fact that these numbers had "nice" linear recurrence relation to describe the exponential generating function of the numerator and denominator. Definition 3.1 maintains this property, but expands the scope of the results to a much large class of functions. To the best of my knowledge, the results in this chapter are new, in the sense that they have not been done in this degree of generality before.

Section 3.2 shows how to calculate the coefficients of the exponential generating function of functions in $\mathcal{R}$ by use of recursion formulae. Section 3.3 will demonstrate the effects of multisectioning

on functions in $\mathcal{R}$. The structure of $\mathcal{R}$ is studied in Section 3.4, examining different rings, subrings, fields and subfields of $\mathcal{R}$, along with some closure properties. In Section 3.5 the examination of subfields of $\mathcal{R}$ is continued, by exploring how these subfields relate to each other. Some metrics of complexity for functions in $\mathcal{R}$ are investigated in Section 3.6. Section 3.7 contains three worked out examples. The last section, Section 3.8 summarizes the main points of this chapter into a final theorem.

3.2 Recursion formula for functions in $\mathcal{R}$.

The study of rational poly-exponential functions begins by looking at an example of how to calculate the coefficients of the exponential generating function of $\frac{x}{e^x-1}$. These are the "*Bernoulli numbers*" (in even suffix notation) [2].

Example 12 *Define*

$$\sum_{k=0}^{\infty} c_k \frac{x^k}{k!} = \frac{x}{e^x - 1} = \frac{\sum_{i=0}^{\infty} b_i \frac{x^i}{i!}}{\sum_{j=0}^{\infty} d_j \frac{x^j}{j!}}.$$

Then the c_k are the Bernoulli numbers. A simple calculation shows that $b_i = 1$ if $i = 1$ and 0 otherwise. Further $d_j = 0$ if $j = 0$ and 1 otherwise.

Now:

$$\begin{aligned}
\sum_{k=0}^{\infty} c_k \frac{x^k}{k!} &= \frac{\sum_{i=0}^{\infty} b_i \frac{x^i}{i!}}{\sum_{j=0}^{\infty} d_j \frac{x^j}{j!}} \\
\sum_{j=0}^{\infty} d_j \frac{x^j}{j!} \sum_{k=0}^{\infty} c_k \frac{x^k}{k!} &= \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} \\
\sum_{k=0}^{\infty} \sum_{j=0}^{k} d_j \frac{x^j}{j!} c_{k-j} \frac{x^{k-j}}{(k-j)!} &= \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} \\
\sum_{k=0}^{\infty} \sum_{j=0}^{k} \binom{k}{j} d_j c_{k-j} \frac{x^k}{k!} &= \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} \\
\sum_{j=0}^{k} \binom{k}{j} d_j c_{k-j} &= b_k.
\end{aligned}$$

From this a recursion formula for the Bernoulli numbers is derived that, for $k > 2$ gives:

$$\sum_{j=1}^{k} \binom{k}{j} c_{k-j} = 0$$

$$c_{k-1} = \frac{-1}{k}\sum_{j=0}^{k-2}\binom{n}{j}c_j.$$

This is the standard recursion formula used for the Bernoulli numbers, as would be found in [2, 10, 16].

Note 3.1 *It is important to note that the term "linear recurrence relation" is different than that of "recursion formula". A recursion formula is a formula where the n-th term depends on the previous $n-1$ terms, where as a linear recurrence relation only requires the previous N terms of which a linear combination is used to determine the n-th term. Examples 12 gives a recursion formula for the Bernoulli numbers.*

It is not always possible to write $f(x) \in \mathcal{R}$ as $\sum_{i=0}^{\infty} c_i \frac{x^i}{i!}$. In particular if $f(x)$ has a pole at 0, this will not be possible (i.e. $\frac{1}{x}$). The restriction to $f(x) \in \mathcal{R}$ which do not have poles at 0, is closed under addition, differentiation, multiplication, $f(x) \to f(\alpha x)$ and multisectioning, by simply looking at the Taylor series under these operations. Denote this set as $\hat{\mathcal{R}}$ to get this definition:

Definition 3.2 ($\hat{\mathcal{R}}$.) *Define*

$$\hat{\mathcal{R}} = \{f(x) : \lim_{x\to 0}\frac{1}{f(x)} \neq 0, f(x) \in \mathcal{R}\}.$$

3.3 Multisectioning.

This section explores the effects of multisectioning on rational poly-exponential functions. The main result of this section allows for the improvement in the efficiency of calculating the coefficients of exponential generating functions for functions in $\mathcal{R}$.

Lemma 3.1 *If $h(x) \in \mathcal{R}$ then $h_m^q(x)$ can be written as $\frac{s_m^q(x)}{t_m^0(x)}$ where $s(x)$, $t(x) \in \mathcal{P}$.*

Proof: Write $h(x) = \frac{s_h(x)}{t_h(x)}$. Thus:

$$\begin{aligned} h_m^q(x) &= \frac{1}{m}\sum_{i=0}^{m-1}\frac{\omega_m^{-iq}s_h(x\omega_m^i)}{t_h(x\omega_m^i)} = \frac{1}{m}\sum_{i=1}^{m-1}\frac{\omega_m^{-iq}s_h(x\omega_m^i)\prod_{j=1}^{m-1}t_h(x\omega_m^{j+i})}{\prod_{j=0}^{m-1}t_h(x\omega_m^j)} \\ &= \frac{\frac{1}{m}\sum_{i=1}^{m-1}\omega_m^{-iq}s_h(x\omega_m^i)\prod_{j=1}^{m-1}t_h(x\omega_m^{j+i})}{\prod_{j=0}^{m-1}t_h(x\omega_m^j)} = \frac{(s_h(x)\prod_{j=1}^{m-1}t_h(x\omega_m^j))_m^q}{(\prod_{j=0}^{m-1}t_h(x\omega_m^j))_m^0}. \end{aligned}$$

Picking $s(x) = s_h(x)\prod_{i=1}^{m-1}t_h(x\omega_m^i)$ and $t(x) = \prod_{i=0}^{m-1}t_h(x\omega_m^i)$ gives the desired result. It is also worthwhile to note that $t_m^0(x) = t(x)$.

■

Theorem 3.1 *Given a function $f(x) \in \hat{\mathcal{R}}$, $m, q \in \mathbb{Z}$, $0 \leq q < m$, a recursion formula can be found for the $mi+q$-th coefficient of the exponential generating function of $f(x)$ that depends only on the $mj+q$-th coefficient, for $j < i$, and two lacunary recurrence relations.*

Later, in Section 3.8, by combining this theorem, Theorem 3.1, with some later results, Lemmas 3.3, 3.4 and 3.6, an even tighter result will be given, the lengths of these lacunary recurrence relations, will be determined, and the ring that their coefficients will lie will be known.

Proof: Let

$$f(x) = \sum_{i=0}^{\infty} c_i \frac{x^i}{i!} = \frac{s_f(x)}{t_f(x)} = \frac{\sum_{i=0}^{\infty} b_i \frac{x^i}{i!}}{\sum_{j=0}^{\infty} d_j \frac{x^j}{j!}},$$

where $s(x)$, $t(x) \in \mathcal{P}$. Lemma 3.1 gives

$$f_m^q(x) = \sum_{i=0}^{\infty} c_{mi+q} \frac{x^{mi+q}}{(mi+q)!} = \frac{s_m^q(x)}{t_m^0(x)} = \frac{\sum_{i=0}^{\infty} \bar{b}_{mi+q} \frac{x^{mi+q}}{(mi+q)!}}{\sum_{j=0}^{\infty} \bar{d}_{mj} \frac{x^{mj}}{(mj)!}},$$

where s_m^q, $t_m^0 \in \mathcal{P}$, and the $\bar{b}_i$ and the $\bar{d}_j$ satisfy lacunary recurrence relations.

A simple calculation shows that

$$\begin{aligned}
\sum_{i=0}^{\infty} c_{mi+q} \frac{x^{mi+q}}{(mi+q)!} &= \frac{\sum_{i=0}^{\infty} \bar{b}_{mi+q} \frac{x^{mi+q}}{(mi+q)!}}{\sum_{j=0}^{\infty} \bar{d}_{mj} \frac{x^{mj}}{(mj)!}} \\
\sum_{j=0}^{\infty} \bar{d}_{mj} \frac{x^{mj}}{(mj)!} \sum_{i=0}^{\infty} c_{mi+q} \frac{x^{mi+q}}{(mi+q)!} &= \sum_{i=0}^{\infty} \bar{b}_{mi+q} \frac{x^{mi+q}}{(mi+q)!} \\
\sum_{i=0}^{\infty} \sum_{j=0}^{i} \binom{mi+q}{mj} \bar{d}_{mj} c_{m(i-j)+q} \frac{x^{mi+q}}{(mi+q)!} &= \sum_{i=0}^{\infty} \bar{b}_{mi+q} \frac{x^{mi+q}}{(mi+q)!} \\
\sum_{j=0}^{i} \binom{mi+q}{mj} \bar{d}_{mj} c_{m(i-j)+q} &= \bar{b}_{mi+q}.
\end{aligned}$$

Picking $s = \min\{j : d_{mj} \neq 0\}$ gives:

$$\begin{aligned}
\sum_{j=s}^{i} \binom{mi+q}{mj} \bar{d}_{mj} c_{m(i-j)+q} &= \bar{b}_{mi+q} \\
\binom{mi+q}{ms} \bar{d}_{ms} c_{m(i-s)+q} &= \bar{b}_{mi+q} - \sum_{j=s+1}^{i} \binom{mi+q}{mj} \bar{d}_{mj} c_{m(i-j)+q} \\
c_{m(i-s)+q} &= \frac{1}{\binom{mi+q}{ms} \bar{d}_{ms}} (\bar{b}_{mi+q} - \sum_{j=s+1}^{i} \binom{mi+q}{mj} \bar{d}_{mj} c_{m(i-j)+q}).
\end{aligned}$$

Let $k = i - s$, to get

$$\begin{aligned} c_{mk+q} &= \frac{1}{\binom{m(s+k)+q}{ms}\bar{d}_{ms}}(\bar{b}_{m(k+s)+q} - \sum_{j=s+1}^{k+s}\binom{m(k+s)+q}{mj}\bar{d}_{mj}c_{m((k+s)-j)+q}) \\ &= \frac{1}{\binom{m(s+k)+q}{ms}\bar{d}_{ms}}(\bar{b}_{m(k+s)+q} - \sum_{j=1}^{k}\binom{m(k+s)+q}{m(j+s)}\bar{d}_{m(j+s)}c_{m(k-j)+q}). \end{aligned}$$

This is a recursion formula for the c_{mk+q} based on the previous c_{mj+q} with $j < k$ and two lacunary recurrence relations for the $\bar{b}_{mi+q}$ and $\bar{d}_{mi}$.

■

The recursion formula associated with $f_m^q(x)$ is called the "*lacunary recursion formula*" [8, 14].

Example 13 *Consider the following example in Maple. For more information about the Maple code, see Appendix A. For the Maple code see Appendix E. The Maple code and help files (including information about syntax) are available on the web at [1].*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider again the Bernoulli numbers $\frac{x}{e^x-1} = \frac{\sum_{i=0}^{\infty}\frac{b_i\,x^i}{i!}}{\sum_{j=0}^{\infty}\frac{d_j\,x^j}{j!}}$. *Multisection this by 3 at 1, using the formula, as given in Lemma 3.1. After this, this example will calculate the 1-st, 4-th 7-th and 10-th Bernoulli number, using the formula given in Theorem 3.1.*

Let $s_h(x) = x$ *and* $t_h(x) = e^x - 1$, *and solve for* $\mathrm{s}(x)$ *and* $\mathrm{t}(x)$ *in the theorem.*

```
> \mapleinline{active}{1d}{s[h] := x -> x;}{%
> }
```

$$s_h := x \to x$$

```
> \mapleinline{active}{1d}{t[h] := (x) -> exp(x)-1;}{%
> }
```

$$t_h := x \to e^x - 1$$

```
> \mapleinline{active}{1d}{omega[3] := exp(2*Pi*I/3);}{%
> }
```

$$\omega_3 := -\frac{1}{2} + \frac{1}{2}\,I\,\sqrt{3}$$

From Lemma 3.1 $\mathrm{s}(x) = s_h(x)\,(\prod_{i=1}^{m-1} t_h\,{\omega_m}^i)$, *and* $\mathrm{t}(x) = \prod_{i=0}^{m-1} t_h(x\,{\omega_m}^i)$, *which, for this particular case is:*

```
> \mapleinline{active}{1d}{S := s[h](x) * t[h](x*omega[3]) *
> t[h](x*omega[3]^2);}{%
> }
```

$$S := x\,(e^{(x\,(-1/2+1/2\,I\,\sqrt{3}))} - 1)\,(e^{(x\,(-1/2+1/2\,I\,\sqrt{3})^2)} - 1)$$

```
> \mapleinline{active}{1d}{T :=
> t[h](x)*t[h](x*omega[3])*t[h](x*omega[3]^2);}{%
> }
```

$$T := (e^x - 1)\,(e^{(x\,(-1/2+1/2\,I\,\sqrt{3}))} - 1)\,(e^{(x\,(-1/2+1/2\,I\,\sqrt{3})^2)} - 1)$$

Now, determine what the linear recurrence relation for this would be.

```
> \mapleinline{active}{1d}{`pe/ms`(S,b,x,3,1);}{%
> }
```

$$\mathrm{b}(x) = -\mathrm{b}(x-12) + 2\,\mathrm{b}(x-6),\ b,\ x,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 0,\ \mathrm{b}(2) = 0,\ \mathrm{b}(3) = 0,\ \mathrm{b}(4) = -12,\ \mathrm{b}(5) = 0,\ \mathrm{b}(6) = 0,\ \mathrm{b}(7) = -7,\ \mathrm{b}(8) = 0,\ \mathrm{b}(9) = 0,\ \mathrm{b}(10) = -30,\ \mathrm{b}(11) = 0,\ \mathrm{b}(12) = 0,\ \mathrm{b}(13) = -13]$$

So $s_3^1(x) = \sum_{i=0}^{\infty} \frac{b_i\,x^i}{i!}$, *where* $b_i = b_{i-12} + 2\,b_{i-6}$, *with initial values of* $b_4 = -12$, $b_7 = -7$, $b_{10} = -30$ *and* $b_{13} = -13$.

```
> \mapleinline{active}{1d}{convert_egf(T,d,x);}{%
> }
```

$$\mathrm{d}(x) = \mathrm{d}(x-6),\ d,\ x,\ [\mathrm{d}(0) = 0,\ \mathrm{d}(1) = 0,\ \mathrm{d}(2) = 0,\ \mathrm{d}(3) = 6,\ \mathrm{d}(4) = 0,\ \mathrm{d}(5) = 0]$$

So the bottom linear recurrence relation $t_3^0(x) = \sum_{j=0}^{\infty} \frac{d_j\,x^i}{j!}$, *where* $d_j = d_{j-6}$, *and the initial values are* $d_3 = 6$.

Equally easy the two built-in commands could have been used to do this in the naive fashion.

```
> \mapleinline{active}{1d}{top := `top/ms/naive`(x,exp(x)-1,b,x,3,1);}{%
> }
```

$$top := \mathrm{b}(x) = -\mathrm{b}(x-12) + 2\,\mathrm{b}(x-6),\ b,\ x,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 0,\ \mathrm{b}(2) = 0,\ \mathrm{b}(3) = 0,\ \mathrm{b}(4) = -12,\ \mathrm{b}(5) = 0,\ \mathrm{b}(6) = 0,\ \mathrm{b}(7) = -7,\ \mathrm{b}(8) = 0,\ \mathrm{b}(9) = 0,\ \mathrm{b}(10) = -30,\ \mathrm{b}(11) = 0,\ \mathrm{b}(12) = 0,\ \mathrm{b}(13) = -13]$$

```
> \mapleinline{active}{1d}{bot := `bottom/ms/naive`(exp(x)-1,d,x,3);}{%
> }
```

$$bot := \mathrm{d}(x) = \mathrm{d}(x-6),\ d,\ x,\ [\mathrm{d}(0) = 0,\ \mathrm{d}(1) = 0,\ \mathrm{d}(2) = 0,\ \mathrm{d}(3) = 6,\ \mathrm{d}(4) = 0,\ \mathrm{d}(5) = 0]$$

Now, to calculate the first few Bernoulli numbers, use the formula as given in Theorem 3.1, first noting that s is equal to 1.

```
> \mapleinline{active}{1d}{Top := `egf/makeproc`(top):}{%
> }

> \mapleinline{active}{1d}{Bot := `egf/makeproc`(bot):}{%
> }

> \mapleinline{active}{1d}{s := 1:}{%
> }

> \mapleinline{active}{1d}{m := 3:}{%
> }

> \mapleinline{active}{1d}{k := 0:}{%
> }

> \mapleinline{active}{1d}{q := 1:}{%
> }

> \mapleinline{active}{1d}{Bernoulli[m * k + q] := 1/binomial(m*(s + k)
> + q, m * s) / Bot(m * s) * }{%
> }

> \mapleinline{active}{1d}{                        (Top(m *(k + s) + q)
> - add(binomial (m *(k + s) + q, }{%
> }

> \mapleinline{active}{1d}{                        m *(j + s)) * Bot(m *
> j) * Bernoulli[m * (k+s-j) + q], }{%
> }

> \mapleinline{active}{1d}{                        j = 1+s .. k+s));}{%
> }
```

$$Bernoulli_1 := \frac{-1}{2}$$

```
> \mapleinline{active}{1d}{k := 1:}{%
> }

> \mapleinline{active}{1d}{Bernoulli[m * k + q] := 1/binomial(m*(s + k)
> + q, m * s) / Bot(m * s) * }{%
> }

> \mapleinline{active}{1d}{                        (Top(m *(k + s) + q)
> - add(binomial (m *(k + s) + q, }{%
> }

> \mapleinline{active}{1d}{                        m *(j + s)) * Bot(m *
> (j + s)) * Bernoulli[m * (k-j) + q], }{%
> }

> \mapleinline{active}{1d}{                        j = 1 .. k));}{%
```

```
> }
```

$$Bernoulli_4 := \frac{-1}{30}$$

```
> \mapleinline{active}{1d}{k := 2:}{%
> }
```

```
> \mapleinline{active}{1d}{Bernoulli[m * k + q] := 1/binomial(m*(s + k)
> + q, m * s) / Bot(m * s) * }{%
> }
```

```
> \mapleinline{active}{1d}{                          (Top(m *(k + s) + q)
> - add(binomial (m *(k + s) + q, }{%
> }
```

```
> \mapleinline{active}{1d}{                          m *(j + s)) * Bot(m *
> (j + s)) * Bernoulli[m * (k-j) + q], }{%
> }
```

```
> \mapleinline{active}{1d}{                          j = 1 .. k));}{%
> }
```

$$Bernoulli_7 := 0$$

```
> \mapleinline{active}{1d}{k := 3:}{%
> }
```

```
> \mapleinline{active}{1d}{Bernoulli[m * k + q] := 1/binomial(m*(s + k)
> + q, m * s) / Bot(m * s) * }{%
> }
```

```
> \mapleinline{active}{1d}{                          (Top(m *(k + s) + q)
> - add(binomial (m* (k + s) + q, }{%
> }
```

```
> \mapleinline{active}{1d}{                          m *(j + s)) * Bot(m *
> (j + s)) * Bernoulli[m * (k-j) + q], }{%
> }
```

```
> \mapleinline{active}{1d}{                          j = 1 .. k));}{%
> }
```

$$Bernoulli_{10} := \frac{5}{66}$$

There is automated code to get the same result.

```
> \mapleinline{active}{1d}{A := `calcul/normal`(10, Top, Bot, 3, 1):}{%
> }
```

```
> \mapleinline{active}{1d}{seq(A[3 * i + 1], i = 0 ..3);}{%
> }
```

$$\frac{-1}{2}, \frac{-1}{30}, 0, \frac{5}{66}$$

3.4 The structure of $\mathcal{R}$.

Like $\mathcal{P}$, this section will show that $\mathcal{R}$ has a rich structure. To explore this structure, this section first makes some definitions for subsets of $\mathcal{R}$ analogous to the Definitions 2.3 and 2.4 for $\mathcal{P}$.

Definition 3.3 ($\mathcal{R}^{R_1,R_2}, \mathcal{R}_{R_1,R_2}$.) *Let R_1 and R_2 be subrings of $\mathbb{C}$. Denote $\mathcal{R}^{R_1,R_2}$ ($\mathcal{R}_{R_1,R_2}$) to be the subset of $\mathcal{R}$, such that all elements can be written in for the form $\frac{s(x)}{t(x)}$ with $s(x)$, $t(x) \in \mathcal{P}^{R_1,R_2}$ ($s(x)$, $t(x) \in \mathcal{P}_{R_1,R_2}$).*

Definition 3.4 ($\hat{\mathcal{R}}^{R_1,R_2}, \hat{\mathcal{R}}_{R_1,R_2}$.) *Let R_1 and R_2 be subrings of $\mathbb{C}$. Define $\hat{\mathcal{R}}^{R_1,R_2} = \mathcal{R}^{R_1,R_2} \cap \hat{\mathcal{R}}$ and $\hat{\mathcal{R}}_{R_1,R_2} = \mathcal{R}_{R_1,R_2} \cap \hat{\mathcal{R}}$.*

First collect some closure properties for $\mathcal{R}$.

Lemma 3.2 *Let R_1, R_2, R_3, and R_4 be subrings of $\mathbb{C}$ and let $h(x) \in \mathcal{R}_{R_1,R_2}$ and $g(x) \in \mathcal{R}_{R_3,R_4}$ then:*

1. $g(x)h(x) \in \mathcal{R}_{\langle R_1,R_3\rangle,R_2R_4}$,
2. $g(x) + h(x) \in \mathcal{R}_{\langle R_1,R_3\rangle,R_2R_4}$,
3. $h'(x) \in \mathcal{R}_{R_1,\langle R_1,R_2\rangle}$,
4. $h_m^q(x) \in \mathcal{R}_{R_1\langle\omega_m\rangle,R_2\langle\omega_m\rangle}$.

Proof: For convenience, write $h(x) = \frac{s_h(x)}{t_h(x)}$, with $s_h(x)$, $t_h(x) \in \mathcal{P}_{R_1,R_2}$, and $g(x) = \frac{s_g(x)}{t_g(x)}$, with $s_g(x)$, $t_g(x) \in \mathcal{P}_{R_3,R_4}$.

1. Now $g(x)h(x) = \frac{s_g(x)s_h(x)}{t_g(x)t_h(x)}$, so by Lemma 2.2 it follows that $s_g(x)s_h(x) \in \mathcal{P}_{\langle R_1,R_3\rangle,R_2R_4}$, and $t_g(x)t_h(x) \in \mathcal{P}_{\langle R_1,R_3\rangle,R_2R_4}$. Consequently $g(x)h(x) \in \mathcal{R}_{\langle R_1,R_3\rangle,R_2R_4}$.
2. Observe that $g(x) + h(x) = \frac{s_h(x)t_g(x)+s_g(x)t_h(x)}{t_g(x)t_h(x)}$. From Lemma 2.2 $s_g(x)t_h(x) + t_g(x)s_h(x) \in \mathcal{P}_{\langle R_1,R_3\rangle,R_2R_4}$, and $t_g(x)t_h(x) \in \mathcal{P}_{\langle R_1,R_3\rangle,R_2R_4}$. Hence $g(x) + h(x) \in \mathcal{R}_{\langle R_1,R_3\rangle,R_2R_4}$.
3. By considering $h'(x) = \frac{s_h'(x)t_h(x)-s_h(x)t_h'(x)}{t_h^2(x)}$, and Lemma 2.2 it is seen that $s_h'(x)t_h(x) - t_h'(x)s_h(x) \in \mathcal{P}_{R_1,\langle R_1,R_2\rangle}$ and $t_h^2(x) \in \mathcal{P}_{R_1,R_2}$. Thus $h'(x) \in \mathcal{R}_{R_1,\langle R_1,R_2\rangle}$.
4. Now $h_m^q(x) = \frac{(s_h(x)\prod_{i=1}^{m-1} t_h(x\omega_m^i))_m^q}{(\prod_{i=0}^{m-1} t_h(x\omega_m^i))_m^0}$ (Lemma 3.1). From Lemma 2.2 the numerator and the denominator are both in $\mathcal{P}_{R_1\langle\omega_m\rangle,R_2\langle\omega_m\rangle}$. This gives $h_m^q(x) \in \mathcal{R}_{R_1\langle\omega_m\rangle,R_2\langle\omega_m\rangle}$.

■

Lemma 3.3 *Let R_1, R_2, R_3, and R_4 be subrings of $\mathbb{C}$ and let $h(x) \in \mathcal{R}^{R_1,R_2}$ and $g(x) \in \mathcal{R}^{R_3,R_4}$ then:*

1. $g(x)h(x) \in \mathcal{R}^{\langle R_1,R_3\rangle,R_2R_4}$,
2. $g(x) + h(x) \in \mathcal{R}^{\langle R_1,R_3\rangle,R_2R_4}$,
3. $h'(x) \in \mathcal{R}^{R_1,R_2}$,
4. $h_m^q(x) \in \mathcal{R}^{R_1\langle\omega_m\rangle,R_2}$.

Proof: For convenience, write $h(x) = \frac{s_h(x)}{t_h(x)}$, with $s_h(x)$, $t_h(x) \in \mathcal{P}^{R_1,R_2}$, and $g(x) = \frac{s_g(x)}{t_g(x)}$, with $s_g(x)$, $t_g(x) \in \mathcal{P}^{R_3,R_4}$.

1. As $g(x)h(x) = \frac{s_g(x)s_h(x)}{t_g(x)t_h(x)}$ and Lemma 2.3 it follows that $s_g(x)s_h(x) \in \mathcal{P}^{\langle R_1,R_3\rangle,R_2R_4}$, and $t_g(x)t_h(x) \in \mathcal{P}^{\langle R_1,R_3\rangle,R_2R_4}$. Consequently $g(x)h(x) \in \mathcal{R}^{\langle R_1,R_3\rangle,R_2R_4}$.
2. Observing that $g(x)+h(x) = \frac{s_h(x)t_g(x)+s_g(x)t_h(x)}{t_g(x)t_h(x)}$, and appealing to Lemma 2.3 gives $s_g(x)t_h(x)$ $+ t_g(x)s_h(x) \in \mathcal{P}^{\langle R_1,R_3\rangle,R_2R_4}$ and $t_g(x)t_h(x) \in \mathcal{P}^{\langle R_1,R_3\rangle,R_2R_4}$. Hence $h(x)+g(x) \in \mathcal{R}^{\langle R_1,R_3\rangle,R_2R_4}$.
3. Now $h'(x) = \frac{s_h'(x)t_h(x)-s_h(x)t_h'(x)}{t_h^2(x)}$. So from Lemma 2.3 it follows that $s_h'(x)t_h(x)-t_h'(x)s_h(x) \in \mathcal{P}^{R_1,R_2}$ and $t_h^2(x) \in \mathcal{P}^{R_1,R_2}$. Thus $h'(x) \in \mathcal{R}^{R_1,R_2}$.
4. As a result of $h_m^q(x) = \frac{(s_h(x)\prod_{i=1}^{m-1} t_h(x\omega_m^i))_m^q}{(\prod_{i=0}^{m-1} t_h(x\omega_m^i))_m^0}$ (Lemma 3.1), and Lemma 2.3 it follows that both the numerator and the denominator are in $\mathcal{P}^{\langle\omega_m\rangle R_1,\langle\omega_m\rangle R_2}$. A tighter bound on the denominator $\prod_{i=0}^{m-1} t_h(x\omega_m^i)$ and numerator $(s_h(x)\prod_{i=1}^{m-1} t_h(x\omega_m^i))_m^q$, by noticing that they are fixed by automorphism of the number field $\langle\omega\rangle$ and hence are in $\mathcal{P}^{\langle\omega_m\rangle R_1,R_2}$.

■

Corollary 6 *Let R_1 and R_2 be subrings of $\mathbb{C}$. Then $\mathcal{R}^{R_1,R_2}$ and $\mathcal{R}_{R_1,R_2}$ are both fields, more over $\mathcal{R}^{R_1,R_2}$ is closed under differentiation.*

Corollary 7 *Let R_1 and R_2 be subrings of $\mathbb{C}$. Then $\hat{\mathcal{R}}^{R_1,R_2}$ and $\hat{\mathcal{R}}_{R_1,R_2}$ are both rings, more over $\hat{\mathcal{R}}^{R_1,R_2}$ is closed under differentiation.*

Now examine some closure properties of the recurrence polynomial.

Lemma 3.4 *Assume that $h(x)$, $g(x) \in \mathcal{R}$, where $h(x) = \frac{s_h(x)}{t_h(x)}$ and $g(x) = \frac{s_g(x)}{t_g(x)}$ with $s_h(x)$, $t_h(x)$, $s_g(x)$, $t_g(x) \in \mathcal{P}$. Let R_1, R_2, R_3 and R_4 be subrings of $\mathbb{C}$ and assume that $P^{s_h}(x) \in R_1[x]$, $P^{t_h}(x) \in R_2[x]$, $P^{s_g}(x) \in R_3[x]$ and $P^{t_g}(x) \in R_4[x]$.*

1. *Then* $g(x)h(x) = \frac{s_{gh}(x)}{t_{gh}(x)}$, *where* $P^{s_{gh}}(x) \in \langle R_1, R_3\rangle[x]$ *and* $P^{t_{gh}}(x) \in \langle R_2, R_4\rangle[x]$.
2. *Then* $g(x) + h(x) = \frac{s_{g+h}(x)}{t_{g+h}(x)}$, *where* $P^{s_{g+h}}(x) \in \langle R_1, R_2, R_3, R_4\rangle[x]$ *and* $P^{t_{g+h}}(x) \in \langle R_2, R_4\rangle[x]$.
3. *Then* $h'(x) = \frac{s_{h'}(x)}{t_{h'}(x)}$, *where* $P^{s_{h'}}(x) \in \langle R_1, R_2\rangle[x]$ *and* $P^{t_{h'}}(x) \in R_2[x]$.
4. *Then* $h_m^q(x) = \frac{s_{h_m^q}(x)}{t_{h_m^q}(x)}$, *where* $P^{s_{h_m^q}}(x) \in \langle R_1, R_2\rangle[x]$ *and* $P^{t_{h_m^q}}(x) \in R_2[x]$.

Proof:

1. By letting $s_{gh}(x) = s_g(x)s_h(x)$ and $t_{gh}(x) = t_g(x)t_h(x)$ the result follows from Corollary 2.
2. By letting $s_{g+h}(x) = s_g(x)t_h(x) + s_h(x)t_g(x)$ and $t_{g+h}(x) = t_g(x)t_h(x)$ the result follows from Corollary 2.
3. By letting $s_{h'}(x) = s_h'(x)t_h(x) - s_h(x)t_h'(x)$ and $t_{h'}(x) = t_h^2(x)$ the result follows from Corollary 2.
4. By letting $s_{h_m^q}(x) = (s_h(x)\prod_{i=1}^{m-1} t_h(x\omega_m^i))_m^q$ and $t_{h_m^q}(x) = (\prod_{i=0}^{m-1} t_h(x\omega_m^i))_m^0$ the result follows from Corollary 2.

■

These results are useful, as they allow the assumption to be made that certain calculations will always be over nice rings, (for example, the lacunary recurrence relation for the Euler numbers will be over the integers).

3.5 Hierarchy of $\mathcal{R}$.

As with $\mathcal{P}$, there is an interrelationship between the different subfields and subrings of $\mathcal{R}$, and a hierarchy of the different subfields.

Theorem 3.2 (Hierarchy.) *If* R_1 *and* R_2 *are subrings of* $\mathbb{C}$ *then the following subset relationships hold:*

1. $\hat{\mathcal{R}}_{R_1,R_2} \subsetneq \mathcal{R}_{R_1,R_2} \subseteq \mathcal{R}^{R_1,R_1R_2}$,
2. $\hat{\mathcal{R}}^{R_1,R_2} \subsetneq \mathcal{R}^{R_1,R_2} \subseteq \mathcal{R}_{R_1,R_1R_2}$.

Proof:

1. If $f(x) \in \mathcal{R}_{R_1,R_2}$, then $f(x) = \frac{s_f(x)}{t_f(x)}$, where $s_f(x),\ t_f(x) \in \mathcal{P}_{R_1,R_2}$, then $s_f(x),\ t_f(x) \in \mathcal{P}^{R_1,\langle R_1,R_1R_2\rangle}$. Take any non-zero element of R_2, say β, and notice that $\beta s_f(x),\ \beta t_f(x) \in \mathcal{P}^{R_1,R_1R_2}$, thus $f(x) = \frac{\beta s_f(x)}{\beta t_f(x)} \in \mathcal{R}^{R_1,R_1R_2}$ as required.

   Noticing that $\hat{\mathcal{R}}_{R_1,R_2} \subsetneq \mathcal{R}_{R_1,R_2}$ follows from noticing that $\hat{\mathcal{R}}_{R_1,R_2}$ is not closed under division.

2. If $f(x) \in \mathcal{R}^{R_1,R_2}$, where $f(x) = \frac{s_f(x)}{t_f(x)}$, with $s_f(x),\ t_s(x) \in \mathcal{P}^{R_1,R_2}$, then $s_f(x),\ t_f(x) \in \mathcal{P}_{R_1,R_2\langle R_1,R_1^{-1}\rangle}$ by Theorem 2.2. Say $s_f(x) = \sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$, and $t_f(x) = \sum_{j=1}^{m} q_j(x)e^{\mu_j x}$, with $p_i(x), q_i(x) \in R_2\langle R_1, R_1^{-1}\rangle$. For each coefficient of $p_i(x)$ and $q_i(x)$, multiply the coefficient by some $\alpha_i \in R_1$ (dependent on $p_i(x)$) so that the resulting coefficients are in R_1R_2. Now taking the least common multiple of all these α_i, gives some $\beta \in R_1$ such that $\beta p_i(x), \beta q_i(x) \in R_1R_2[x]$ for all i. Then write this as $f(x) = \frac{s_f(x)}{t_f(x)} = \frac{\beta s_f(x)}{\beta t_f(x)}$, where $\beta s_f(x), \beta t_f(x) \in \mathcal{P}_{R_1,R_1R_2}$. Hence $f(x) \in \mathcal{R}_{R_1,R_1R_2}$.

   Noticing that $\hat{\mathcal{R}}^{R_1,R_2} \subsetneq \mathcal{R}^{R_1,R_2}$ follows from noticing that $\hat{\mathcal{R}}^{R_1,R_2}$ is not closed under inversion.

■

Corollary 8 *Let R_1 and R_2 be subrings of $\mathbb{C}$. If $1 \in R_1 \subseteq R_2$ then $\mathcal{R}^{R_1,R_2} = \mathcal{R}_{R_1,R_2}$.*

The next two examples show that the set of rings $\mathcal{R}^{R_1,R_2}$ and that of $\mathcal{R}_{R_1,R_2}$ share neither a superset nor a subset relationship with each other. These examples are such that $\mathcal{R}^{R_1,R_2}$ for particular R_1 and R_2 that cannot be written as $\mathcal{R}_{R_3,R_4}$ for any R_3 and R_4 and vice-versa.

Example 14 *Let $f(x) = e^{\sqrt{2}x} \in \mathcal{R}_{\mathbb{Q}(\sqrt{2}),\mathbb{Q}}$. Notice that $f'(x) = \sqrt{2}e^{\sqrt{2}x} \notin \mathcal{R}_{\mathbb{Q}(\sqrt{2}),\mathbb{Q}}$. But $\mathcal{R}^{R_1,R_2}$ is closed under differentiation. Consequently there do not exist rings R_1, R_2 such that $\mathcal{R}_{\mathbb{Q}(\sqrt{2}),\mathbb{Q}} = \mathcal{R}^{R_1,R_2}$.*

Example 15 *The goal here is to show that there do not exist subrings R_1 and R_2 of $\mathbb{C}$ such that $\mathcal{R}^{\mathbb{Z}[\sqrt{2}],\mathbb{Q}} = \mathcal{R}_{R_1,R_2}$. Consider $s_c(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$ where b_i satisfies $b_i = 2c^2 b_{i-2}$ for $c \in \mathbb{Z}$, with $b_0, b_1 \in \mathbb{Z}$. Then $s_c(x) \in \mathcal{R}^{\mathbb{Z}[\sqrt{2}],\mathbb{Q}}$. Further this is equivalent to*

$$s_c(x) = \alpha_1 e^{c\sqrt{2}x} + \alpha 2e^{-c\sqrt{2}x},$$

where $\alpha_1 = \frac{b_0}{2} + \frac{b_1}{2\sqrt{2}c}$ and $\alpha_2 = \frac{b_0}{2} - \frac{b_1}{2\sqrt{2}c}$. From this conclude that if $\mathcal{R}^{\mathbb{Z}[\sqrt{2}],\mathbb{Q}} = \mathcal{R}_{R_1,R_2}$, then $\mathcal{R}_{\mathbb{Z}[\sqrt{2}],\mathbb{Q}[\sqrt{2}]} \subseteq \mathcal{R}_{R_1,R_2}$.

Observing that $\mathcal{R}^{\mathbb{Z}[\sqrt{2}],\mathbb{Q}[\sqrt{2}]} = \mathcal{R}^{\mathbb{Z}[\sqrt{2}],\mathbb{Q}[\sqrt{2}]} \neq \mathcal{R}^{\mathbb{Z}[\sqrt{2}],\mathbb{Q}}$, as $\sqrt{2} \in \mathcal{R}^{\mathbb{Z}[\sqrt{2}],\mathbb{Q}[\sqrt{2}]}$ and $\sqrt{2} \notin \mathcal{R}^{\mathbb{Z}[\sqrt{2}],\mathbb{Q}}$, gives that $\mathcal{R}^{\mathbb{Z}\langle\sqrt{2}\rangle,\mathbb{Q}} \neq \mathcal{R}_{\mathbb{Z}[\sqrt{2}],\mathbb{Q}[\sqrt{2}]}$ from which the desired result follows.

3.6 Some complexity bounds.

This section determines some metrics of complexity of functions in $\mathcal{R}$, as was done earlier for functions in $\mathcal{P}$ (Section 2.6). This section uses the metrics from Definition 2.7 on the numerator and denominator of functions in $\mathcal{R}$ to get the following lemmas:

Lemma 3.5 (deg^d.) *Let $h(x) = \frac{s_h(x)}{t_h(x)}$, $g(x) = \frac{s_g(x)}{t_g(x)} \in \mathcal{R}$, such that $s_h(x)$, $t_h(x)$, $s_g(x)$, $t_g(x) \in \mathcal{P}$. Then:*

1. *Then $f(x) = \frac{s_f(x)}{t_f(x)} = g(x)h(x)$, where $1 \leq deg^d(s_f(x)) \leq deg^d(s_g(x)) + deg^d(s_h(x))$ and $1 \leq deg^d(t_f(x)) \leq deg^d(t_g(x)) + deg^d(t_h(x))$.*
2. *Then $f(x) = \frac{s_f(x)}{t_f(x)} = g(x) + h(x)$, where $0 \leq deg^d(s_f(x)) \leq \max(deg^d(s_g(x)) + deg^d(t_h(x)), deg^d(s_h(x)) + deg^d(t_g(x)))$ and $0 \leq deg^d(t_f(x)) \leq deg^d(t_g(x)) + deg^d(t_h(x))$.*
3. *Then $f(x) = \frac{s_f(x)}{t_f(x)} = g'(x)$, where $deg^d(s_f(x)) \leq deg^d(s_g(x)) + deg^d(t_g(x))$ and $deg^d(t_f(x)) \leq 2deg^d(t_g(x))$.*
4. *Then $f(x) = \frac{s_f(x)}{t_f(x)} = g_m^q(x)$, where $deg^d(s_f(x)) \leq deg^d(s_g(x)) + (m-1)deg^d(t_g(x))$ and $deg^d(t_f(x)) \leq m \times deg^d(t_g(x)))$.*

Proof:

1. By letting $s_f(x) = s_g(x)s_h(x)$ and $t_f(x) := t_g(x)t_h(x)$ the upper bounds follows from Lemma 2.4. The lower bounds follow by taking $f(x) = \frac{1}{g(x)}$.
2. By letting $s_f(x) = s_g(x)t_h(x) + s_h(x)t_g(x)$ and $t_f(x) = t_g(x)t_h(x)$ the upper bounds follow from Lemma 2.4. The lower bounds follow by taking $f(x) = -g(x)$.
3. By letting $s_f(x) = s'_g(x)t_g(x) - s_g(x)t'_g(x)$ and $t_f(x) = t_g^2(x)$ the upper bounds follow from Lemma 2.4.
4. By letting $s_f(x) = (s_g(x)\prod_{i=1}^{m-1} t_g(x\omega_m^i))_m^q$ and $t_f(x) = (\prod_{i=0}^{m-1} t_g(x\omega_m^i))_m^0$ the upper bounds follow from Lemma 2.4.

■

Lemma 3.6 (deg^P.) *Let $h(x) = \frac{s_h(x)}{t_h(x)}$, $g(x) = \frac{s_g(x)}{t_g(x)} \in \mathcal{R}$, such that $s_h(x), t_h(x), s_g(x), t_g(x) \in \mathcal{P}$.*

1. *Then $f(x) = \frac{s_f(x)}{t_f(x)} = g(x)h(x)$, where $1 \leq deg^P(s_f(x)) \leq deg^P(s_g(x))deg^P(s_h(x))$ and $1 \leq deg^P(t_f(x)) \leq deg^P(t_g(x))deg^P(t_h(x))$.*

2. *Then* $f(x) = \frac{s_f(x)}{t_f(x)} = g(x) + h(x)$, *where* $0 \leq deg^P(s_f(x)) \leq deg^P(s_g(x))deg^P(t_h(x)) + deg^P(s_h(x))\ deg^P(t_g(x)))$ *and* $1 \leq deg^P(t_f(x)) \leq deg^P(t_g(x))deg^P(t_h(x))$.

3. *Then* $f(x) = \frac{s_f(x)}{t_f(x)} = g'(x)$, *where* $deg^P(s_f(x)) \leq 2deg^P(s_g(x))deg^P(t_g(x))$ *and* $deg^P(t_f(x)) \leq deg^P(t_g(x))^2$.

4. *Then* $f(x) = \frac{s_f(x)}{t_f(x)} = g^q_m(x)$, *where* $deg^P(s_f(x)) \leq m \times deg^P(s_g(x))deg^P(t_g(x))^{m-1}$ *and also that* $deg^P(t_f(x)) \leq deg^P(t_g(x))^m$.

Proof:

1. By letting $s_f(x) = s_g(x)s_h(x)$ and $t_f(x) = t_g(x)t_h(x)$ the upper bounds follows from Lemma 2.5. The lower bounds follow by taking $f(x) = \frac{1}{g(x)}$.

2. By letting $s_f(x) = s_g(x)t_h(x) + s_h(x)t_g(x)$ and $t_f(x) = t_g(x)t_h(x)$ the upper bounds follow from Lemma 2.5. The lower bounds follow by taking $f(x) = -g(x)$.

3. By letting $s_f(x) = s'_g(x)t_g(x) - s_g(x)t'_g(x)$ and $t_f(x) = t^2_g(x)$ the upper bounds follow from Lemma 2.5.

4. By letting $s_f(x) = (s_g(x)\prod_{i=1}^{m-1} t_g(x\omega^i_m))^q_m$ and $t_f(x) = (\prod_{i=0}^{m-1} t_g(x\omega^i_m))^0_m$ the upper bounds follow from Lemma 2.5.

■

Note 3.2 *It is worth noting that the metrics under the operations of* $f(x) \to f(\alpha x)$ *was not examined as nothing interesting happens, and integration of functions in* $\mathcal{R}$ *was not examined as* $\mathcal{R}$ *is not closed under integration.*

These bounds will be used later in Chapter 5, as many methods to determine lacunary recurrence relations require bounds on the , size of these lacunary recurrence relations and also bounds on the multiplicity of the roots associated with their recurrence polynomials.

3.7 Examples.

This section does three detailed examples. That of $f(x) = \frac{1}{p(x)} \in \hat{\mathcal{R}}$ with $p(x)$ a polynomial, of $g(x) = \frac{1}{\sum_{i=1}^n \alpha_i e^{\lambda_i x}} \in \hat{\mathcal{R}}$, and lastly the Bernoulli polynomials.

Example 16 *Consider* $f(x) = \frac{1}{p(x)} \in \hat{\mathcal{R}}$. *Let* $p(x) = \alpha_n x^n + ... + \alpha_0$. *As* $f(x) \in \hat{\mathcal{R}}$, *notice that* $a_0 \neq 0$.

Then:

$$\begin{aligned}\sum_{k=0}^{\infty} c_k \frac{x^k}{k!} &= \frac{1}{\alpha_n x^n + ... + \alpha_0} \\ \sum_{i=0}^{n} \alpha_i i! \frac{x^i}{i!} \sum_{k=0}^{\infty} c_k \frac{x^k}{k!} &= 1 \\ \sum_{k=0}^{\infty} \sum_{i=0}^{n} \binom{k}{i} c_{k-i} \alpha_i i! \frac{x^k}{k!} &= 1.\end{aligned}$$

Considering $k = 0$ *gives* $c_0 = \frac{1}{\alpha_0}$*, and considering* $k > 0$ *demonstrates that:*

$$\begin{aligned}\sum_{i=0}^{n} \binom{k}{i} c_{k-i} \alpha_i i! &= 0 \\ c_k = \frac{-1}{\alpha_0} \sum_{i=1}^{n} \binom{k}{i} c_{k-i} \alpha_i i! &= 0.\end{aligned}$$

So a recursion formula for c_k *was derived that only requires the previous* $n - 1$ *terms.*

Example 17 *Consider* $g(x) \in \hat{\mathcal{R}}$ *where* $g(x) = \frac{1}{\sum_{i=1}^{n} \alpha_i e^{\lambda_i x}}$*. A simple calculation gives* $s(x) = \frac{1}{\sum_{i=0}^{\infty} b_i \frac{x^i}{i!}}$*, where the* $b_j = \sum_{i=1}^{n} \alpha_i \lambda_i^j$*. This example will use this knowledge throughout.*

Hence:

$$\begin{aligned}\sum_{k=0}^{\infty} c_k \frac{x^k}{k!} &= \frac{1}{\sum_{j=0}^{\infty} \sum_{i=1}^{n} \alpha_i \lambda_i^j \frac{x^j}{j!}} \\ \sum_{j=0}^{\infty} \sum_{i=1}^{n} \alpha_i \lambda_i^j \frac{x^j}{j!} \sum_{k=0}^{\infty} c_k \frac{x^k}{k!} &= 1 \\ \sum_{j=0}^{\infty} \sum_{k=0} j \binom{j}{k} c_k \sum_{i=1}^{n} \alpha_i \lambda_i^{j-k} \frac{x^j}{j!} &= 1.\end{aligned}$$

Considering $k = 0$ *shows that* $c_0 = \frac{1}{\sum_{i=1}^{n} a_i}$*. As* $g(x) \in \hat{\mathcal{R}}$ *it follows that* $c_0 \neq 0$*. Considering* $k > 0$ *gives:*

$$c_k = \frac{1}{\sum_{i=1}^{n} a_i} (- \sum_{j=1}^{k} \binom{k}{i} \sum_{i=1}^{n} \alpha_i \lambda_i^j c_{m-j}).$$

Example 18 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

This example will demonstrate how the methods of multisectioning can be applied to functions with symbolic parameters for parameters of the exponentials of rational poly-exponential functions. Define

*the "*Bernoulli polynomials*" to be the coefficients of the exponential generating function of* $\frac{x\,e^{(t\,x)}}{e^x-1}$ *in* x*. The denominator and numerator of this function have very complicated lacunary recurrence relations, even when multisectioning by a small value such as 3 (at 0).*

```
> \mapleinline{active}{1d}{top := x* exp(t*x):}{%
> }

> \mapleinline{active}{1d}{bot := exp(x)-1:}{%
> }

> \mapleinline{active}{1d}{botlrr := `bottom/ms`(bot, f, x, 3);}{%
> }
```

$$botlrr := \mathrm{f}(x) = \mathrm{f}(x-6),\ f,\ x,\ [\mathrm{f}(0)=0,\ \mathrm{f}(1)=0,\ \mathrm{f}(2)=0,\ \mathrm{f}(3)=6,\ \mathrm{f}(4)=0,\ \mathrm{f}(5)=0]$$

```
> \mapleinline{active}{1d}{toplrr :=
> collect([`top/ms/linalg/sym`(top,bot, f, x, 3, 0)],f);}{%
> }
```

$$\begin{aligned}
toplrr := [\mathrm{f}(x) = {} & (-7152\,t^{14} - 7152\,t^{16} + 1932\,t^{11} - 3599\,t^{18} - 840\,t^{20} - t^6 + 5544\,t^{17} \\
& + 7780\,t^{15} + 286\,t^{21} + 5544\,t^{13} + 12\,t^7 - 72\,t^{22} - t^{24} - 72\,t^8 + 1932\,t^{19} \\
& + 12\,t^{23} - 840\,t^{10} + 286\,t^9 - 3599\,t^{12})\mathrm{f}(x-24) + 2(4\,t^{18} - 42\,t^{17} + 216\,t^{16} \\
& - 722\,t^{15} + 1764\,t^{14} - 3366\,t^{13} + 5244\,t^{12} - 6894\,t^{11} + 7836\,t^{10} - 7813\,t^9 \\

```

$$[[\mathrm{f}(x) = -\mathrm{f}(x-18) + 2\,\mathrm{f}(x-15) + \mathrm{f}(x-12) - 4\,\mathrm{f}(x-9) + \mathrm{f}(x-6) + 2\,\mathrm{f}(x-3),\ f,\ x,\ [$$
$$\mathrm{f}(0) = 0,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = 0,\ \mathrm{f}(3) = 6,\ \mathrm{f}(4) = 0,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 0,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 0,$$
$$\mathrm{f}(9) = 18,\ \mathrm{f}(10) = 0,\ \mathrm{f}(11) = 0,\ \mathrm{f}(12) = 0,\ \mathrm{f}(13) = 0,\ \mathrm{f}(14) = 0,\ \mathrm{f}(15) = 30,$$
$$\mathrm{f}(16) = 0,\ \mathrm{f}(17) = 0,\ \mathrm{f}(18) = 0,\ \mathrm{f}(19) = 0,\ \mathrm{f}(20) = 0,\ \mathrm{f}(21) = 42,\ \mathrm{f}(22) = 0,$$
$$\mathrm{f}(23) = 0]]]$$

This example is interesting because it demonstrates how large and complicated the results get when done symbolically, but still shows that feasibility of doing these calculations.

3.8 Conclusion.

By combining Theorem 3.1, Lemmas 3.3, 3.4 and 3.6 the follow results follow: Although some corollaries of this result are know, (for examples, for the particular cases of the Bernoulli, Euler, Genocchi, or Lucas type II numbers), to the best of my knowledge, they have not been done to this degree of generality before

Theorem 3.3 *Let $f(x) \in \hat{\mathcal{R}}$, $m, q \in \mathbb{Z}$, $0 \leq q < m$.*

1. *Then a lacunary recursion formula can be found for the $mi+q$-th coefficient of the exponential generating function of $f(x)$ that depends only on the $mj+q$-th coefficient, for $j = 0, 1, ..., i-1$, and two lacunary recurrence relations.*
2. *Moreover, if $f(x) = \frac{s(x)}{t(x)}$ then upper bounds on the length of the two lacunary recurrence relations are $m \times deg^P(s(x))deg^P(t(x))^{m-1}$ for the numerator and $deg^P(t(x))^m$ for the denominator.*
3. *Furthermore if $f(x) \in \hat{\mathcal{R}}^{R_1,R_2}$, then the two lacunary recurrence relations are both in $\mathcal{P}^{R_1\langle\omega_m^i\rangle,R_2}$.*
4. *Lastly, if the recurrence polynomials of $s(x)$ and $t(x)$ are in $R_3[x]$, then the recurrence polynomials of the two lacunary recurrence relations are in $R_3[x]$.*

Corollary 9 *A lacunary recursion formula can be found for the $(mi+q)$-th Bernoulli number that depends only on the $(mj+q)$-th Bernoulli number, for $j = 0, 1, ..., i-1i$, and two lacunary recurrence relations, with upper bounds on their sizes of $m2^m$ and 2^m respectively, where all the terms of the lacunary recurrence relations and the recurrence polynomials themselves are in $\mathbb{Z}$.*

Note 3.3 *Tighter upper bounds for the sizes of the lacunary recurrence relations were determined by Chellali [9] for the Bernoulli numbers. This was*

$$\sum_{d|m,\text{odd}} \mu(d)2^{m/d}/2m$$

for the lacunary recurrence relation that is derived from the denominators and twice this for that of the numerator, when multisectioning by m. Here μ is the Mobius function, as defined in [2]. This result requires specialized techniques and does not follow directly follow from any of the results in this thesis.

Chapter 4

Calculations of recurrences for $\mathcal{P}$.

In the previous chapters a very naive approach was used to calculate the lacunary recurrence relations that would be needed for the calculation of the coefficients to the exponential generating functions of the functions in both $\mathcal{P}$ and $\mathcal{R}$. The function's representation as polynomials and exponential functions, was naively multisectioned using the formula in Definition 2.6. After this, the multisectioned function was converted to a formula where the lacunary recurrence relation could be observed. The goal of the next two chapters is to show some other, more efficient ways, by which these lacunary recurrence relations and lacunary recursion formulae can be computed.

In this chapter, different methods to multisection functions in $\mathcal{P}$ are examined, and Chapter 5 examines different methods for those functions in $\mathcal{R}$.

Section 4.1 looks at how to use recurrence polynomials to multisection poly-exponential functions. This method takes advantage of the factorization of m, the quantity by which the poly-exponential function is multisectioned. Section 4.2 looks at how to use recurrence polynomials and resultants to multisection poly-exponential functions. Using linear algebra to find the new lacunary recurrence relations of a poly-exponential functions that are multisectioned, as well as how to use symbolic differentiation with linear algebra is looked at in Section 4.3 and 4.4. Section 4.5 looks at how to take advantage of the factorization of m, by iteratively compressing the results. Section 4.6 and 4.7 looks at two theories where by the problem being studied can be simplified. The last section, Section 4.8, makes some conclusions based on empirical evidence as to which methods are best.

4.1 Multisectioning the recurrence polynomial.

Recall that if $s(x) \in \mathcal{P}$ then $P^s(x)$ is the recurrence polynomial associated with $s(x)$ (Definition 2.2). The first thing needed was shown in Corollary 2 and Lemma 2.5 which is reiterated here:

Lemma 4.1 *If $s(x)$, $t(x) \in \mathcal{P}$, $\alpha \neq 0$ where $s(x) = \sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$ and where $t(x) = \sum_{j=1}^{m} q_j(x)e^{\mu_j x}$ then:*

1. $P^{st}(x) | \prod_{i=1,j=1}^{i=n,j=m} (x - \lambda_i - \mu_j)^{\deg(p_i(x))+\deg(q_i(x))}$,
2. $P^{s+t}(x) | P^s(x)P^t(x)$,
3. $P^{s(\alpha x)}(x) = P^s(\alpha x)$,
4. $P^{\alpha s}(x) = P^s(x)$.

By using this information, the linear recurrence relation for a poly-exponential function may be multisectioned by only looking at the recurrence polynomial.

Lemma 4.2 *If $s(x) \in \mathcal{P}$ then*

$$P^{s^q_m(x)}(x) | \prod_{i=0}^{m-1} P^s(x\omega_m^i).$$

Proof: By noticing that $P^{s+t}(x) | P^s(x)P^t(x)$, and $P^{s(\alpha x)}(x) = P^s(\alpha x)$ from Lemma 4.1, it follows that:

$$P^{s^q_m(x)}(x) \quad = \quad P^{\frac{1}{m}\sum_{i=0}^{m-1} \omega_m^{-qi} s(x\omega_m^i)}(x) | \prod_{i=0}^{m-1} P^{s(x\omega_m^i)}(x) = \prod_{i=0}^{m-1} P^s(x\omega_m^i).$$

■

By recalling that any polynomial which the recurrence polynomial divides is a valid recurrence polynomial (Section 2.3), the above product $\prod_{i=0}^{m-1} P^s(x\omega_m^i)$ will give a valid lacunary recurrence relation for $s^q_m(x)$. Further it is fairly easy to do this computationally. With the additional information of $deg^d(s(x))$, an even better recurrence polynomial can be found, as $deg^d(s^q_m(x)) = deg^d(s(x))$ (Lemma 2.4). Hence this shows that the recurrence polynomial can have no roots of multiplicity greater than $deg^d(s(x)) + 1$ (Corollary 1).

From a computational point of view, the order in which the $P^s(x\omega_m^i)$ for $0 \leq i \leq m-1$ are multiplied together is important. For example if $m = 2^k$ and $P^s(x) \in \mathbb{Z}[x]$ then: $P^s(x), P^s(-x) \in \mathbb{Z}[x]$, and further that $P^s(x)P^s(-x) \in \mathbb{Z}[x^2]$. It follows that $P^s(ix)P^s(-ix) \in \mathbb{Z}[x^2]$ and hence $P^s(x)P^s(-x)P^s(ix)P^s(-ix) \in \mathbb{Z}[x^4]$. Etc.

In general, if $m = d_1 d_2 ... d_k$, for $d_i \in \mathbb{Z}$ where $2 \leq d_i$, then this computation is best done as:

$$\prod_{i_k=0}^{d_k-1} ... \prod_{i_2=0}^{d_2-1} \prod_{i_1=0}^{d_1-1} P^s(x\omega_{d_1}^{i_1}\omega_{d_1 d_2}^{i_2} ... \omega_{d_1 d_2 .. d_k}^{i_k}),$$

performing the computation at the inner levels first, and using scaling to perform the next level out.

As a result of implementing this, a bug in Maple was found, which made the original method to scaling very inefficient. See Appendix D Section D.1 for more information about this.

Example 19 *Consider the following example in Maple. For more information about the Maple code, see Appendix A. For the Maple code see Appendix E. The Maple code and help files (including information about syntax) are available on the web at [1].*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the exponential generating function $\mathrm{s}(x) = \sum_{i=0}^{\infty} \frac{b_i x^i}{i!}$ *with a linear recurrence relation* $b_i = b_{i-1} - b_{i-2} + b_{i-3}$*, with initial values of* $b_0 = 1$, $b_1 = 1$ *and* $b_2 = 1$*. This example multisections this linear recurrence relation by 16 at 0, using the methods described in this section. First determine the value of* $deg^d(s(x))$.

```
> \mapleinline{active}{1d}{s := b(x) = b(x-1)-b(x-2)+b(x-3), b,
> x, [b(0) = 1, b(1) = 1, b(2) = 1];}{%
> }
```

$$\mathrm{s} := \mathrm{b}(x) = \mathrm{b}(x-1) - \mathrm{b}(x-2) + \mathrm{b}(x-3),\ b,\ x,\ [\mathrm{b}(0) = 1,\ \mathrm{b}(1) = 1,\ \mathrm{b}(2) = 1]$$

```
> \mapleinline{active}{1d}{`egf/metric/d`(s);}{%
> }
```

$$0$$

From this it follows that the multisectioned recurrence polynomial can have no multiple roots.

So now determine the recurrence polynomial.

```
> \mapleinline{active}{1d}{P := convert_poly(s);}{%
> }
```

$$P := x^3 - x^2 + x - 1$$

Now multiply $\mathrm{P}(x)$ *by* $\mathrm{P}(-x)$ *and expand.*

```
> \mapleinline{active}{1d}{P2 := expand(subs(x=-x,P)*P);}{%
> }
```

$$P2 := -x^6 - x^4 + x^2 + 1$$

Now this polynomial should have no multiple roots, so get rid of the multiple roots.

```
> \mapleinline{active}{1d}{P2p := quo(P2,gcd(P2, diff(P2,x)),x);}{%
> }
```

$$P2p := -x^4 + 1$$

Now multiply $\mathrm{P2p}(x)$ *by* $\mathrm{P2p}(x\,I)$*, and expand. This gives a recurrence polynomial that divides* $\mathrm{P}(x)\,\mathrm{P}(-x)\,\mathrm{P}(I\,x)\,\mathrm{P}(-I\,x)$ *and has no multiple roots.*

```
> \mapleinline{active}{1d}{P4 := expand(subs(x=x*I,P2p)*P2p);}{%
> }
```

$$P4 := x^8 - 2\,x^4 + 1$$

Again, get rid of the multiple roots.

```
> \mapleinline{active}{1d}{P4p := quo(P4, gcd(P4, diff(P4,x)),x);}{%
> }
```

$$P4p := x^4 - 1$$

Lastly, multiply $\mathrm{P4p}(x)$ *by* $\mathrm{P4p}(x\,\sqrt{I})$ *and expand. This gives a recurrence polynomial that divides* $\mathrm{P}(x)\,\mathrm{P}(-x)\,\mathrm{P}(I\,x)\,\mathrm{P}(-I\,x)\,\mathrm{P}(\sqrt{I}\,x)\,\mathrm{P}(-\sqrt{I}\,x)\,\mathrm{P}(I\,\sqrt{I}\,x)\,\mathrm{P}(-I\,\sqrt{I}\,x)$ *and has no multiple roots.*

```
> \mapleinline{active}{1d}{P8 := expand(subs(x=x*sqrt(I),P4p)*P4p);}{%
> }
```

$$P8 := -x^8 + 1$$

Again, get rid of the multiple roots.

```
> \mapleinline{active}{1d}{P8p := quo(P8, gcd(P8, diff(P8,x)),x);}{%
> }
```

$$P8p := -x^8 + 1$$

So converting back gives a linear recurrence relation of:

```
> \mapleinline{active}{1d}{convert_rec(P8p,b,x);}{%
> }
```

$$\mathrm{b}(x) = \mathrm{b}(x-8)$$

This is the same linear recurrence relation that is derived using the naive technique discussed in Example 13.

```
> \mapleinline{active}{1d}{`egf/ms/naive`(s,8,0);}{%
> }
```

$$\mathrm{b}(x) = \mathrm{b}(x-8),\ b,\ x,\ [\mathrm{b}(0) = 1,\ \mathrm{b}(1) = 0,\ \mathrm{b}(2) = 0,\ \mathrm{b}(3) = 0,\ \mathrm{b}(4) = 0,\ \mathrm{b}(5) = 0,\ \mathrm{b}(6) = 0,\ \mathrm{b}(7) = 0]$$

This has been automated as the Maple command 'egf/ms/rec'.

```
> \mapleinline{active}{1d}{`egf/ms/rec`(s,8,0);}{%
> }
```

$$\mathrm{b}(x) = \mathrm{b}(x-8),\ b,\ x,$$
$$[\mathrm{b}(0) = 1,\ \mathrm{b}(1) = 0,\ \mathrm{b}(2) = 0,\ \mathrm{b}(3) = 0,\ \mathrm{b}(4) = 0,\ \mathrm{b}(5) = 0,\ \mathrm{b}(6) = 0,\ \mathrm{b}(7) = 0]$$

4.2 Multisectioning via resultants.

In the previous section, the recurrence polynomials of $s(x) \in \mathcal{P}$, say $P^s(x)$, was multisectioned by computing $\prod_{i=0}^{m-1} P^s(x\omega_m^i)$ in a naive fashion, and then getting rid of root with too high of an order. This section again computes $\prod_{i=0}^{m-1} P^s(x\omega_m^i)$ but in a more sophisticated manner; by using resultants [20].

Definition 4.1 *Let $p(x) = a\prod_{i=1}^{n}(x-\lambda_i)$ and $q(x) = b\prod_{j=1}^{m}(x-\mu_j)$. The "*resultant*", denoted $\mathrm{Res}_x(p(x), q(x))$ is defined as:*

$$\mathrm{Res}_x(p(x), q(x)) = a^m b^n \prod_{i=1,j=1}^{i=n,j=m} (\lambda_i - \mu_j).$$

This next theorem follows from the definition of the resultant.

Theorem 4.1 *Let $s(x) \in \mathcal{P}$, and $P^s(x)$ be the recurrence polynomial for $s(x)$ and $P^{s_m^q(x)}(x)$ the recurrence polynomial for $s_m^q(x)$. Then:*

$$P^{s_m^q(x)}(x) | \mathrm{Res}_y(y^m - x^m, P^s(y))$$

Proof: Write $P^s(y) = \prod_{i=1}^{n}(y-\lambda_i)$. Notice that $y^m - x^m = \prod_{i=1}^{m}(y-\omega_m^i x)$. Thus from Lemma 4.2 it follows that $P^{s_m^q(x)}(x) | \prod_{j=0}^{m-1} P^s(x\omega_m^j)$. Further:

$$\prod_{j=0}^{m-1} P^s(x\omega_m^j) = \prod_{j=0}^{m-1}\prod_{i=1}^{n}(\omega_m^j x - \lambda_i) = \mathrm{Res}_y(y^m - x^m, P^s(y)).$$

Which is the desired result.

■

There are many good methods for computing resultants efficiently, in a symbolic setting. See, for example [12, 13].

Example 20 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the example of the Padovan numbers defined in [28] . Let $\mathrm{s}(x) = \sum_{i=0}^{\infty} \frac{b_i\, x^i}{i!}$*, where* $b_i = b_{i-2} + b_{i-3}$ *and* $b_0 = 1$*,* $b_1 = 0$*, and* $b_2 = 1$ *. Consider multisectioning this by 17 at 0. This example will do this by computing the resultant of* $\mathrm{P}^{\mathrm{s}}(y)$ *with* $y^{17} - x^{17}$*.*

```
> \mapleinline{active}{1d}{s := b(y) = b(y-2) + b(y-3), b, y, [b(0) =
> 1, b(1) = 0, b(2) = 1];}{%
> }
```

$$\mathrm{s} := \mathrm{b}(y) = \mathrm{b}(y-2) + \mathrm{b}(y-3),\, b,\, y,\, [\mathrm{b}(0) = 1,\, \mathrm{b}(1) = 0,\, \mathrm{b}(2) = 1]$$

```
> \mapleinline{active}{1d}{poly := convert_poly(s);}{%
> }
```

$$poly := y^3 - y - 1$$

```
> \mapleinline{active}{1d}{poly := resultant(y^17-x^17,poly,y);}{%
> }
```

$$poly := -18\, x^{17} - 1 - 119\, x^{34} + x^{51}$$

```
> \mapleinline{active}{1d}{convert_rec(poly, f, x);}{%
> }
```

$$\mathrm{f}(x) = 18\, \mathrm{f}(x-34) + \mathrm{f}(x-51) + 119\, \mathrm{f}(x-17)$$

There is a command in Maple to do this called 'egf/ms/result'.

```
> \mapleinline{active}{1d}{`egf/ms/result`(s,17,0);}{%
> }
```

$$\begin{aligned}\mathrm{b}(y) = {} & 18\, \mathrm{b}(y-34) + \mathrm{b}(y-51) + 119\, \mathrm{b}(y-17),\, b,\, y, [\mathrm{b}(0) = 1,\, \mathrm{b}(1) = 0,\, \mathrm{b}(2) = 0,\\ & \mathrm{b}(3) = 0,\, \mathrm{b}(4) = 0,\, \mathrm{b}(5) = 0,\, \mathrm{b}(6) = 0,\, \mathrm{b}(7) = 0,\, \mathrm{b}(8) = 0,\, \mathrm{b}(9) = 0,\, \mathrm{b}(10) = 0,\\ & \mathrm{b}(11) = 0,\, \mathrm{b}(12) = 0,\, \mathrm{b}(13) = 0,\, \mathrm{b}(14) = 0,\, \mathrm{b}(15) = 0,\, \mathrm{b}(16) = 0,\, \mathrm{b}(17) = 49,\\ & \mathrm{b}(18) = 0,\, \mathrm{b}(19) = 0,\, \mathrm{b}(20) = 0,\, \mathrm{b}(21) = 0,\, \mathrm{b}(22) = 0,\, \mathrm{b}(23) = 0,\, \mathrm{b}(24) = 0,\\ & \mathrm{b}(25) = 0,\, \mathrm{b}(26) = 0,\, \mathrm{b}(27) = 0,\, \mathrm{b}(28) = 0,\, \mathrm{b}(29) = 0,\, \mathrm{b}(30) = 0,\, \mathrm{b}(31) = 0,\\ & \mathrm{b}(32) = 0,\, \mathrm{b}(33) = 0,\, \mathrm{b}(34) = 5842,\, \mathrm{b}(35) = 0,\, \mathrm{b}(36) = 0,\, \mathrm{b}(37) = 0,\, \mathrm{b}(38) = 0,\\ & \mathrm{b}(39) = 0,\, \mathrm{b}(40) = 0,\, \mathrm{b}(41) = 0,\, \mathrm{b}(42) = 0,\, \mathrm{b}(43) = 0,\, \mathrm{b}(44) = 0,\, \mathrm{b}(45) = 0,\\ & \mathrm{b}(46) = 0,\, \mathrm{b}(47) = 0,\, \mathrm{b}(48) = 0,\, \mathrm{b}(49) = 0,\, \mathrm{b}(50) = 0]\end{aligned}$$

This gives the same result.

4.3 Using linear algebra on $\mathcal{P}$.

If $s(x) \in \mathcal{P}$, and an upper bound on the size of the linear recurrence relation is known, then this linear recurrence relation can be determined by the early cases.

This can be written concisely as:

Lemma 4.3 *If $s(x) \in \mathcal{P}$ and $deg^P(s(x)) \leq N$ and $deg^d(s(x)) = k$, then $P^s(x)$ can be calculated by the first $2N + k$ values.*

This result is fairly well know, and can be found in a number of difference linear algebra text books as an application of linear algebra. It is included here for completeness sake.

Proof: If b_{k+1}, b_{k+2}, ..., b_{k+2N} are the initial values of some linear recurrence relation, then this leads to the following system of N linear equations:

$$\begin{aligned} a_N b_{k+1} + a_{N-1} b_{k+2} + ... + a_1 b_{k+N} &= b_{k+N+1} \\ a_N b_{k+2} + a_{N-1} b_{k+3} + ... + a_1 b_{k+N+1} &= b_{k+N+2} \\ &\vdots \\ a_N b_{k+N} + a_{N-1} b_{k+N+1} + ... + a_1 b_{k+2N-1} &= b_{k+2N}. \end{aligned}$$

There are N linear equations, and N unknowns $(a_1, ..., a_N)$, hence a solution exists. To rewrite this in the language of linear algebra, find the values $a_1, ..., a_N$ so that they satisfy the equation:

$$\begin{bmatrix} b_{k+1} & b_{k+2} & ... & b_{k+N} \\ b_{k+2} & b_{k+3} & ... & b_{k+N+1} \\ \vdots & \vdots & \ddots & \vdots \\ b_{k+N} & b_{k+N+1} & ... & b_{k+2N-1} \end{bmatrix} \begin{bmatrix} a_N \\ a_{N-1} \\ \vdots \\ a_1 \end{bmatrix} = \begin{bmatrix} b_{k+N+1} \\ b_{k+N+2} \\ \vdots \\ b_{k+2N} \end{bmatrix}.$$

■

If when solving for the a_1, ..., a_N above, a unique solution is not found, set a_N to zero, and see if that gives a unique solution. If not, set a_{N-1} to 0, and see if that gives a unique solution. Continue in this manner. In this way when a unique solution is found, it will be of the shortest possible length.

It is also worth noting that if the order of all the columns is reversed then the resulting matrix is a Toeplitz matrix (this would mean that the expected solution is also reversed). This is nice, because there is an $\mathcal{O}(n^2)$ algorithm for solving $n \times n$ Toeplitz matrix [15].

This algorithm was not implemented with the Maple package included with this thesis, as most of the problems would still finish in a reasonable amount of time with Maple's less efficient linear algebra package.

This lemma is of great use for the computation of Bernoulli numbers, as an upper bound for $\prod_{i=0}^{m-1}(e^{\omega_m^i x}-1)$ is determined in a paper by Chellali [9], as being:

$$\sum_{d|m,\text{odd}} \mu(d)2^{m/d}/2m. \tag{4.1}$$

Here μ is the Mobius function, as defined in [2]. Later in Section 5.2 of Chapter 5, it will be seen how to use this.

Example 21 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the example of the Fibonacci numbers. Let $\mathrm{s}(x) = \sum_{i=0}^{\infty} \frac{b_i\, x^i}{i!}$, *where* $b_0 = 0$ *and* $b_1 = 1$. *Consider multisectioning this by 17 at 0. From Lemma 2.5, the size of the new linear recurrence relation will be at most 17 times* $deg^P(s(x)) = 2$. *Further* $deg^d(s(x)) = 0$ *so it follows that the values* b_1, b_2, ... $b_{17\times 2\times 2}$ *are needed. All but* b_{17}, b_{34}, b_{51}, *and* b_{68} *will be zero, so only these four values are needed to determine the linear recurrence relation.*

```
> \mapleinline{active}{1d}{s := b(i) = b(i-1) + b(i-2), b, i, [b(0) =
> 0, b(1) = 1];}{%
> }
```

$$\mathrm{s} := \mathrm{b}(i) = \mathrm{b}(i-1) + \mathrm{b}(i-2),\ b,\ i,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 1]$$

```
> \mapleinline{active}{1d}{`egf/metric/P`(s);}{%
> }
```

$$2$$

```
> \mapleinline{active}{1d}{`egf/metric/d`(s);}{%
> }
```

$$0$$

```
> \mapleinline{active}{1d}{Fib := `egf/makeproc`(s):}{%
> }
```

So this gives the following two linear equations:

```
> \mapleinline{active}{1d}{eqn1 := a[1] * Fib(17) + a[2] * Fib(34) =
> Fib(51);}{%
> }
```

$$eqn1 := 1597\, a_1 + 5702887\, a_2 = 20365011074$$

```
> \mapleinline{active}{1d}{eqn2 := a[1] * Fib(34) + a[2] * Fib(51) =
> Fib(68);}{%
> }
```

$$eqn2 := 5702887\,a_1 + 20365011074\,a_2 = 72723460248141$$

Solving these two equations gives a_1 *and* a_2*.*

```
> \mapleinline{active}{1d}{solve(\{eqn1, eqn2\});}{%
> }
```

$$\{a_1 = 1,\, a_2 = 3571\}$$

So this gives the linear recurrence relation $b_i = 3571\,b_{i-17} + b_{i-28}$*. This could have also been solved by using the linear algebra package in Maple in the following way.*

```
> \mapleinline{active}{1d}{C = matrix(2,2,[Fib(17), Fib(34), Fib(34),
> Fib(51)]);}{%
> }
```

$$C := \begin{bmatrix} 1597 & 5702887 \\ 5702887 & 20365011074 \end{bmatrix}$$

```
> \mapleinline{active}{1d}{B = vector(2, [Fib(51), Fib(68)]);}{%
> }
```

$$B := [20365011074,\, 72723460248141]$$

```
> \mapleinline{active}{1d}{linsolve(C,B);}{%
> }
```

$$[1,\, 3571]$$

There is also a command in Maple to do this called 'egf/ms/linalg'.

```
> \mapleinline{active}{1d}{`egf/ms/linalg`(s,17,0);}{%
> }
```

$$\begin{aligned} &\mathrm{b}(i) = \mathrm{b}(i-34) + 3571\,\mathrm{b}(i-17),\, b,\, i, [\mathrm{b}(0) = 0,\, \mathrm{b}(1) = 1,\, \mathrm{b}(2) = 0,\, \mathrm{b}(3) = 0,\, \mathrm{b}(4) = 0,\\ &\quad \mathrm{b}(5) = 0,\, \mathrm{b}(6) = 0,\, \mathrm{b}(7) = 0,\, \mathrm{b}(8) = 0,\, \mathrm{b}(9) = 0,\, \mathrm{b}(10) = 0,\, \mathrm{b}(11) = 0,\, \mathrm{b}(12) = 0,\\ &\quad \mathrm{b}(13) = 0,\, \mathrm{b}(14) = 0,\, \mathrm{b}(15) = 0,\, \mathrm{b}(16) = 0,\, \mathrm{b}(17) = 0,\, \mathrm{b}(18) = 2584,\, \mathrm{b}(19) = 0,\\ &\quad \mathrm{b}(20) = 0,\, \mathrm{b}(21) = 0,\, \mathrm{b}(22) = 0,\, \mathrm{b}(23) = 0,\, \mathrm{b}(24) = 0,\, \mathrm{b}(25) = 0,\, \mathrm{b}(26) = 0,\\ &\quad \mathrm{b}(27) = 0,\, \mathrm{b}(28) = 0,\, \mathrm{b}(29) = 0,\, \mathrm{b}(30) = 0,\, \mathrm{b}(31) = 0,\, \mathrm{b}(32) = 0,\, \mathrm{b}(33) = 0] \end{aligned}$$

So this again gives the same result.

4.4 Using symbolic differentiation with linear algebra.

Section 4.3 used knowledge about what the linear recurrence relation to determine the first $2N + k$ cases, (N and k defined as before). If $s(x)$ is function instead in poly-exponential form, then symbolic differentiation can be used to find the first $2N + k$ cases.

Example 22 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):with(linalg):}{%
> }
```

Consider the poly-exponential function $\mathrm{s}(x) = e^{(2\,x)}\,x^3 + e^{(3\,x)}$. *Notice that* $deg^P(s(x)) = 5$ *and* $deg^d(s(x)) = 3$. *Hence to multisection by 7 at 4, we need only look at the values for* b_4, b_{11}, b_{18}..., b_{74}.

```
> \mapleinline{active}{1d}{s := exp(2*x)*x^3 + exp(3*x);}{%
> }
```

$$\mathrm{s} := e^{(2\,x)}\,x^3 + e^{(3\,x)}$$

```
> \mapleinline{active}{1d}{`pe/metric/P`(s,x);}{%
> }
```

$$5$$

```
> \mapleinline{active}{1d}{`pe/metric/d`(s,x);}{%
> }
```

$$3$$

```
> \mapleinline{active}{1d}{for i from 4 to 74 by 7 do}{%
> }
> \mapleinline{active}{1d}{    b[i] := eval(diff(s,x$i),x=0);}{%
> }
> \mapleinline{active}{1d}{od;}{%
> }
```

$$b_4 := 129$$

$$b_{11} := 430587$$

$$b_{18} := 547852617$$

$$b_{25} := 905170004643$$

$$b_{32} := 1868997467192961$$

$$b_{39} := 4056323316806318091$$

$$b_{46} := 8863739267804963800569$$

$$b_{53} := 19383403919667326068655667$$

$$b_{60} := 42391187864946619249022072241$$

$$b_{67} := 92709468450045486192098346397467$$

$$b_{74} := 20275559682282062436318697487084228 1$$

Set the matrix C equal to $\begin{bmatrix} b_{11} & b_{18} & b_{25} & b_{32} & b_{39} \\ b_{18} & b_{25} & b_{32} & b_{39} & b_{46} \\ b_{25} & b_{32} & b_{39} & b_{46} & b_{53} \\ b_{32} & b_{39} & b_{46} & b_{53} & b_{60} \\ b_{39} & b_{46} & b_{53} & b_{60} & b_{67} \end{bmatrix}$.

```
> \mapleinline{active}{1d}{C :=
> matrix(5,5,[seq(seq(b[4+7*(i+j-1)],i=1..5),j=1..5)]):}{%
> }
```

Set the vector v equal to $[b_{44}, b_{51}, b_{58}, b_{65}, b_{72}]$.

```
> \mapleinline{active}{1d}{v := vector(5, [seq(b[4+7*i+35],i=1..5)]):}{%
> }
```

Now solve.

```
> \mapleinline{active}{1d}{linsolve(C,v);}{%
> }
```

$$[587068342272, -18614321152, 223379456, -1218048, 2699]$$

This gives a linear recurrence relation of $d_i = 587068342272 d_{i-35} - 18614321152 b_{i-28} + 223379456\, b_{i-21} - 1218048 b_{i-14} + 2699 b_{i-7}$.

This could have also been done by the Maple function 'pe/ms/linalg/sym'.

```
> \mapleinline{active}{1d}{`pe/ms/linalg/sym`(s,f, x,7,2);}{%
> }
```

$$\begin{aligned} \mathrm{f}(x) = {} & 587068342272\,\mathrm{f}(x-35) - 18614321152\,\mathrm{f}(x-28) + 223379456\,\mathrm{f}(x-21) \\ & - 1218048\,\mathrm{f}(x-14) + 2699\,\mathrm{f}(x-7),\ f,\ x, [\mathrm{f}(0) = 0,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = 9,\ \mathrm{f}(3) = 0, \\ & \mathrm{f}(4) = 0,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 0,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 0,\ \mathrm{f}(9) = 51939,\ \mathrm{f}(10) = 0, \\ & \mathrm{f}(11) = 0,\ \mathrm{f}(12) = 0,\ \mathrm{f}(13) = 0,\ \mathrm{f}(14) = 0,\ \mathrm{f}(15) = 0,\ \mathrm{f}(16) = 70571841, \end{aligned}$$

f(17) = 0, f(18) = 0, f(19) = 0, f(20) = 0, f(21) = 0, f(22) = 0,
f(23) = 105285347403, f(24) = 0, f(25) = 0, f(26) = 0, f(27) = 0, f(28) = 0,
f(29) = 0, f(30) = 209160675948729, f(31) = 0, f(32) = 0, f(33) = 0,
f(34) = 0]

Which is the same result.

4.5 Using compression.

In most situations, the main interest is the lacunary recurrence relations not the poly-exponential functions themselves. Define a new operation that will maintain the useful information of a lacunary recurrence relation such that the function under this operation will have a smaller recurrence polynomial.

Definition 4.2 (C_m^q.) *Define C_m^q that acts on $\sum_{i=0}^{\infty} b_{mi+q}\frac{x^{mi+q}}{(mi+q)!}$ by $C_m^q(\sum_{i=0}^{\infty} b_{mi+q}\frac{x^{mi+q}}{(mi+q)!}) = \sum_{i=0}^{\infty} b_{im+q}\frac{x^i}{i!}$.*

The term "*compressing*" will be used to describe this process. When saying a function $s(x)$ is "*compressed by m*", $C_m^q(s(x))$ is being looked at for some q. When saying a function $s(x)$ is "*compressed by m at q*", then $C_m^q(s(x))$ is being studied.

Methods similiar to those that arrive via compressing can be found for Fibonacci or Lucas numbers [16]. To the best of my knowledge, the definition, or consequences of compressing have not been written in this way before.

Some properties of compression are enumerated below.

Lemma 4.4 *Let $s(x) \in \mathcal{P}$ and let R_1, R_2 be subrings of $\mathbb{C}$, then:*

1. *If $s_m^q(x) \in \mathcal{P}^{R_1,R_2}$ then $C_m^q(s_m^q(x)) \in \mathcal{P}^{R_1,R_2}$.*
2. *If $s_m^q(x) \in \mathcal{P}_{R_1,R_2}$ then $C_m^q(s_m^q(x)) \in \mathcal{P}_{R_1,R_2\langle R_1,R_1^{-1}\rangle}$.*
3. *If $P^{s_m^q(x)}(x) \in R_1[x]$ then $P^{C_m^q(s_m^q(x))}(x) \in R_1[x]$.*
4. *Then $deg^d(s_m^q(x)) \geq deg^d(C_m^q(s_m^q(x)))$.*
5. *Then $deg^P(s_m^q(x)) = m \times deg^P(C_m^q(s_m^q(x)))$.*

Proof:

1. If $P^{s^q_m(x)}(x) = \prod_{i=1}^{n}(x^m - \lambda_i)$ then $P^{C^q_m(s^q_m(x)}(x) = \prod_{i=1}^{n}(x - \lambda_i)$, hence the recurrence polynomial for $C^q_m(s^q_m(x))$ splits in R_1. The coefficients of the exponential generating function are still in R_2, as they haven't changed value, only positions within the exponential generating function.

2. This follows from the hierarchy theorem (Theorem 2.2) as if $s^q_m(x) \in \mathcal{P}_{R_1,R_2}$ then $s^q_m(x) \in \mathcal{P}^{R_1,\langle R_1R_2,R_2\rangle}$. Hence from part 1 of this lemma, as $(s^q_m(x)) \in \mathcal{P}^{R_1,\langle R_1R_2,R_2\rangle}$ then $C^q_m(s^q_m(x)) \in \mathcal{P}^{R_1,\langle R_1R_2,R_2\rangle}$. This again from Theorem 2.2 gives that $C^q_m(s^q_m(x)) \in \mathcal{P}_{R_1,\langle R_1R_2,R_2\rangle\langle R_1,R_1^{-1}\rangle}$ which is equal to $\mathcal{P}_{R_1,R_2\langle R_1,R_1^{-1}\rangle}$.

3. If $P^{s^q_m(x)}(x) = x^{mn} + a_{n-1}x^{m(n-1)} + ...a_0$, then $P^{C^q_m(s^q_m(x))} = x^n + a_{n-1}x^{n-1} + ...a_0$. From this coefficients of $P^{C^q_m(s^q_m(x))}$ are still in R_1.

4. The recurrence polynomial of $s^q_m(x)$ can be written as a polynomial in x^m, say $\prod_{i=1}^{n}(x^m - \lambda_i)$. After the compression, the recurrence polynomial will be written as a polynomial in x, namely $\prod_{i=1}^{n}(x - \lambda_i)$. If some λ_i has multiplicity $deg^d(C^q_m(s^q_m(x)))$ in $\prod_{i=1}^{n}(x - \lambda_i)$, then λ_i will also appear with that multiplicity in $\prod_{i=1}^{n}(x^m - \lambda_i)$. From this $deg^d(s^q_m(x)) \geq deg^d(C^q_m(s^q_m(x)))$.

5. The recurrence polynomial of $s^q_m(x)$ can be written as a polynomial in x^m say $x^{mn} + a_{n-1}x^{m(n-1)} + ... + a_0$. After the compression, it will be written as a polynomial in x, namely $x^n + a_{n-1}x^{n-1} + ...a_0$, in x^m. This is a polynomial with the same coefficients, but with $\frac{1}{m}$-th the degree. Thus $deg^P(s^q_m(x)) = m \times deg^P(C^q_m(s^q_m(x)))$.

■

Theorem 4.2 *Let $s(x) \in \mathcal{P}$, with $m = d_1...d_n$, and $q = a_1(d_2...d_n) + a_2(d_3...d_n) + ... + a_n$ where $0 \leq a_i < d_i$. Consequently:*

$$C^q_m(s^q_m(x)) = C^{a_1}_{d_1}((C^{a_2}_{d_2}((...C^{a_n}_{d_n}(s^{a_n}_{d_n}(x)))^{a_{n-1}}_{d_{n-1}}...)^{a_1}_{d_1}).$$

Proof: Show that if $m = d_1d_2$ and $q = a_2d_1 + a_1$ for $d_i \in \mathbb{Z}$ where $2 \leq d_i$, and $0 \leq a_i < d_i$ then:

$$C^q_m(s^q_m(x)) = C^{a_1}_{d_1}((C^{a_2}_{d_2}(s^{a_2}_{d_2}(x)))^{a_1}_{d_1}).$$

and then the result will follow by induction.

Assume that $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$. Then:

$$\begin{aligned}
C^{a_1}_{d_1}((C^{a_2}_{d_2}(s^{a_2}_{d_2}(x)))^{a_1}_{d_1}) &= C^{a_1}_{d_1}((C^{a_2}_{d_2}((\sum_{i=0}^{\infty} b_i \frac{x^i}{i!})^{a_2}_{d_2}))^{a_1}_{d_1}) = C^{a_1}_{d_1}((C^{a_2}_{d_2}(\sum_{i=0}^{\infty} b_{d_2i+a_2} \frac{x^{d_2i+a_2}}{(d_2i+a_1)!}))^{a_1}_{d_1}) \\
&= C^{a_1}_{d_1}((\sum_{i=0}^{\infty} b_{d_2i+a_2} \frac{x^i}{i!})^{a_1}_{d_1}) = C^{a_1}_{d_1}(\sum_{i=0}^{\infty} b_{d_1(d_2i+a_2)+a_1} \frac{x^{d_1i+a_1}}{(d_1i+a_1)!}) \\
&= \sum_{i=0}^{\infty} b_{d_1(d_2i+a_2)+a_1} \frac{x^i}{i!} = \sum_{i=0}^{\infty} b_{d_1d_2i+d_1a_2+a_1} \frac{x^i}{i!} = \sum_{i=0}^{\infty} b_{mi+q} \frac{x^i}{i!}.
\end{aligned}$$

But this is precisely $C_m^q(s_m^q(x))$, hence the result follows by induction.

■

This is of great value as $C_{d_1}^{a_1}((C_{d_2}^{a_2}((...C_{d_n}^{a_n}(s_{d_n}^{a_n}(x)))_{d_{n-1}}^{a_{n-1}}...)_{d_1}^{a_1})$ is much easier to compute than is $C_m^q(s_m^q(x))$. This method of iteratively multisectioning requires less memory and time than doing the multisectioning process all in one calculation.

To see this, first let $f(m)$ be the complexity of the underlying algorithm that a poly-exponential function $s(x)$ is being multisectioned, when multisectioned by m. (This is something roughly linear for a fixed $s(x)$ but the exact order is not relevant to this argument.) Consider multisectioning by $m = p_1p_2....p_n$, where p_i is a non-decreasing sequence of primes (not necessarily distinct). Then to iteratively perform this multisectioning by m requires $\mathcal{O}(f(p_1) + f(p_2) + ...f(p_n)) \leq \mathcal{O}(mf(p_n))$. Thus even if $f(n) \geq n$ (i.e. $f(n)$ is worse than linear), and to multisection by a power of a prime p, say $m = p^n$, then the running time is logarithmic in m (regardless of the running time of the actual algorithm). (This ignores some of the problems associated with large integers, but is essentially correct.)

Example 23 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

This example looks at the Lucas numbers type I. Consider the linear recurrence relation $b_i = b_{i-1} + b_{i-2}$ *where* $b_0 = 2$ *and* $b_1 = 1$. *Multisection this by 8 at 2. Notice that* $8 = 2^3$ *and further that 2 = 0 (4) + 1 (2) + 0. Any method can be used to compute the intermediate multisectioning. For this example the naive method is used.*

So the first step is to calculate $s_2^0(x)$, *where* $\mathrm{s}(x) = \sum_{i=0}^{\infty} \frac{b_i\, x^i}{i!}$ *with the* b_i*s defined as above.*

```
> \mapleinline{active}{1d}{s := b(i) = b(i-1) + b(i-2) , b, i, [b(0) =
> 2, b(1) = 1];}{%
> }
```

$$s := \mathrm{b}(i) = \mathrm{b}(i-1) + \mathrm{b}(i-2),\, b,\, i,\, [\mathrm{b}(0) = 2,\, \mathrm{b}(1) = 1]$$

```
> \mapleinline{active}{1d}{t := `egf/ms/naive`(s,2,0);}{%
> }
```

$$t := \mathrm{b}(i) = 3\,\mathrm{b}(i-2) - \mathrm{b}(i-4),\, b,\, i,\, [\mathrm{b}(0) = 2,\, \mathrm{b}(1) = 0,\, \mathrm{b}(2) = 3,\, \mathrm{b}(3) = 0]$$

Now compress this result.

```
> \mapleinline{active}{1d}{s2 := readlib(`egf/compress`)(t, 2, 0);}{%
> }
```

$$s2 := \mathrm{b}(i) = 3\,\mathrm{b}(i-1) - \mathrm{b}(i-2),\, b,\, i,\, [\mathrm{b}(0) = 2,\, \mathrm{b}(1) = 3]$$

The second step is to calculate the multisectioning of the above function s2 by 2 at 1.

```
> \mapleinline{active}{1d}{t2 := `egf/ms/naive`(s2, 2, 1);}{%
> }
```

$$t2 := \mathrm{b}(i) = 7\,\mathrm{b}(i-2) - \mathrm{b}(i-4),\ b,\ i,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 3,\ \mathrm{b}(2) = 0,\ \mathrm{b}(3) = 18]$$

Now compress the result.

```
> \mapleinline{active}{1d}{s3 := `egf/compress`(t2, 2, 1);}{%
> }
```

$$s3 := \mathrm{b}(i) = 7\,\mathrm{b}(i-1) - \mathrm{b}(i-2),\ b,\ i,\ [\mathrm{b}(0) = 3,\ \mathrm{b}(1) = 18]$$

Now the last step is to multisection the above function s3 by 2 at 0.

```
> \mapleinline{active}{1d}{t3 := `egf/ms/naive`(s3, 2, 0);}{%
> }
```

$$t3 := \mathrm{b}(i) = 47\,\mathrm{b}(i-2) - \mathrm{b}(i-4),\ b,\ i,\ [\mathrm{b}(0) = 3,\ \mathrm{b}(1) = 0,\ \mathrm{b}(2) = 123,\ \mathrm{b}(3) = 0]$$

By compressing this result, a linear recurrence relation for the Lucas numbers type I is found using only every 8-th term.

```
> \mapleinline{active}{1d}{s4 := `egf/compress`(t3, 2, 0);}{%
> }
```

$$s4 := \mathrm{b}(i) = 47\,\mathrm{b}(i-1) - \mathrm{b}(i-2),\ b,\ i,\ [\mathrm{b}(0) = 3,\ \mathrm{b}(1) = 123]$$

Uncompress this result to get the answer, as expected from the other commands.

```
> \mapleinline{active}{1d}{readlib(`egf/uncompress`)(s4, 8, 2);}{%
> }
```

$$\mathrm{b}(i) = 47\,\mathrm{b}(i-8) - \mathrm{b}(i-16),\ b,\ i,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 0,\ \mathrm{b}(2) = 3,\ \mathrm{b}(3) = 0,\ \mathrm{b}(4) = 0,\ \mathrm{b}(5) = 0,\ \mathrm{b}(6) = 0,\ \mathrm{b}(7) = 0,\ \mathrm{b}(8) = 0,\ \mathrm{b}(9) = 0,\ \mathrm{b}(10) = 123,\ \mathrm{b}(11) = 0,\ \mathrm{b}(12) = 0,\ \mathrm{b}(13) = 0,\ \mathrm{b}(14) = 0,\ \mathrm{b}(15) = 0]$$

Notice that using the naive method directly to multisection by 8 at 2 gives the same result, but the method takes much longer to work.

```
> \mapleinline{active}{1d}{`egf/ms/naive`(s,8,2);}{%
> }
```

$$\mathrm{b}(i) = 47\,\mathrm{b}(i-8) - \mathrm{b}(i-16),\ b,\ i,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 0,\ \mathrm{b}(2) = 3,\ \mathrm{b}(3) = 0,\ \mathrm{b}(4) = 0,\ \mathrm{b}(5) = 0,\ \mathrm{b}(6) = 0,\ \mathrm{b}(7) = 0,\ \mathrm{b}(8) = 0,\ \mathrm{b}(9) = 0,\ \mathrm{b}(10) = 123,\ \mathrm{b}(11) = 0,\ \mathrm{b}(12) = 0,\ \mathrm{b}(13) = 0,\ \mathrm{b}(14) = 0,\ \mathrm{b}(15) = 0]$$

This process has been automated with the Maple command 'egf/ms/compress'. The last option of the command specifies to use the naive method to do the underlying computation.

```
> \mapleinline{active}{1d}{`egf/ms/compress`(s, 8, 2, naive);}{%
> }
```

$$\mathrm{b}(i) = 47\,\mathrm{b}(i-8) - \mathrm{b}(i-16),\ b,\ i,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 0,\ \mathrm{b}(2) = 3,\ \mathrm{b}(3) = 0,\ \mathrm{b}(4) = 0,\ \mathrm{b}(5) = 0,\ \mathrm{b}(6) = 0,\ \mathrm{b}(7) = 0,\ \mathrm{b}(8) = 0,\ \mathrm{b}(9) = 0,\ \mathrm{b}(10) = 123,\ \mathrm{b}(11) = 0,\ \mathrm{b}(12) = 0,\ \mathrm{b}(13) = 0,\ \mathrm{b}(14) = 0,\ \mathrm{b}(15) = 0]$$

Which gives the same results.

4.6 Computing over the integers.

Doing calculations over the rationals is always expensive. This is because of the inherent problem of rational numbers of computing the greatest common divisor with every addition or multiplication. As well, memory requirements double for each addition of comparable sized rationals. For a more detailed description of these problems see Graham, Knuth and Patashnik's book *Concrete Mathematics* [16].

For this reason, it is desirable to perform the calculations over the integers if possible. Below are some conditions and techniques to get the computations to work for the integers.

Lemma 4.5 *If $s(x) \in \mathcal{P}^{\mathbb{C},\mathbb{Q}}$ say $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$, where $P^s(x) \in \mathbb{Q}[x]$, then all calculations can be performed for the b_i over the integers.*

Proof: To do this, make two observations.

The first observation is that if:

$$b_i = \frac{a_1}{c_1} b_{i-1} + ... + \frac{a_m}{c_m} b_{i-m},$$

with a_i, $c_i \in \mathbb{Z}$, then:

$$d^i b_i \quad = \quad \frac{a_1}{c_1} d^i b_{i-1} + ... + \frac{a_m}{c_m} d^i b_{i-m} = \frac{a_1 d}{c_1} d^{i-1} b_{i-1} + ... + \frac{a_m d^m}{c_m} d^{i-m} b_{i-m}.$$

So choose d such that $\frac{a_1 d}{c_1}$, ..., $\frac{a_m d^m}{c_m} \in \mathbb{Z}$. This will give the relation:

$$\bar{b}_i = \bar{a}_1 \bar{b}_{i-1} + ... + \bar{a}_m \bar{b}_{i-m},$$

with $\bar{b}_i = b_i d^i$, and $\bar{a}_i = \frac{a_i d^i}{c_i} \in \mathbb{Z}$.

Notice that the initial values are changed to $\bar{b}_0 = b_0 d^0$, ..., $\bar{b}_m = b_0 d^m$.

The second observations is that if $\bar{b}_0 = \frac{e_0}{f_0}$, ..., $\bar{b}_m = \frac{e_m}{f_m}$, e_i, $f_i \in \mathbb{Z}$ are the initial conditions for the linear recurrence relation then by letting $\bar{d} = \mathrm{lcm}(f_0, ..., f_m)$, the linear recurrence relation:

$$\bar{d}\bar{b}_i = \bar{d}\bar{a}_1\bar{b}_{i-1} + ... + \bar{d}\bar{a}_m\bar{b}_{i-m},$$

is a calculation made completely over the integers.

■

Example 24 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the exponential generating function $\mathrm{s}(x) = \sum_{i=0}^{\infty} \frac{b_i x^i}{i!}$, *where* b_i *satisfy the linear recurrence relation* $b_i = \frac{b_{i-1}}{2} + \frac{b_{i-2}}{4}$, *with initial conditions of* $b_0 = 0$, $b_1 = \frac{1}{3}$. *Notice that the computation* $bp_i = 2^i\, b_i$ *using the linear recurrence relation* $2^i\, b_i = 2^{(i-1)}\, b_{i-1} + 2^{(i-2)}\, b_{i-2}$, *or equivalently* $bp_i = bp_{i-1} + bp_{i-2}$ *gives the same result. Remember that now the initial values are* $bp_0 = 0$ *and* $bp_1 = \frac{2}{3}$. *Now notice that if instead* $bpp_i = 3\, bp_i$ *is computed then the computation is wholly within the integers, as are the initial values. So from this it follows that* $b_i = \frac{bpp_i}{2^i\, 3}$. *Check this by computing the first few terms of both* $\frac{bpp_i}{2^i\, 3}$ *and* b_i.

```
> \mapleinline{active}{1d}{Bpp := `egf/makeproc`(bpp(i) = bpp(i-1) +
> bpp(i-2), bpp, i, }{%
> }

> \mapleinline{active}{1d}{    [bpp(0)= 0, bpp(1) = 2]):}{%
> }

> \mapleinline{active}{1d}{seq(1/3*(1/2)^i*Bpp(i),i=0..10);}{%
> }
```

$$0, \frac{1}{3}, \frac{1}{6}, \frac{1}{6}, \frac{1}{8}, \frac{5}{48}, \frac{1}{12}, \frac{13}{192}, \frac{7}{128}, \frac{17}{384}, \frac{55}{1536}$$

```
> \mapleinline{active}{1d}{B := `egf/makeproc`(b(i) = b(i-1)/2+b(i-2)/4,
> b, i, [b(0) = 0, b(1) = 1/3]):}{%
> }

> \mapleinline{active}{1d}{seq(B(i),i=0..10);}{%
> }
```

$$0, \frac{1}{3}, \frac{1}{6}, \frac{1}{6}, \frac{1}{8}, \frac{5}{48}, \frac{1}{12}, \frac{13}{192}, \frac{7}{128}, \frac{17}{384}, \frac{55}{1536}$$

4.7 Techniques for smaller recurrences.

This section is interested in methods to speed up the calculation of the coefficients of poly-exponential functions. One way, that was suggested by Wilf [30], is to do a calculation of a simpler linear recurrence relation, and then use a non-linear (yet simple) means to get the desired sequence.

This is stated formally as:

Theorem 4.3 *Let* $t(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!} \in \mathcal{P}$ *have an* N*-term linear recurrence relation* $b_i = \alpha_1 b_{i-1} + ...\alpha_N b_{i-N}$. *Let* $p(x) = \beta_n x^n + ... + \beta_0$ *be some polynomial in* $\mathbb{C}[x]$. *Then* $p(x)t(x) = \sum_{j=0}^{\infty} d_j \frac{x^j}{j!}$, *where* $d_i = \beta_n i^{(n)} b_{i-n} + \beta_{n-1} i^{(n-1)} b_{i-n+1} + ...\beta_0 b_i$.

Proof: Then:

$$\begin{aligned}\sum_{j=0}^{\infty} d_j \frac{x^j}{j!} &= p(x)t(x) = p(x)\sum_{i=0}^{\infty} b_i \frac{x^i}{i!} = \sum_{i=0}^{\infty}(\beta_n x^n + ... + \beta_0) b_i \frac{x^i}{i!} \\ &= \sum_{i=0}^{\infty} \beta_n b_i \frac{x^{i+n}(i+n)^{(n)}}{(i+n)!} + ... + \beta_0 b_i \frac{x^i}{(i)!} = \sum_{i=0}^{\infty} \beta_n b_{i-n} i^{(n)} \frac{x^i}{i!} + ...\beta_0 b_i \frac{x^i}{i!}.\end{aligned}$$

■

Example 25 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the function $\mathrm{s}(x) = (x^2+1)\left(\sum_{i=0}^{\infty} \frac{b_i x^i}{i!}\right)$, *where the* b_i*s are the Fibonacci numbers satisfing* $b_i = b_{i-1} + b_{i-2}$ *with initial values of* $b_0 = 0$ *and* $b_1 = 1$. *This example shows how to determine the linear recurrence relation for* $\mathrm{s}(x) = \sum_{i=0}^{\infty} \frac{d_i x^i}{i!}$, *where the* d_i *are to be written as functions of the* b_i. *But this can just be rewritten as* $\left(\sum_{i=0}^{\infty} \frac{b_i x^{(i+2)}}{i!}\right) + \left(\sum_{i=0}^{\infty} \frac{b_i x^i}{i!}\right)$, *which is just* $\left(\sum_{i=0}^{\infty} \frac{b_i (i+2)(i+1) x^{(i+2)}}{(i+2)!}\right) + \left(\sum_{i=0}^{\infty} \frac{b_i x^i}{i!}\right)$, *or in other words* $\sum_{i=0}^{\infty} \frac{(b_{i-2} i (i-1) + b_i) x^i}{i!}$. *There is a facility in Maple to make procedures with this additional information of the* $p(x)$ *in Theorem 4.3, (in this case* x^2+1*).*

```
> \mapleinline{active}{1d}{t := b(i) = b(i-1) + b(i-2), b, i,
> [b(0)=0,b(1)=1];}{%
> }
```

$$\mathrm{t} := \mathrm{b}(i) = \mathrm{b}(i-1) + \mathrm{b}(i-2),\ b,\ i,\ [\mathrm{b}(0) = 0,\ \mathrm{b}(1) = 1]$$

```
> \mapleinline{active}{1d}{T := `egf/makeproc`(t):}{%
> }

> \mapleinline{active}{1d}{S := `egf/makeproc`(t,i^2+1):}{%
> }
```

Check the first few cases to see if it is correct.

```
> \mapleinline{active}{1d}{seq(i*(i-1)*T(i-2)+T(i),i=0..10);}{%
> }
```

$$0, 1, 1, 8, 15, 45, 98, 223, 469, 970, 1945$$

```
> \mapleinline{active}{1d}{seq(S(i),i=0..10);}{%
> }
```

$$0, 1, 1, 8, 15, 45, 98, 223, 469, 970, 1945$$

4.8 Conclusions.

The conclusion that are listed in this section are conclusions as to which implemenations are faster, the conclusions are not for which methods are faster. This is because Maple combines a relatively sophisticate code to deal with certain problems, and some very naive methods for others. Hence the implementation of any method in this chapter can be greatly impacted on by the underlying methods used by Maple for certain problems, (for examples, solving linear systems of equations, how it performs resultants, etc).

The different methods that are possible (in combination or otherwise) are:

1. naive method (Chapter 2 Definition 2.6),
2. multiplying recurrence polynomial (Section 4.1),
3. using resultants on recurrence polynomial (Section 4.2),
4. linear algebra, (Section 4.3),
5. linear algebra with symbolic differentiation, (Section 4.4),
6. compression with any of the above methods, (Section 4.5),
7. working over the integers with any of the above methods, (Section 4.6),
8. factoring out a polynomial to reduce the size of the recurrence polynomial with any of the above methods, (Section 4.7).

- Of the first five, methods 4 and 5 are the most efficient. Multisectioning by m for $m > 7000$ are very doable problems.
- The naive method (method 1) is slow, and works poorly for $m > 14$.
- The recurrence polynomial method (method 2) works well for m that is a product of a large number of small primes. In general though, it does not work for large prime values; for primes $m > 43$, it is not really a feasible method.
- The resultant method (method 3), although not as bad as method 1 or 2 is noticeably slower than method 4 or 5. (For the situation of multisectioning the Fibonacci numbers by 1000, method 4 is faster than method 3 by a factor of 20.)
- The compression techniques (method 6) will improve the efficiency of methods 1, 3, 4, or 5, but do little for method 2, (as this method already takes into account the factorization of m). Here it is easy to do problems on the order of 10^5 (when used in combination with method 4).
- Functions rarely meet the criteria for methods 7 and 8 to be used, so they are not of interest.

Chapter 5

Calculations of recurrences for $\mathcal{R}$.

The previous chapter studied methods to determine the lacunary recurrence relations for multisectioned functions in $\mathcal{P}$. This chapter examines techniques for functions in $\mathcal{R}$.

Section 5.1 of this chapter deals with how to multisection the bottom of a rational poly-exponential function, (i.e. perform the necessary multiplication of poly-exponential functions) by looking at the recurrence polynomial and resultants. Section 5.2 looks at two different related methods to perform the multiplication for the bottom linear recurrence relation using fast Fourier transforms and linear algebra. These methods are also extended to determine the top recurrence. How to determine the top linear recurrence relation by using the knowledge about the bottom and about the numbers themselves is examined in Section 5.3. Section 5.4 investigates how symmetries in a poly-exponential function can simplify the calculation of the bottom lacunary recurrence relation. Sections 5.5 and 5.6 investigates two different methods to simplify the problem, by making sure that the work is always done over the integers, or by factoring out polynomials. The last section, Section 5.7 makes some conclusions about which methods are best for which problems.

5.1 Multisectioning recurrence polynomials by resultants.

Given $s(x)$, $t(x) \in \mathcal{P}$, with recurrence polynomials $P^s(x)$, P^t(x), it is difficult to calculate $P^{st}(x)$, the recurrence polynomial of $s(x)t(x)$. This section will demonstrate a method using resultants to perform this calculation.

Combining the results in Lemma 4.1 with the resultant (Definition 4.1) gives:

Lemma 5.1 *Let $s(x)$ and $t(x) \in \mathcal{P}$, where $s(x) = \sum_{i=1}^{n} p_i(x)e^{\lambda_i x}$ and $t(x) = \sum_{j=1}^{m} q_j(x)e^{\mu_j x}$. Then*

$P^{st}(x)|\prod_{i=1,j=1}^{i=n,j=m}(x-\lambda_i-\mu_j)^{\deg(p_i(x))+\deg(q_i(x))} = \mathrm{Res}_y(P^s(x-y),P^t(y))$.

Recall in Section 4.1 that the order in which the calculations were done made a difference in the efficiency of the computation. Here too, the same order is desirable for calculating the linear recurrence relation of $\prod_{i=0}^{m-1} t(x\omega_m^i)$.

Example 26 *Consider the following example in Maple. For more information about the Maple code, see Appendix A. For the Maple code see Appendix E. The Maple code and help files (including information about syntax) are available on the web at [1].*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the Genocchi numbers, as defined by Lehmer [19] having an exponential generating function of $\frac{2x}{e^x+1}$. *The calculation of* $\prod_{i=0}^{m-1}(e^{(x\,{\omega_m}^i)}+1)$, *where* ω_m *is* $e^{(\frac{2\pi I}{m})}$ *is of interest to compute the recurrence of the denominator. Set* $t(x)=e^x+1$ *and* $s(x)=2x$. *Assume that this function is to be multisectioned by 4. Then to do this with recurrence polynomials, first find the recurrence polynomial of* $\mathrm{t}(x)=e^x+1$. *Notice* $deg^d(t(x))=0$ *hence* $deg^d(\prod_{i=0}^{m-1}\mathrm{t}(x\,{\omega_m}^i))=0$. *This means that the resulting recurrence polynomial may have no multiple roots.*

```
> \mapleinline{active}{1d}{t := exp(x)+1;}{%
> }
```

$$t := e^x+1$$

```
> \mapleinline{active}{1d}{poly := convert_poly(convert_egf(t,f,x));}{%
> }
```

$$poly := x^2-x$$

Scale this to get the recurrence polynomial of $\mathrm{t}(-x)$ *and then use the resultant to get the result of multiplying the two poly-exponential functions together.*

```
> \mapleinline{active}{1d}{poly2 := subs(x=-x,poly);}{%
> }
```

$$poly2 := x^2+x$$

```
> \mapleinline{active}{1d}{poly3 :=
> resultant(subs(x=x-y,poly),subs(x=y,poly2),y);}{%
> }
```

$$poly3 := (x^2-x)\,(x^2+x)$$

There are no multiple roots, so factor out multiple root, and factor out the leading coefficient.

```
> \mapleinline{active}{1d}{gcd(poly3, diff(poly3,x), 'poly4'): poly4 :=
> expand(poly4/lcoeff(poly4,x));}{%
> }
```

$$poly4 := x^3 - x$$

Scale this again, to get the recurrence polynomial for $\mathrm{t}(I\,x)\,\mathrm{t}(-I\,x)$*, and then use the resultant to get the result of multiplying the two poly-exponential functions together.*

```
> \mapleinline{active}{1d}{poly5 := subs(x=I*x,poly4);}{%
> }
```

$$poly5 := -I\,x^3 - I\,x$$

```
> \mapleinline{active}{1d}{poly6 :=
> resultant(subs(x=x-y,poly4),subs(x=y,poly5),y);}{%
> }
```

$$poly6 := I\,(x^3 - x)\,(-x^4 - 4\,x^2 - 4 - x^6)$$

There will be no multiple roots, so factor out spurious multiple roots, and factor out the leading coefficient..

```
> \mapleinline{active}{1d}{gcd(poly6, diff(poly6,x), 'poly7'): poly7 :=
> expand(poly7/lcoeff(poly7,x));}{%
> }
```

$$poly7 := 3\,x^5 + x^9 - 4\,x$$

Now determine the linear recurrence relation.

```
> \mapleinline{active}{1d}{convert_rec(poly7,f,x);}{%
> }
```

$$\mathrm{f}(x) = -3\,\mathrm{f}(x-4) + 4\,\mathrm{f}(x-8)$$

Alternatively, the automated function in Maple could have been used.

```
> \mapleinline{active}{1d}{`bottom/ms/result`(t,f,x,4);}{%
> }
```

$$\mathrm{f}(x) = -3\,\mathrm{f}(x-4) + 4\,\mathrm{f}(x-8),\ f,\ x,$$
$$[\mathrm{f}(0) = 16,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = 0,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = -8,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 0,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 72]$$

Which gives the same result.

This example demonstrates how the order in which the resultants are taken is important. Also shown is how the use of the metric $deg^d(t(x))$ can be used to simplify the computation.

5.2 Fast Fourier transforms and linear algebra.

The methods of linear algebra from Section 4.3 needed to know the first $2N + k$ values, where N is the length of the recurrence polynomial, and k is a bound on the multiplicity of the roots. In a practical situation, the calculation of $\prod_{i=1}^{m} t(\omega_m^i x)$ is of interest where $f(x) = \frac{s(x)}{t(x)}$, $s(x)$, $t(x) \in \mathcal{P}$. If $t(x)$ is easy to approximate as a polynomials, then $t(x\omega_m^i)$ is also easy to approximate as a polynomial, via scaling.

Multiplying polynomials can be done quickly via the "*fast Fourier transform*". Maple uses a "*divide and conquer*" method instead of fast Fourier transform, which is still asymptotically better that the naive polynomial multiplication. All of these algorithms can use fast Fourier transform as the basis of polynomial multiplication, but it was deemed beyond the scope of this thesis to implement this method within Maple. See [12] for a proper definition of the divide and conquer and of fast Fourier transform.

Recall in Section 4.1 that the order in which the calculations were done made a difference in the efficiency of the computation. Here too, the same order is desirable for calculating the linear recurrence relation for $\prod_{i=0}^{m-1} t(x\omega_m^i)$. To determine the top linear recurrence relation, the order is not useful, and the polynomials can only be multiplied together in a naive fashion.

The calculation of multisectioning by m, where $m = d_1 d_2 ... d_k$ with $d_i \in \mathbb{Z}$ where $d_i \geq 2$, where an upper bound for $deg^P(\prod_{i=0}^{m-1}(t(x\omega_m^i))$ (from Lemma 2.5), say N and an upper bound for $deg^d(\prod_{i=0}^{m-1} t(x\omega_m^i))$ (from Lemma 2.4), say k, can use two different approaches to determine the new linear recurrence relation.

5.2.1 Fast Fourier transform method 1.

Calculate a polynomial approximation of $t(x)$ to degree $2N + k$, call this $p(x)$. Then iteratively perform:

$$\prod_{i_k=0}^{d_k-1} ... \prod_{i_2=0}^{d_2-1} \prod_{i_1=0}^{d_1-1} p(x\omega_{d_1}^{i_1}\omega_{d_1 d_2}^{i_2}...\omega_{d_1 d_2 .. d_k}^{i_k}),$$

by the fast Fourier transform, doing the inner multiplication first, and using scaling for the next level out, etc. Each time a multiplication is done, truncate the polynomial to degree $2N + k$ as any component of the polynomial past that point is not of interest. After this, use linear algebra on the coefficients, to determine what the linear recurrence relation would be. Scaling by a factor of $(2N + k)!$ avoids using rationals in these calculations (assuming $t(x) \in \mathcal{P}^{\mathbb{C},\mathbb{Z}}$).

The problem with this is that the first few multiplications are expensive, as these are dense polynomials of typically large degree.

As a result of implementing this, a bug in Maple was found, which made the original method to scaling very inefficient. This bug had to do with inefficient powering of roots of unity. See Appendix D Section D.1 for more information about this.

Example 27 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

*When looking at the "*Euler numbers*" [2], generated by* $\frac{2}{e^x+e^{(-x)}}$*, the calculation of* $\prod_{i=0}^{m-1}(e^{(x\,{\omega_m}^i)}+e^{(-x\,{\omega_m}^i)})$*, where* ω_m *is* $e^{(\frac{2\,\pi\,I}{m})}$ *is of interest. Set* $\mathrm{t}(x)=e^x+e^{(-x)}$ *and* $\mathrm{s}(x)=2$*. This example will multisection by 4. An upper bound on the size of the linear recurrence relation is 16 from Lemma 2.5. Also* $deg^d(t(x))=0$*, and hence* $deg^d(\prod_{i=0}^{m-1}\mathrm{t}(x\,{\omega_m}^i))=0$*. So polynomials of degree 32 needs to be calculated, and then linear algebra is used to determine the result. So first calculate the Taylor series approximation for* $32!\,\mathrm{t}(x)$*, call this* $\mathrm{T}(x)$ *(scaling by* $32!$ *will mean that the calculation will avoid working over the rationals).*

```
> \mapleinline{active}{1d}{t := exp(x)+exp(-x);}{%
> }
```

$$\mathrm{t} := e^x + e^{(-x)}$$

```
> \mapleinline{active}{1d}{T :=
> convert(taylor(t,x=0,33),polynom)*32!;}{%
> }
```

$$\begin{aligned}\mathrm{T} := {} & 526261673867387060334436024320000000 \\ & + 263130836933693530167218012160000000\,x^2 \\ & + 21927569744474460847268167680000000\,x^4 \\ & + 730918991482482028242272256000000\,x^6 \\ & + 13052124847901464790040576000000\,x^8 \\ & + 145023609421127386556006400000\,x^{10} \\ & + 1098663707735813534515200000\,x^{12} \\ & + 6036613778768206233600000\,x^{14} + 2515255741153419264000\,x^{16} \\ & + 82197900037693440000\,x^{18} + 21631026325708800\,x^{20} \\ & + 468204033024000\,x^{22} + 848195712000\,x^{24} + 1304916480\,x^{26} \\ & + 1726080\,x^{28} + 1984\,x^{30} + 2\,x^{32}\end{aligned}$$

Now multiply $\mathrm{T}(x)$ *by* $\mathrm{T}(-x)$ *and divide by* $32!$*.*

```
> \mapleinline{active}{1d}{T2 := convert(series(expand(T *
> subs(x=-x, T)),x,33),polynom)/32!;}{%
> }
```

$$\begin{aligned}\mathrm{T2} := {} & 10525233477347741206688720486400000000 \\ & + 10525233477347741206688720486400000000\,x^2 \\ & + 350841115911591373556290682880000000\,x^4 \\ & + 46778815454878849807505424384000000\,x^6 \\ & + 3341343961062774986250387456000000\,x^8 \\ & + 148504176047234443833350553600000\,x^{10} \\ & + 4500126546885892237374259200000\,x^{12} \\ & + 98903880151338290931302400000\,x^{14} \\ & + 1648398002522304848855040000\,x^{16} \\ & + 21547686307481109135360000\,x^{18} + 2268177506050643066880000\,x^{20} \\ & + 196379004852869529600\,x^{22} + 14230362670497792000\,x^{24} \\ & + 87571462587678720\,x^{26} + 463341071892480\,x^{28} + 2130303778816\,x^{30} \\ & + 8589934592\,x^{32}\end{aligned}$$

Now scale this by I, so that the product will give an approximation for $\frac{\mathrm{T}(x)\,\mathrm{T}(-x)\,\mathrm{T}(I\,x)\,\mathrm{T}(-I\,x)}{32!}$.

```
> \mapleinline{active}{1d}{T3 := convert(series(expand(T2 *
> subs(x=I*x, T2)),x,33),polynom)/32!;}{%
> }
```

$$\begin{aligned}\mathrm{T3} := {} & 421009339093909648267548819456000000\,0 \\ & - 14033644636463654942251627315200000000\,x^4 \\ & + 12028838259825989950501394841600000\,0\,x^8 \\ & - 55801569181385063743440814080000\,0\,x^{12} \\ & + 85057336930150930200920064000\,0\,x^{16} \\ & - 46361548223675144287027200\,0\,x^{20} + 11663205244739990323200\,0\,x^{24} \\ & - 1518090687948521472\,0\,x^{28} + 1125934266580992\,x^{32}\end{aligned}$$

Now collect the coefficients of importance (the non-zero ones).

```
> \mapleinline{active}{1d}{for i from 0 to 32 by 4 do}{%
> }
```

```
> \mapleinline{active}{1d}{    b[i/4] := coeff(T3,x,i)*i!/32!;}{%
> }
```

```
> \mapleinline{active}{1d}{od;}{%
> }
```

$$b_0 := 16$$

$$b_1 := -128$$

$$b_2 := 18432$$

$$b_3 := -1015808$$

$$b_4 := 67633152$$

$$b_5 := -4286578688$$

$$b_6 := 275012124672$$

$$b_7 := -17590038560768$$

$$b_8 := 1125934266580992$$

Now use linear algebra to solve the linear recurrence relation.

```
> \mapleinline{active}{1d}{`recurrence/solve/linalg`(b, f, x, 4);}{%
> }
```

$$\mathrm{f}(x) = 1024\,\mathrm{f}(x-8) - 48\,\mathrm{f}(x-4)$$

This could also have be done by using the Maple function for this technique

```
> \mapleinline{active}{1d}{`bottom/ms/linalg/fft`(t,f,x,4);}{%
> }
```

$$\mathrm{f}(x) = 1024\,\mathrm{f}(x-8) - 48\,\mathrm{f}(x-4),\ f,\ x, [\mathrm{f}(0) = 16,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = 0,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = -128,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 0,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 18432]$$

Which is the same result.

5.2.2 Fast Fourier transform method 2.

Again, the calculation of interest is

$$\prod_{i_k=0}^{d_k-1} \cdots \prod_{i_2=0}^{d_2-1} \prod_{i_1=0}^{d_1-1} t(x\omega_{d_1}^{i_1}\omega_{d_1 d_2}^{i_2} \ldots \omega_{d_1 d_2 \ldots d_k}^{i_k})$$

with $t(x) \in \mathcal{P}$. Recall that method 1 (Subsection 5.2.1) performed all of these calculations with a large degree polynomial, performing the inner calculations first, and then the next level out, etc. This method differs in that the inner computation is done with a small degree polynomial, the linear recurrence relation for the inner multiplication is then determined with linear algebra, after which the large degree polynomial needed for the next computation is constructed. By scaling out a factor of $(2N+k)!$ each time, (for the various N and k as they apply to each step), can avoid using rationals in these calculations (assuming $t(x) \in \mathcal{P}^{\mathbb{C},\mathbb{Z}}$).

The advantage to this over method 1 is that the polynomials are of small degree near the beginning of the calculation when they are densest. The disadvantage is that linear algebra is repeatedly used.

As a result of implementing this, a bug in Maple was found, which made the original method to scaling very inefficient. This bug had to do with inefficient powering of roots of unity. See Appendix D Section D.1 for more information about this.

As a result of testing this on large examples, some inefficiencies with the factorial function in Maple were discovered. For more information about this, see Appendix D Section D.6.

Example 28 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the Lucas numbers as defined by Lehmer, [19]. To avoid confusion with the Lucas numbers defined in Graham, Knuth and Patashnik, [16] we will call these Lucas numbers, "Lucas numbers type II". When looking at the Lucas numbers type II generated by $\frac{x\,e^x}{e^{(2\,x)}-1}$*, the calculation of interest is* $\prod_{i=0}^{m-1}(e^{(2\,x\,{\omega_m}^i)}-1)$*, where* ω_m *is* $e^{(\frac{2\,\pi\,I}{m})}$*. Set* $\mathrm{t}(x)=e^{(2\,x)}-1$ *and* $\mathrm{s}(x)=x\,e^x$*. Assume that the function is being multisectioned by 4. Notice* $deg^d(t(x))=0$*, and hence that* $deg^d(\prod_{i=0}^{m-1}\mathrm{t}(x\,{\omega_m}^i))=0$*. Notice that* $deg^P(\mathrm{t}(x))=2$*, hence* $deg^P(\mathrm{t}(x)\,\mathrm{t}(-x))$ *is at most 4. So for the first step only a linear recurrence relation to degree 8 is needed. So first calculate the taylor series approximation for* $\mathrm{t}(x)$*, call this* $8!\,\mathrm{T}(x)$ *(scale by* $8!$ *to avoid having to work over the rationals).*

```
> \mapleinline{active}{1d}{t := exp(2*x)-1;}{%
> }
```

$$\mathrm{t} := e^{(2\,x)}-1$$

```
> \mapleinline{active}{1d}{T :=
> convert(taylor(t,x=0,9),polynom)*8!;}{%
> }
```

$$\mathrm{T} := 80640\,x+80640\,x^2+53760\,x^3+26880\,x^4+10752\,x^5+3584\,x^6+1024\,x^7 + 256\,x^8$$

Now multiply $\mathrm{T}(x)$ *by* $\mathrm{T}(-x)$ *and divide by 8!.*

```
> \mapleinline{active}{1d}{T2 := convert(series(expand(T *
> subs(x=-x,}{%
> }
```

```
> \mapleinline{active}{1d}{T)),x,9),polynom)/8!;}{%
> }
```

$$\mathrm{T2} := -161280\,x^2-53760\,x^4-7168\,x^6-512\,x^8$$

Determine the interesting (non-zero) values.

```
> \mapleinline{active}{1d}{for i from 0 to 4 do }{%
> }

> \mapleinline{active}{1d}{    b[i] := coeff(T2,x,2*i)*(2*i)!/8!; }{%
> }

> \mapleinline{active}{1d}{od;}{%
> }
```

$$b_0 := 0$$

$$b_1 := -8$$

$$b_2 := -32$$

$$b_3 := -128$$

$$b_4 := -512$$

Solve this linear recurrence relation.

```
> \mapleinline{active}{1d}{rec := `recurrence/solve/linalg`(b, f, x,
> 2);}{%
> }
```

$$rec := \mathrm{f}(x) = 4\,\mathrm{f}(x-2)$$

```
> \mapleinline{active}{1d}{t2 := rec, f, x, [f(0) = b[0], f(1) = 0,
> }{%
> }

> \mapleinline{active}{1d}{f(2) = b[1], f(3) = 0, f(4) = b[2], f(5) = 0,
> }{%
> }

> \mapleinline{active}{1d}{f(6) = b[3], f(7) = 0, f(8) = b[4]];}{%
> }
```

$$\mathrm{t2} := \mathrm{f}(x) = 4\,\mathrm{f}(x-2),\ f,\ x, [\mathrm{f}(0) = 0,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = -8,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = -32,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = -128,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = -512]$$

Now determine what $deg^P(T2(x))$ and $deg^d(T2(x))$ are, as these will be useful in the calculation.

```
> \mapleinline{active}{1d}{`egf/metric/P`(t2);}{%
> }
```

```
> \mapleinline{active}{1d}{‘egf/metric/d‘(t2);}{%
> }
```

$$0$$

Notice that $deg^P(t2(x)) = 3$*, and hence* $deg^P(t2(x) * t2(I * x))$ *is at most 9. Thus only the first 18 terms of the polynomial approximation needs to be calculated, say* $18!\,\mathrm{t2}(x)$ *(scale by* $18!$ *to avoid having to work over the rationals). Call this T2(x).*

```
> \mapleinline{active}{1d}{Fun := ‘egf/makeproc‘(t2):}{%
> }
```

```
> \mapleinline{active}{1d}{T2 := add (Fun(i)*x^i/i!,i=0..18)*18!;}{%
> }
```

$$\begin{aligned}\mathrm{T2} := &-25609494822912000\,x^2 - 8536498274304000\,x^4 \\ &- 1138199769907200\,x^6 - 81299983564800\,x^8 - 3613332602880\,x^{10} \\ &- 109494927360\,x^{12} - 2406481920\,x^{14} - 40108032\,x^{16} - 524288\,x^{18}\end{aligned}$$

So now multiply $\mathrm{T2}(x)$ *by* $\mathrm{T2}(I\,x)$ *and divide by 18!.*

```
> \mapleinline{active}{1d}{T3 := convert(series(expand(T2 *
> subs(x=I*x, T2)),x,19),polynom)/18!;}{%
> }
```

$$\begin{aligned}\mathrm{T3} := &-102437979291648000\,x^4 + 2276399539814400\,x^8 \\ &- 14453330411520\,x^{12} + 20374880256\,x^{16}\end{aligned}$$

Collect the interesting (non-zero) terms.

```
> \mapleinline{active}{1d}{for i from 0 to 4 do }{%
> }
```

```
> \mapleinline{active}{1d}{    b[i] := coeff(T3,x,4*i)*(4*i)!/18!;
> }{%
> }
```

```
> \mapleinline{active}{1d}{od;}{%
> }
```

$$b_0 := 0$$

$$b_1 := -384$$

$$b_2 := 14336$$

$$b_3 := -1081344$$

$$b_4 := 66584576$$

Solve this linear recurrence relation.

```
> \mapleinline{active}{1d}{rec := ‘recurrence/solve/linalg‘(b, f, x,
> 4);}{%
> }
```

$$rec := \mathrm{f}(x) = 1024\,\mathrm{f}(x-8) - 48\,\mathrm{f}(x-4)$$

This also could have been done by using the Maple function for this technique

```
> \mapleinline{active}{1d}{‘bottom/ms/linalg/fft2‘(t,f,x,4);}{%
> }
```

$$\mathrm{f}(x) = 1024\,\mathrm{f}(x-8) - 48\,\mathrm{f}(x-4),\ f,\ x, [\ \mathrm{f}(0) = 0,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = 0,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = -384,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 0,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 14336]$$

Which is the same result.

It is worth pointing out in this example that fewer terms of the polynomial needed to be worked out. This was because a better bound for $deg^P(\prod_{i=0}^{m-1} t(x\omega_m^i)$ was known as a result of the iteratively calculating $t(x)t(-x)$ and then $t(x)t(-x)t(Ix)t(-Ix)$.

5.3 Using the bottom linear recurrence relation.

The method described in Section 4.3 is easy if $s(x) \in \mathcal{P}$ is known in poly-exponential function form. But there are situations when to explicitly calculate what $s(x)$ is in poly-exponential function form is space consuming and undesirable. For example when trying to determine the top linear recurrence relation of a rational poly-exponential function.

Consider a rational poly-exponential function $\frac{s(x)}{t(x)}$ where $s(x)$, $t(x) \in \mathcal{P}$ with $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$ and $t(x) = \sum_{j=0}^{\infty} d_j \frac{x^j}{j!}$. Further assume $\frac{s(x)}{t(x)} = \sum_{i=0}^{\infty} c_i \frac{x^i}{i!}$. This gives

$$\sum_{j=s}^{i} \binom{i}{j} d_j c_{i-j} \quad = \quad b_i \tag{5.1}$$

Then if a simple formulae for the d_is and c_is are known, then the b_i can be determined using Equation 5.1. If a bound on the size of the linear recurrence relation for the b_i is known, say N, and a bound for the metric deg^d on the linear recurrence relation for the b_i is known, say k, then only the first $2N + k$ values of b_i need be calculated to determine the linear recurrence relation for the b_i.

Recall from Section 2.4 that typically the linear recurrence relation for multisectioning some q will be the same regardless of the value of q. This can be utilized here by using the process above

for the top when multisectioned by m at 0, and then assume that the linear recurrence relation will be the same when multisectioning at other values of q. Hence linear algebra need not be used to determine the linear recurrence relation but instead simply reuse the linear recurrence relation from the first calculation, thus simplifying future calculations immensely.

Example 29 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

This example tries to find the linear recurrence relation for the top of the Euler numbers $\mathrm{f}(x) = \frac{2}{e^x+e^{(-x)}} = \sum_{i=0}^{\infty} \frac{c_i\, x^i}{i!} = \frac{\sum_{i=0}^{\infty} \frac{b_i\, x^i}{i!}}{\sum_{j=0}^{\infty} \frac{d_j\, x^j}{j!}}$ *given the bottom linear recurrence relation, when multisectioning by 4 at 0. As the function is being multisectioned by 4 at 0, then only those* b_i *where* $i = 0 \bmod 4$ *are needed.*

```
> \mapleinline{active}{1d}{bot :=
> `bottom/ms/linalg/fft2`(exp(x)+exp(-x),f,x,4);}{%
> }
```

$$bot := \mathrm{f}(x) = 1024\,\mathrm{f}(x-8) - 48\,\mathrm{f}(x-4),\ f,\ x, [\mathrm{f}(0) = 16,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = 0,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = -128,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 0,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 18432]$$

```
> \mapleinline{active}{1d}{Bot := `egf/makeproc`(bot):}{%
> }
```

Now $b_i = \sum_{j=0}^{i} \mathrm{binomial}(i,\, j)\, c_{i-j}\, d_j$ *from Equation 5.1. An upper bound of the number of* b_i *needed as* $4\,2^3\,2\,2 + 2 = 130$ *by Lemma 2.5.*

```
> \mapleinline{active}{1d}{F := i ->
> add(binomial(i,j)*euler(i-j)*`Bot`(j),j=0..i);}{%
> }
```

```
Warning, `j` in call to `add` is not local
```

$$F := i \to \mathrm{add}(\mathrm{binomial}(i,\, j)\, \mathrm{euler}(i-j)\, \mathrm{Bot}(j),\ j = 0..i)$$

```
> \mapleinline{active}{1d}{for i from 4 to 130 by 4 do}{%
> }
> \mapleinline{active}{1d}{    b[i/4] := F(i):}{%
> }
> \mapleinline{active}{1d}{od:}{%
> }
> \mapleinline{active}{1d}{rec := `recurrence/solve/linalg`(b,f,x,4);}{%
```

```
> }
```

$$rec := \mathrm{f}(x) = 625\,\mathrm{f}(x-12) - 611\,\mathrm{f}(x-8) - 13\,\mathrm{f}(x-4)$$

This could have also been discovered by using some of the other built in functions.

```
>
> \mapleinline{active}{1d}{`top/ms/linalg/fft`(2,exp(x)+exp(-x),f,x,4,2);
> }{%
> }
```

$$\mathrm{f}(x) = 625\,\mathrm{f}(x-12) - 611\,\mathrm{f}(x-8) - 13\,\mathrm{f}(x-4),\ f,\ x, [\mathrm{f}(0) = 0,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = -16,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = 0,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 944,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 0,\ \mathrm{f}(9) = 0,\ \mathrm{f}(10) = 1904,\ \mathrm{f}(11) = 0]$$

```
>
> \mapleinline{active}{1d}{`top/ms/linalg/sym`(2,exp(x)+exp(-x),f,x,4,2);
> }{%
> }
```

$$\mathrm{f}(x) = 625\,\mathrm{f}(x-12) - 611\,\mathrm{f}(x-8) - 13\,\mathrm{f}(x-4),\ f,\ x, [\mathrm{f}(0) = 0,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = -16,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = 0,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 944,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 0,\ \mathrm{f}(9) = 0,\ \mathrm{f}(10) = 1904,\ \mathrm{f}(11) = 0]$$

This method is automated with the given function below.

```
> \mapleinline{active}{1d}{`top/ms/linalg/know`(Bot, euler, f, x, 4, 2,
> 16, 2);}{%
> }
```

$$\mathrm{f}(x) = 625\,\mathrm{f}(x-12) - 611\,\mathrm{f}(x-8) - 13\,\mathrm{f}(x-4),\ f,\ x, [\mathrm{f}(0) = 0,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = -16,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = 0,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 944,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 0,\ \mathrm{f}(9) = 0,\ \mathrm{f}(10) = 1904,\ \mathrm{f}(11) = 0]$$

Which all give the same result.

Now determine the linear recurrence relation multisectioned by 4 at 2. Taking advantage of the fact of what the linear recurrence relation most likely is, all that really needs to be done is to determine the initial values, and see if the linear recurrence relation is correct. By looking at the recurrence that for the top multisectioned by 4 at 0 that there are only about 12 terms needed. Calculate the first 32 terms for when the function is multisectioned by 4 at 2, and see if this linear recurrence relation holds.

```
> \mapleinline{active}{1d}{initial :=
> [seq( op([ f(4*i) = F(4*i), f(4*i+1) = 0, f(4*i+2) = 0, f(4*i+3) \newline
> = 0 ]), i=0..8)];}{
> %
> }
```

$$\begin{aligned} \mathit{initial} := [&\mathrm{f}(0) = 16, \mathrm{f}(1) = 0, \mathrm{f}(2) = 0, \mathrm{f}(3) = 0, \mathrm{f}(4) = -48, \mathrm{f}(5) = 0, \mathrm{f}(6) = 0, \\ &\mathrm{f}(7) = 0, \mathrm{f}(8) = -4208, \mathrm{f}(9) = 0, \mathrm{f}(10) = 0, \mathrm{f}(11) = 0, \mathrm{f}(12) = 94032, \\ &\mathrm{f}(13) = 0, \mathrm{f}(14) = 0, \mathrm{f}(15) = 0, \mathrm{f}(16) = 1318672, \mathrm{f}(17) = 0, \mathrm{f}(18) = 0, \\ &\mathrm{f}(19) = 0, \mathrm{f}(20) = -77226288, \mathrm{f}(21) = 0, \mathrm{f}(22) = 0, \mathrm{f}(23) = 0, \\ &\mathrm{f}(24) = 257003152, \mathrm{f}(25) = 0, \mathrm{f}(26) = 0, \mathrm{f}(27) = 0, \mathrm{f}(28) = 44668390992, \\ &\mathrm{f}(29) = 0, \mathrm{f}(30) = 0, \mathrm{f}(31) = 0] \end{aligned}$$

```
> \mapleinline{active}{1d}{`egf/clean`(rec, f, x, initial);}{%
> }
```

$$\begin{aligned} \mathrm{f}(x) = 625\,\mathrm{f}(x-12) - 611\,\mathrm{f}(x-8) - 13\,\mathrm{f}(x-4),\ &f,\ x, [\mathrm{f}(0) = 16, \mathrm{f}(1) = 0, \mathrm{f}(2) = 0, \\ &\mathrm{f}(3) = 0, \mathrm{f}(4) = -48, \mathrm{f}(5) = 0, \mathrm{f}(6) = 0, \mathrm{f}(7) = 0, \mathrm{f}(8) = -4208, \mathrm{f}(9) = 0, \\ &\mathrm{f}(10) = 0, \mathrm{f}(11) = 0] \end{aligned}$$

When cleaning up all of the terms, (getting rid of the terms that can be calculated based on the linear recurrence relation) then fewer than the 32 terms are left. Hence, this linear recurrence relation is most probably correct.

This could have done this with the automated function.

```
> \mapleinline{active}{1d}{`top/ms/know`(rec, Bot, euler, f, x, 4, 0,
> 130);}{%
> }
```

$$\begin{aligned} \mathrm{f}(x) = 625\,\mathrm{f}(x-12) - 611\,\mathrm{f}(x-8) - 13\,\mathrm{f}(x-4),\ &f,\ x, [\mathrm{f}(0) = 16, \mathrm{f}(1) = 0, \mathrm{f}(2) = 0, \\ &\mathrm{f}(3) = 0, \mathrm{f}(4) = -48, \mathrm{f}(5) = 0, \mathrm{f}(6) = 0, \mathrm{f}(7) = 0, \mathrm{f}(8) = -4208, \mathrm{f}(9) = 0, \\ &\mathrm{f}(10) = 0, \mathrm{f}(11) = 0] \end{aligned}$$

Which gives the same result.

As a result of working on this example, a bug in the help for the Euler function in Maple was found. For more information see Appendix D Section D.2.

5.4 Symmetries.

Recall Lemma 3.1 showed that when multisectioning a rational poly-exponential function $\frac{s(x)}{t(x)}$ by m at q then the bottom poly-exponential function could be written as $\prod_{i=0}^{m-1} t(x\omega_m^i)$ and the top as $(s(x)\prod_{i=1}^{m-1} t(x\omega_m^i))_m^q$. Doing this made the simplifying assumption that there were no common factors among the $t(x\omega_m^i)$, as $0 \leq i \leq m-1$. For numerous examples of functions, such as the Bernoulli, Euler, Genocchi and Lucas type II numbers, this assumption is not true. (Some rewriting of the Bernoulli and Genocchi functions are needed for this.) This section explores a small subset of the possible situations where this assumption is not valid, and how, by looking at these common factors, the size of the linear recurrence relation can be reduced for the bottom.

These properties have been exploited before in the standard papers on Bernoulli and Euler numbers [9, 19], but, to the best of my knowledge, have not been written in this type of generality before, nor has there been a formal theory behind what is being done.

To this end, define a symmetry.

Definition 5.1 (Symmetry.) *A poly-exponential function, $s(x)$ has a "*symmetry of order p*" if*

$$s(x\omega_p) = \omega_p^k s(x)$$

for some integer k.

Example 30 *The denominator of the Euler numbers $e^x + e^{-x}$ has a symmetry of order 2.*

Note 5.1 *If $s(x)$ has a symmetry of order p, say $s(x\omega_p) = \omega_p^k s(x)$, then $s(x) = s_p^k(x)$.*

If a symmetry of a function is known, then it can be taken advantage of to find a smaller form for the linear recurrence relation of the denominator of a multisectioned rational poly-exponential function.

Theorem 5.1 *Let $f(x) = \frac{s(x)}{t(x)}$, where $s(x)$, $t(x) \in \mathcal{P}$, and let $t(x)$ have a symmetry of order p, say $t(x\omega_p) = \omega_p^k t(x)$. Further, let $p|m$. Then a recursion formula can be found for the coefficients of x^{mi+q} of the exponential generating function of $f(x)$ that depends only on the coefficients of x^{mj+q}, for $j < i$, and two lacunary recurrence relations, where the lacunary recurrence relation for the denominator has a smaller upper bound on its length than that of Theorem 3.3.*

Proof: Now

$$f_m^q(x) = \frac{1}{m}\sum_{i=0}^{m-1} \frac{\omega_m^{-iq} s(x\omega_m^i)}{t(x\omega_m^i)} = \frac{1}{m}\sum_{i=0}^{m/p-1}\sum_{j=0}^{p-1} \frac{\omega_m^{-(i+j(m/p))q} s(x\omega_m^{i+j(m/p)})}{t(x\omega_m^{i+j(m/p)})}$$

$$
\begin{aligned}
&= \frac{1}{m}\sum_{i=0}^{m/p-1}\sum_{j=0}^{p-1}\frac{\omega_m^{-iq}\omega_p^{-jq}s(x\omega_m^i\omega_p^j)}{t(x\omega_m^i\omega_p^j)} = \frac{1}{m}\sum_{i=0}^{m/p-1}\sum_{j=0}^{p-1}\frac{\omega_m^{-iq}\omega_p^{-jq}s(x\omega_m^i\omega_p^j)}{\omega_p^{jk}t(x\omega_m^i)}\\
&= \frac{1}{m}\sum_{i=0}^{m/p-1}\sum_{j=0}^{p-1}\frac{\omega_m^{-iq}\omega_p^{-jq-jk}s(x\omega_m^i\omega_p^j)}{t(x\omega_m^i)}\\
&= \frac{1}{m}\sum_{j=0}^{p-1}\sum_{i=0}^{m/p-1}\frac{\omega_m^{-iq}\omega_p^{-jq-jk}s(x\omega_m^i\omega_p^j)\prod_{l=1}^{m/p-1}t(x\omega_m^l)}{\prod_{l=0}^{m/p-1}t(x\omega_m^l)}\\
&= \frac{\frac{1}{m}\sum_{j=0}^{p-1}(\sum_{i=0}^{m/p-1}\omega_m^{-iq}\omega_p^{-jq-jk}s(x\omega_m^i\omega_p^j)\prod_{l=1}^{m/p-1}t(x\omega_m^l))}{\prod_{l=0}^{m/p-1}t(x\omega_m^l)}
\end{aligned}
$$

By observing that $t(x) = t_p^k(x)$ a careful analysis shows that $\prod_{l=0}^{m/p-1}t(x\omega_m^l) = (\prod_{l=0}^{m/p-1}\ t(x\ \omega_m^l))_m^{km/p}$. Denote this $r_m^{km/p}(x)$. Further, letting $r_m^{km/p}(x) = \sum_{j=0}^{\infty} d_j\frac{x^j}{j!}$, $f(x) = \sum_{i=0}^{\infty} c_i\frac{x^i}{i!}$ and the numerator as $\sum_{i=0}^{\infty} b_i\frac{x^i}{i!}$ gives, from Equation 5.1 that $b_i = 0$ unless $i \equiv q + m/pk \pmod m$. So both the numerator and the denominator are lacunary recurrence relation.

Further, from Lemma 2.5 the denominator $r_m^{mk/p}(x)$ has the property that $deg^P(r_m^{km/p}(x)) \leq deg^P(t(x))^{m/p}$, which is better than the upper bound in Theorem 3.3 of $deg^P(t(x))^m$.

■

Example 31 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

Consider the example of the Euler numbers, given by the exponential generating function of $\frac{2}{e^x+e^{(-x)}}$. *The denominator of this has a symmetry of order 2. Below are two methods to compute the recurrence for the denominator, when multisectioned by 8. The first method does not take into account the symmetry, where as the second does. Also demonstrated in this section is the code 'egf/strip', which will strip away the useless zeros.*

```
> \mapleinline{active}{1d}{botNoSym :=

```
> \mapleinline{active}{1d}{topSym :=
> `egf/strip`(`top/ms/linalg/know`(BotSym, euler, f, x, 8, 0, 30,
> 2),8,0);}{%
> }
```

$topSym :=$

$\mathrm{f}(x) = -6561\,\mathrm{f}(x-32) + 7571428\,\mathrm{f}(x-24) - 45798\,\mathrm{f}(x-16) + 1188\,\mathrm{f}(x-8),$

$f,\ x,\ [\mathrm{f}(0) = 16,\ \mathrm{f}(8) = 4752,\ \mathrm{f}(16) = 5278992,\ \mathrm{f}(24) = 6144667536]$

So both the top and the bottom recurrences are smaller when the symmetries of the denominator are taken into account.

5.5 Computing over the integers.

Recall in Section 4.6 that all of the calculations of the coefficients of the exponential generating function of a poly-exponential function can be calculated over the integers if certain criteria are met. Here, a similar result holds, given certain criteria all of the calculations of the coefficients of the exponential generating function of a rational poly-exponential function can be done over the integers.

Consider the equations in Theorem 3.1 again. This gives the following lemma.

Lemma 5.2 *If $f(x) = \frac{s(x)}{t(x)} = \sum_{i=0}^{\infty} c_i \frac{x^i}{i!}$ where $s(x)$, $t(x) \in \mathcal{P}$, with $s(x) = \sum_{i=0}^{\infty} b_i \frac{x^i}{i!}$ and $t(x) = \sum_{j=0}^{\infty} d_j \frac{x^j}{j!}$ such that $d_0 \neq 0$, where d_i, $b_i \in \mathbb{Q}$, and $P^s(x)$, $P^t(x) \in \mathbb{Q}[x]$ then all of the calculations of the c_i can be done over the integers.*

Proof: A few observations are needed to see this.

Without loss of generality, let $m = 1$ and $q = 0$. Based on the equation of Theorem 3.1 the following equation holds:

$$c_{k-s} = \frac{1}{\binom{k}{s} d_s}(b_k - \sum_{j=s+1}^{k} \binom{i}{j} d_j c_{i-j})$$

Hence, if b_i, $d_i \in \mathbb{Z}$ for all i, $s = 0$, and $d_s = \pm 1$ then $c_i \in \mathbb{Z}$. (This is in fact the case with the Euler numbers.)

Now if $s = 0$, and $d_0 \neq \pm 1$ and $d_0 \in \mathbb{Z}$, then instead calculate $c_i^* = c_i d_0^i$. Notice that:

$$\begin{aligned} d_0^i c_i &= \frac{d_0^i}{d_0}(b_i - \sum_{j=1}^{i} \binom{i}{j} d_j c_{i-j}) \\ c_i^* &= (d_0^{i-1} b_i - \sum_{j=1}^{i} \binom{i}{j} d_0^{i-1} d_j c_{i-j}) \\ c_i^* &= (d_0^{i-1} b_i - \sum_{j=1}^{i} \binom{i}{j} d_0^{j-1} d_j (d_0^{i-j} c_{i-j})) \end{aligned}$$

$$c_i^* = (d_0^{i-1}b_i - \sum_{j=1}^{i}\binom{i}{j}d_0^j d_j c_{i-j}^*).$$

which will remain in the integers.

Further, if b_i and d_i come from functions $s(x)$ and $t(x)$, both of which satisfy all of the conditions of Lemma 4.5, namely that $P^s(x)$, $P^t(x) \in \mathbb{Q}[x]$, where $s(x)$, $t(x) \in \mathcal{P}^{\mathbb{C},\mathbb{Q}}$, then by the c_n^* can be altered so that all the calculations are still done over the integers.

Here take e_b and f_b as the d and c in the proof of Lemma 4.5, as it applies to b_i, and set $\bar{e}_i = b_i e_b^i f_b$. Similarly set $\bar{d}_i = d_i e_d^i f_d$, where e_d and f_d have similar definitions. Further assume that $f_d = 1$.

So now consider calculating $\bar{c}_i = c_i^* \mathrm{lcm}(e_b, e_d)^n \mathrm{lcm}(f_b, f_d)$ For ease of notation, denote $e = \mathrm{lcm}(e_b, e_d)$ and f similarly. For ease of notation, denote $\bar{e}_b = \frac{e}{e_d}$, and define $\bar{e}_d$, $\bar{f}_b$ and $\bar{f}_d$ similarly.

Then:

$$\begin{aligned}
e^i f c_i^* &= e^i f(d_0^i b_i - \sum_{j=1}^{i}\binom{i}{j}d_0^j d_j c_{i-j}^*) \\
\bar{c}_i &= (d_0^i e^i f b_i - \sum_{j=1}^{i}\binom{i}{j}d_0^j e^i f d_j c_{i-j}^*) \\
\bar{c}_i &= (d_0^i (\bar{e}_b)^i \bar{f}_b \bar{b}_i - \sum_{j=1}^{i}\binom{i}{j}d_0^j e^j d_j f e^{i-j} c_{i-j}^*) \\
\bar{c}_i &= (d_0^i (\bar{e}_b)^i \bar{f}_b \bar{b}_i - \sum_{j=1}^{i}\binom{i}{j}d_0^j (\bar{e}_d)^j \bar{d}_j \bar{c}_{i-j}).
\end{aligned}$$

Where finally everything is calculated over the integers.

■

Corollary 10 *The Euler numbers and the Genocchi numbers are integers. Moreover the recursion formula and lacunary recursion formula used to compute the Euler and Genocchi numbers are also over the integers.*

5.6 Techniques for smaller linear recurrence relations.

As before, in Section 4.7, polynomials can be factored from a poly-exponential function, to make the linear recurrence relations easier to solve. Write $t(x) = p(x)\bar{t}(x)$, the denominator of some

rational poly-exponential function, for $t(x)$, $\bar{t}(x) \in \mathcal{P}$ and $p(x)$ a polynomials. Then notice, that for calculating the denominator, then a factor of $\prod_{i=0}^{m-1} p(x\omega_m^i)$ can be pulled out.

A similar process for the top linear recurrence relation can be done, but some extra care need be taken.

Example 32 *Consider the following example in Maple.*

```
> \mapleinline{active}{1d}{with(MS):}{%
> }
```

This example looks at the Bernoulli numbers. But for this example, modify the equation, so that it can be demonstrated how common factors of polynomials can be taken out. So examine $\frac{x^2+x}{x\,e^x-x+e^x-1} = \frac{\sum_{i=0}^{\infty} \frac{b_i\,x^i}{i!}}{\sum_{j=0}^{\infty} \frac{d_j\,x^j}{j!}}$. *Now multisection this by 4 at 2.*

So the bottom can be

$\prod_{i=0}^{3} (x\,{\omega_4}^i + 1)\,(e^{(x\,{\omega_4}^i)} - 1) = (\prod_{i=0}^{3} (x\,{\omega_4}^i - 1))\,(\prod_{i=0}^{3} (e^{(x\,{\omega_4}^i)} - 1))$. *So there is a polynomial that can be factored out. After this simply work out the normal linear recurrence relation for the bottom. This could have done automatically by:*

```
> \mapleinline{active}{1d}{`bottom/ms/factor`((x+1)*(exp(x)-1),f,x,4);}{
> %
> }
```

$$\mathrm{f}(x) = 4\,\mathrm{f}(x-8) - 3\,\mathrm{f}(x-4),\ f,\ x,\ [\ \mathrm{f}(0) = 0,\ \mathrm{f}(1) = 0,\ \mathrm{f}(2) = 0,\ \mathrm{f}(3) = 0,\ \mathrm{f}(4) = -24,\ \mathrm{f}(5) = 0,\ \mathrm{f}(6) = 0,\ \mathrm{f}(7) = 0,\ \mathrm{f}(8) = 56]\ ,\ -x^4 + 1$$

5.7 Conclusions.

The conclusion that are listed in this section are conclusions as to which implemenations are faster, the conclusions are not for which methods are faster. This is because Maple combines a relatively sophisticate code to deal with certain problems, and some very naive methods for others. Hence the implementation of any method in this chapter can be greatly impacted on by the underlying methods used by Maple for certain problems, (for examples, solving linear systems of equations, how it performs resultants, etc).

5.7.1 Denominator.

The different methods that are possible for determining the bottom linear recurrence relation of a multisectioned rational poly-exponential function are:

1. naive method, (Chapter 3, Lemma 3.1),
2. the recurrence polynomial with resultants (Section 5.1),
3. linear algebra, with symbolic differentiation (Chapter 4, Section 4.3),
4. linear algebra, fast Fourier transform method 1, (Subsection 5.2.1),
5. linear algebra, fast Fourier transform method 2, (Subsection 5.2.2),
6. looking at symmetries of the denominator, (Section 5.4),
7. computing over the integers, (Section 5.5),
8. factoring polynomials out, in combination with any of the above, (Section 5.6).

- Here, the use of some knowledge (of how large the linear recurrence relation will be) is of great use to method 3 and 4. For example, without this knowledge, trying to determine the bottom linear recurrence relation of the Euler numbers when multisectioned by 8 takes over 60 seconds and 10.65 for methods 3 and 4 respectively, where as with this knowledge this take 4.58 and 3.86 seconds.
- The naive method, method 1, although the easiest to implement, is not very efficient taking 11 seconds to do this problem, whereas method 2 and 5 take 2.72 seconds and 1.42 seconds respectively.
- If the same problem is looked at, but multisectioning by 9 instead of by 8, then of all the methods from 1 to 5, with the exception of method 5, take too long to be practical (even with knowledge).

- Method 5 takes about 126.9 seconds.
- By taking into account a symmetry (method 6) of order p, the existing methods can be expected to be able to multisection by a factor of p more. For example, with the Euler numbers, instead of having a upper bound of 12 for multisectioning, an upper bound of about 24 is achieved. (The Euler numbers have a symmetry of order 2 in the denominator.)
- Methods 7 and 8 are of little interest, as rarely do functions meet the criteria that would be required for these methods to be of use.
- (These times were done on "bb" (2 180 MHZ IP27 Processors, Main memory size, 256 Mbytes), using the Maple interpretation of a CPU second.)

5.7.2 Numerator.

The different methods that are possible for determining the top linear recurrence relation of a multisectioned rational poly-exponential function are:

1. naive method, (Chapter 3, Lemma 3.1),
2. the recurrence polynomial and resultants (Section 5.1),
3. linear algebra with symbolic differentiation, (Chapter 4, Section 4.3),
4. linear algebra, fast Fourier transform, (Subsection 5.2),
5. factoring polynomials out, in combination with any of the above, (Section 5.6),
6. using information about the bottom linear recurrence relation. (Section 5.3).

- Again the problem of the Euler numbers was looked at - trying to determine the top linear recurrence relation.
- An examination of the times gives that method 6 is by far the best.
- When multisectioning by 8 at 2, the other methods, in order take;
  - with method 1, 201.733 seconds,
  - with method 2, over 1000 seconds,
  - with method 3, over 1000 seconds,
  - with method 3, 55.62 (with knowledge),
  - with method 4, over 1000 seconds, and

  - with method 4, 494.15 (with knowledge).

- This is in comparison to method 6, which took only 30.467 seconds.
- If the denominator had a symmetry of order p, then it becomes possible to multisection by a factor of p more. For example, instead of having an upper bound of multisectioning by 12 for the Euler numbers, the upper bound becomes 24. (The Euler numbers have a symmetry of order 2 in the denominator.)
- (These times were done on "bb" (2 180 MHZ IP27 Processors, Main memory size, 256 Mbytes), using the Maple interpretation of a CPU second.)

Chapter 6

Doing the calculation.

When doing calculations, there are numerous things that can be done at the programming level to speed up the calculations. The first two sections, Sections 6.1 and 6.2 talk about methods where concurrence is exploited. The third section, Section 6.3 discusses the largest problems at the time of submission of this thesis that these techniques have been used for. The last section, Section 6.4 discusses some methods of validating the correctness of the results.

The methods in this thesis so far have allowed the calculation of terms of rational poly-exponential functions to be run on m different machines by multisectioning by m. After the problem is divided up by multisectioning, to m different computers, no communication is needed between these computers. The method of multisectioning is limited by the size m, as multisectioning by large m quickly becomes impractical. After multisectioning by m, the computation can only be done on at most m different machines.

This does not mean though that only m different processors can be used. By allowing communication between processors, the problem can be broken up further. The basis of this idea is that to calculate the k-th number, the previous $k-1$ numbers are needed, but not all of them need to be known when the computation is started. When calculating the k-th number, have n other processors working out the $k-1$, $k-2$, ..., $k-n$ numbers. So long as this information is available by the end of the computation there is no problem. Many of the techniques for concurrency used here are described in Snow, [27].

There are two different techniques described here. The first as described in Section 6.1 is in the case with n processors, where all the processors are the same speed (i.e. a dedicated multi-processor machine). This type of problem does not need to worry about load balancing.

The second case, as described in Section 6.2 is that with multiple CPU's, not all of which are

the same speed (i.e. a cluster of PCs with different clock speeds). To properly take advantage of the CPUs to their maximum efficiency, more complicated code need be written that will attempt to balance the load. Failing to do this will lead to a computation on n CPU's that is only n times faster than the slowest processor.

6.1 Load balanced code.

6.1.1 Overview.

Assume there are n processors, all of which are the same speed, and the calculations are of well-distributed difficulty (as is the case with rational poly-exponential function), then give every n-th problem to each CPU. At the end of each calculation, the results are communicated to the other processors.

For this problem, the master/slave paradigm is used, as it reduces the number of communication channels that are required. The "*process*" package in Maple was used, which utilized the Unix commands of fork, pipe, wait, block, etc. As a result in implementing this, and preparing the worksheets, numerous bugs in the "*process*" package in Maple were found. For more information see Appendix D Sections D.3, D.4, and D.5.

6.1.2 Details of algorithm.

Assume the program is run with n slaves. Using the master/slave paradigm, have the master tell the slave which calculation to start with, and how large an increment to use. So slave 1 is told to calculate b_1, b_{1+n}, b_{1+2n}, ..., up to some maximum, slave 2 will calculate b_2, b_{2+n}, ..., etc. The slave, when it has done a calculation will tell the master. The master then passes this information on to all of the other $n-1$ slaves.

When the slave needs information, it simply waits for the master to provide this information. This is one of the reasons why in this model it is very important that the slaves are the same speed. If one slaves is slower than the other slaves, then all of these slaves will constantly be waiting for this one slave to complete its calculation before they can continue.

This is summarized below in Figure 6.1.

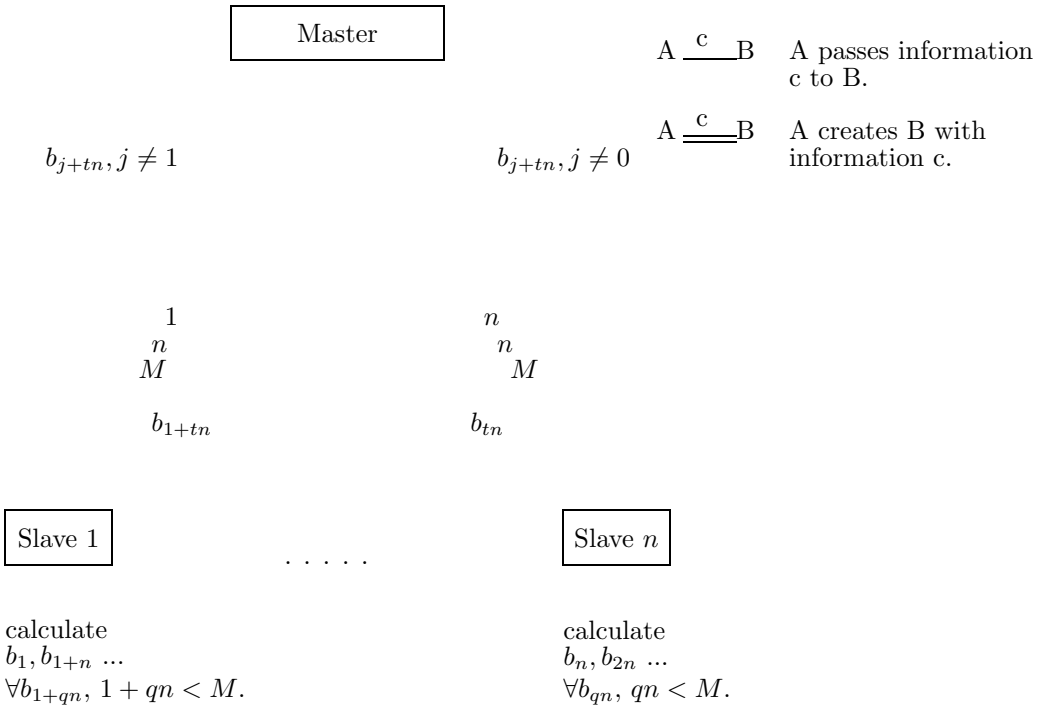

Figure 6.1: Load balanced master/slave diagram.

For more information, see Appendix A, Subsection A.7.2.

Example 33 *Consider the problem of calculating the Genocchi numbers, defined by the exponential generating function* $\frac{2x}{e^x+1}$. *For more information about the Maple code, see Appendix A. For the Maple code see Appendix E. The Maple code and help files (including information about syntax) are available on the web at [1]. For this, consider the calculation given that the recursion formula is multisectioned by 2 at 0. Further assume that there are two slaves (i.e. a 2 CPU machine).*

6.2 Load balancing code.

6.2.1 Overview.

If the system does not have balanced CPU power, then the code must balance the load.

Again this method uses the master/slave paradigm, although refinements to this have been made which will be discussed later. Say at some time in the calculation there are k processes running to

calculate b_n, b_{n+1}, ..., b_{n+k}. If on the computation $n+s$, $(1 \leq s \leq k)$, the processor can do no more calculations until the information of the value of b_n is provided to it. Instead of waiting (as would have been done in Section 6.1), this process will ask for more work. It will then start calculating b_{n+k+1}, and will get back to the calculations of b_{n+s} when the necessary information is available.

For technical reasons it was decided to have an intermediate process, the overseer, between the master and the slave. This overseer's job is to provide communication between the master and the slave, as well as deciding when a slave can no longer continue working (as the information needed is not available yet), and start a new calculation.

6.2.2 Details of algorithm.

There is one overseer per machine, and one master.

The master will wait until it receives a "need work" message from an overseer. At this point, the master will send the overseer an index of something to be computed.

The overseer will first delegate the work to some slave (if creating the slave, the overseer will also tell the slave everything that the overseer knows).

The slave upon creation/call will start its calculation of the index i given to it. If the slave gets to a point where it needs more information, it will ask the overseer. Upon completion, it will send back the calculation to the overseer and await new work.

The overseer, when it gets a request for information from a slave, will send the information, if it is known. If the information is not known then the overseer will send a message to the master asking for more work. The overseer will keep track that this slave is waiting for this information, and when the overseer acquires this information, it will provide this information to the slave. When the overseer receives the result of a calculation, it will send the result of this calculation to the master. The overseer will ask for work if it has no slaves working (slaves get in each other's way).

The overseer will constantly be waiting for information from the master. The master, when it has a new calculation, will send the information to the other overseers.

This is summarized below in Figure 6.2.

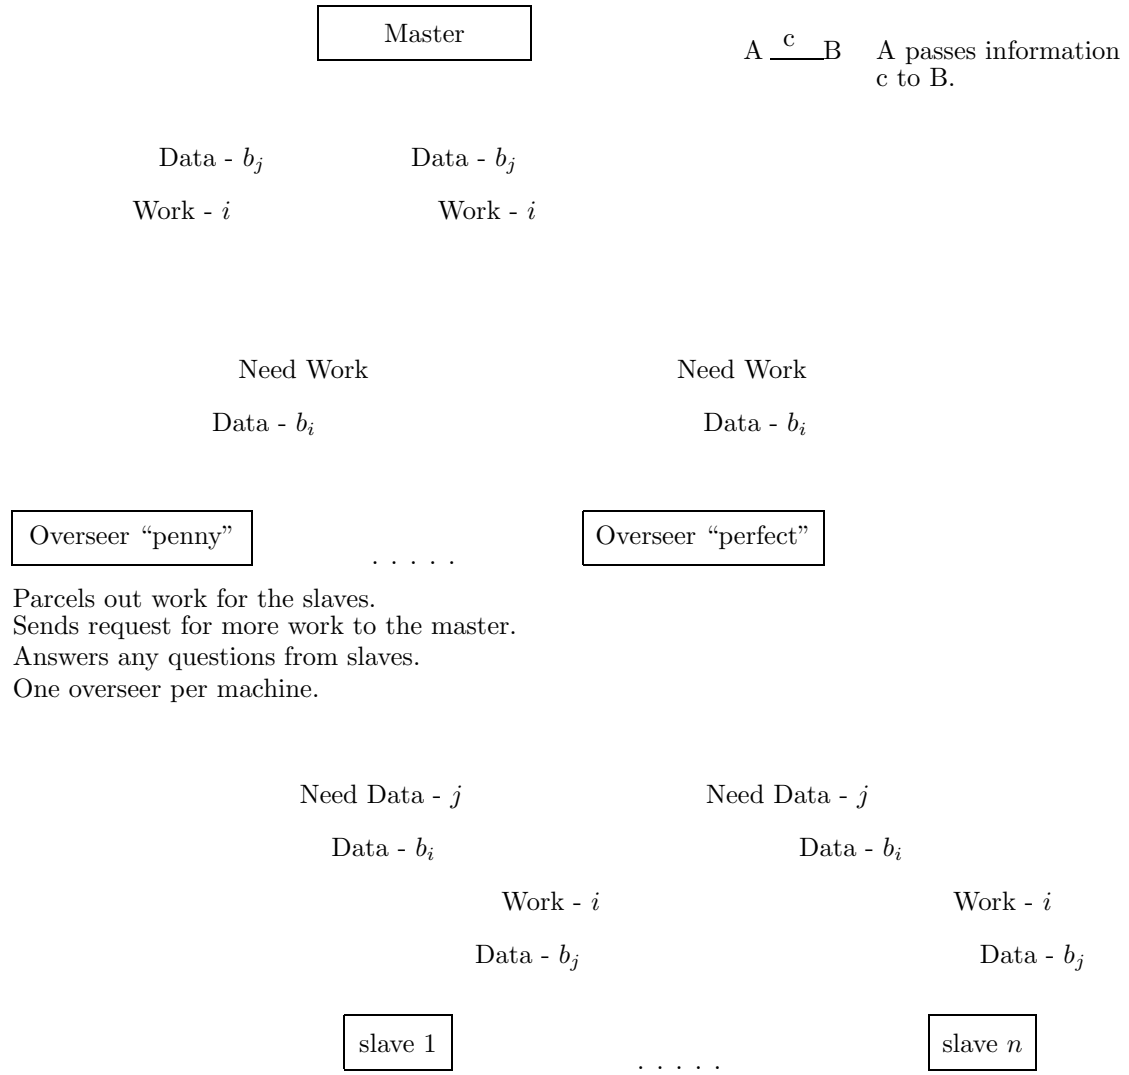

Figure 6.2: Load balancing master/overseer/slave diagram.

Example 34 *Consider the following example. The first part is the master, which shows what the*

master is asking the overseer to do. The second and third parts are the two overseers, which demonstrates their side of the conversation.

1. *The master,*

6.3 A large calculation.

As of submitting this thesis, the following upper bounds of calculations have been completed, as shown in the Table 6.1. These calculations are available on the web at [1].

	Bernoulli numbers	Euler numbers	Genocchi numbers	Lucas numbers type II
Bottom recurrence	20	24	20	20
Top recurrence	18	16	20	14
Largest number	35 298	8 500	8 700	5 404

Table 6.1: Upper bounds of completed calculations.

The typical bottle neck for a calculation is with the linear algebra. If a proper Toeplitz matrix solver were used, one would predict that the time to perform a calculation would be much improved. For example, to calculate the denominator of the Bernoulli numbers, multisectioned by 20, it requires only 7 minutes 15 seconds to determine the underlying matrix; the rest of the 2.6 days is to find the solution associated with this 90×90 matrix. (The time here represents a CPU second as measured by Maple on "penny", CPU: MIPS R10000 Processor Chip Revision: 2.7.)

Similarly, when multisectioning the numerator of the Bernoulli numbers by 18 it takes 69.6 seconds to determine the underlying 24×24 matrix and the remained of the 116.35 seconds to solve this linear algebra problem. (The time here represents a CPU second as measured by Maple on "pecos", CPU: MIPS R10000 Processor Chip Revision: 2.7.)

Next consider a large calculation of the Bernoulli numbers, say the first 1 800 Bernoulli numbers. It takes 30.56 seconds to perform this calculation, using recurrences that have been multisectioned by 18. (Hence only $\frac{1}{9}$-th of the information is calculated.) In contrast, the normal recurrence (which by the nature of the Bernoulli numbers is multisectioned by 2) takes 527.61 seconds. Thus there is a speed up of a factor of $\frac{527.61}{30.56 \times 9} = 1.92$ by multisectioning by 18. (Here, the extra factor of 9 comes

in because one would have to perform 9 different calculations to get all of the information using the multisectioned method.) This demonstrates that these multisectioned recursion formulae, even when used in serial environment upon a single computer, represent a significant speed up over the traditional recursion formula.

If the multi-processor method described in Section 6.1 is used, with 5 slaves, with the recurrences that has been multisectioned by 18, then it takes on average 6.20 seconds for each slave. (The master takes an insignificant amount of processor time; taking less than half a second.) So the total processor time is bounded above by 31.5 seconds. This indicates that about 3% of the processors time, when using a multi-processor method, goes towards the overhead of communication. (In actual fact, this is too high an estimate when doing a large calculation, but relatively little numerical data is available at this time.) So these calculations can advantageously exploit parallel computing techniques. (The time here represents a CPU second as measured by Maple on "manyjars", 8 250 MHZ IP27 Processors CPU: MIPS R10000 Processor Chip Revision: 3.4.)

6.4 Validating results.

When doing large calculations such as these, some methods to test if the calculations are done correctly are needed, both for confidence and as a useful aid to debugging.

6.4.1 Validating the Bernoulli numbers.

To test if the calculation for the Bernoulli numbers is done correctly, the following theorem of von Staudt [17] is used.

Theorem 6.1 (Clausen - von Staudt Theorem) *Let B_{2k} be the $2k$-th Bernoulli number. If $k \geq 1$, then*

$$(-1)^k B_{2k} \equiv \sum \frac{1}{p} \pmod 1$$

the summation being extended over the primes p such that $(p-1)|2k$.

From which it follows that:

Corollary 11 *If $k \geq 1$, then the denominator of $(-1)^k B_{2k}$, where B_{2k} is the $2k$-th Bernoulli number is equal to the denominator of $\sum \frac{1}{p}$ the summation being extended over the primes p such that $(p-1)|2k$.*

Example 35 *Thus, to test if the 10 008-th Bernoulli number, calculated as*

$$\frac{N}{3262901044146573454170}$$

where N is a 27716 digit number, is correct, the denominator need only be checked.

Calculate $(-1)^k \sum \frac{1}{p}$ for $(p-1)|2k$ where $2k = 10008$ yields:

$$\frac{4402843531608629672099}{3262901044146573454170}$$

Noticing that the denominator of these two numbers is the same is a good indication that the calculation was done correctly.

6.4.2 Validating the Euler numbers.

To test if the calculation for the Euler numbers is done correctly, the following theorem of Glaisher [14] is used.

Theorem 6.2 *Let E_{2k} be the $2k$-th Euler number. For $k > 0$, and any $r > 0$:*

$$E_{2k} \equiv (-1)^k 2[1^{2k} - 3^{2k} + 5^{2k} - .... + (-1)^{1/2(r-2)}(r-2)^{2k}] \pmod{r}.$$

Combining this with Fermat's little theorem gives that:

Theorem 6.3 *Let p be prime. If $2k \equiv 2j \pmod{p-1}$ and E_{2k}, E_{2j} the $2k$-th and $2j$-th Euler numbers respectively then*

$$E_{2k} \equiv E_{2j} \pmod{p}.$$

Example 36 *Thus, to test if the 8 000-th Euler number, calculated as N where N is a 26 184 digit number, is correct, look at N modulo a number of small primes.*

$$\begin{aligned} N &\equiv 2 \pmod{3}, \\ N &\equiv 0 \pmod{5}, \\ N &\equiv 6 \pmod{7}, \\ N &\equiv 2 \pmod{11}, \\ N &\equiv 7 \pmod{13}, \\ N &\equiv 0 \pmod{17}. \end{aligned}$$

Notice that

$$\begin{aligned}
8000 &\equiv 2 \pmod 2 \text{ and } E_2 \equiv 2 \pmod 3,\\
8000 &\equiv 4 \pmod 4 \text{ and } E_4 \equiv 0 \pmod 5,\\
8000 &\equiv 2 \pmod 6 \text{ and } E_2 \equiv 6 \pmod 7,\\
8000 &\equiv 10 \pmod{10} \text{ and } E_{10} \equiv 2 \pmod{11},\\
8000 &\equiv 8 \pmod{12} \text{ and } E_8 \equiv 7 \pmod{13},\\
8000 &\equiv 16 \pmod{16} \text{ and } E_{16} \equiv 0 \pmod{17}.
\end{aligned}$$

Thus N has the correct residues to be the 8 000-th Euler number, and it passes the test.

Chapter 7

Conclusion.

This thesis highlights the complex issues that arise when working in an environment, such as Maple, where the code is not all written by the principle author, or to an agreed standard. One problem in such a system is the necessary reliance on a mixture of code, some of which is very sophisticated, some of which is more naive, some of which is written for a very general problem, and some of which has been tailored to a specific problem. Hence the caveat in Sections 4.8 and 5.7 that the conclusions therein were as to which implementation was fastest, and not to which method was fastest. Another problem is in the debugging of code, where the underlying problem being tracked down in the debugging process might not be within the code written, but instead in the system being used. This could be either an incompatibility of the different functions within the system, a misuse of an algorithm being offered by the system, or an actual problem with the algorithm within the system. Hence the inclusion of Appendix D for bugs or weakness found in Maple.

Some of the achievements of this thesis include implementations of algorithms to multisection rational poly-exponential functions. The new recursion formulae, that these algorithms yield, represent an improvement over the traditional methods of computing Bernoulli numbers, Euler numbers, and other rational poly-exponential functions. Traditionally multisectioning has been looked at in the narrow setting to its use in calculating Bernoulli numbers and Euler numbers. Here, the investigation was done in a more general setting; allowing a wider applicability of the multisectioning process.

Appendix A

Outline of code.

This code can be found on my homepage [1]. It can also be found in Appendix E.

The appendix is laid into five sections. The first section will look at code for manipulating poly-exponential functions. Section A.2 will look at code for manipulating exponential generating functions. Section A.3 looks at the code to determine the metrics of different poly-exponential functions. Section A.4 looks at the code to convert poly-exponential functions to exponential generating functions and back, as well as code to convert linear recurrence relation to the recurrence polynomial and back. Then Section A.5 will look at code for manipulating the bottom linear recurrence relation of a rational poly-exponential function. After which Section A.6 will look at code for manipulating the top linear recurrence relation of a rational poly-exponential function. Lastly Section A.7 will deal with code to do the calculation, after the linear recurrence relations are know.

Within each section, a brief description of a piece of code, the command name, file where it can be found, which example in the thesis demonstrates how it is used with a page reference, the expected input and output of the command, and a reference to which theorems or definitions it automates.

A.1 Code for poly-exponential functions.

A.1.1 Naive method.

This will take a poly-exponential function and multisection it using the naive method, using the definition of multisectioning as given in Definition 2.6.

- file: Pe,

- command: ‘pe/ms/naive‘,
- examples: Example 5 pp. 17,
- input: exponential generating function, m,
- output: exponential generating function multisectioned by m,
- reference: Lemma 2.1, Definition 2.6 and Theorem 2.1.

A.1.2 Linear algebra and symbolic differentiation method.

This method will take a poly-exponential function and multisection it by using symbolic differentiation after which point the method will use linear algebra.

- file: Pe,
- command: ‘pe/ms/linalg/sym‘,
- examples: Example 22 pp. 53,
- input: exponential generating function, $(M, opt), m, q$,
- output: exponential generating function of the poly-exponential function multisectioned by m at q,
- reference: Section 4.3.

A.2 Code for exponential generating functions.

A.2.1 Making procedure from an exponential generating function.

This will turn a linear recurrence relation into a procedure, which will calculate any particular value of the linear recurrence relation.

- file: Egf,
- command: ‘egf/makeproc‘,
- examples: Example 21 pp. 51, Example 24 pp. 60, Example 25 pp. 61, Example 28 pp. 71, Example 29 pp. 75, Example 33 pp. 91, and Example 34 pp. 95,
- input: exponential generating function,
- output: Function.

A.2.2 Stripping zeros from exponential generating function.

This will take a multisectioned exponential generating function, and strip out the terms that are known to be zero.

- file: Egf,
- command: ‘egf/strip‘
- examples: Example 31 pp. 79,
- input: exponential generating function, m, q,
- output: exponential generating function.

A.2.3 Naive method to multisection.

This will take an exponential generating function and multisection it using the naive method as given in Definition 2.6.

- file: Egf,
- command: ‘egf/ms/naive‘,
- examples: Example 5 pp. 17,
- input: exponential generating function, m, q
- output: exponential generating function multisectioned by m, at q,
- reference: Lemma 2.1, Definition 2.6 and Theorem 2.1.

A.2.4 Recurrence polynomial method.

This will take an exponential generating function and multisection it by multiplication of its recurrence polynomial.

- file: Egf,
- command: ‘egf/ms/rec‘,
- examples: Example 19 pp. 46,

- input: exponential generating function, m, q,
- output: exponential generating function multisectioned by m, at q,
- reference: Section 4.1.

A.2.5 Recurrence polynomial via resultants method.

This will take an exponential generating function and multisection it by using resultants.

- file: Egf,
- command: 'egf/ms/result',
- examples: Example 20 pp. 49,
- input: exponential generating function, m, q,
- output: exponential generating function multisectioned by m, at q,
- reference: Section 4.2.

A.2.6 Linear algebra method.

This will take the exponential generating function and use linear algebra to multisection the linear recurrence relation.

- file: Egf,
- command: 'egf/ms/linalg',
- examples: Example 21 pp. 51,
- input: exponential generating function, M, m, q,
- output: exponential generating function multisectioned by m, at q,
- reference: Section 4.3.

A.2.7 Compression method.

This will use compression techniques to multisection the linear recurrence relation of an exponential generating function.

- file: Egf,
- command: ‘egf/ms/compress‘,
- examples: Example 23 pp. 57,
- input: exponential generating function, m, q,
- output: exponential generating function multisectioned by m, at q,
- reference: Section 4.5.

A.3 Metrics.

A.3.1 Metric deg^d.

This is the code that will return $deg^d(s(x))$ given input $s(x)$.

- file: Metric,
- command: ‘egf/metric/d‘, ‘pe/metric/d‘,
- examples: Example 8 pp. 20,
- input: exponential generating function or poly-exponential function,
- output: $deg^d(s(x))$,
- reference: Definition 2.7.

A.3.2 Metric deg^P.

This is the code that will return $deg^P(s(x))$ given input $s(x)$.

- file: Metric,
- command: ‘egf/metric/P‘, ‘pe/metric/P‘,

- examples: Example 8 pp. 20,
- input: exponential generating function or poly-exponential function,
- output: $deg^P(s(x))$,
- reference: Definition 2.7.

A.4 Conversions.

A.4.1 Convert to the recurrence polynomial.

This will convert a linear recurrence relation to a recurrence polynomial.

- file: Convert,
- command: 'convert_poly',
- examples: Example 3 pp. 8,
- input: linear recurrence relation,
- output: recurrence polynomial,
- reference: Definition 2.2.

A.4.2 Convert to the linear recurrence relation.

This will convert a recurrence polynomial to a linear recurrence relation.

- file: Convert,
- command: 'convert_rec',
- examples: Example 3 pp. 8,
- input: recurrence polynomial,
- output: linear recurrence relation,
- reference: Definition 2.2.

A.4.3 Convert to the exponential generating function.

This will convert a poly-exponential function into an exponential generating function so that the linear recurrence relation is easily read.

- file: Convert,
- command: ‘convert_egf‘,
- examples: Example 1 pp. 7,
- input: poly-exponential function,
- output: exponential generating function,
- reference: Lemma 2.1 and Theorem 2.1.

A.4.4 Convert to the exponential generating function.

This will convert an exponential generating function where the linear recurrence relation is easily readable into a poly-exponential function.

- file: Convert,
- command: ‘convert_pe‘,
- examples: Example 2 pp. 8,
- input: exponential generating function,
- output: poly-exponential function,
- reference: Theorem 2.1.

A.5 Bottom linear recurrence relation.

A.5.1 Naive method.

This code will naively use the formula in Lemma 3.1 to determine the bottom linear recurrence relation.

- file: Bottom,

- command: ‘bottom/ms/naive‘,
- examples: Example 13 pp. 30,
- input: poly-exponential function $t(x)$, m,
- output: exponential generating function of $\prod_{i=1}^{m} t(x\omega_m^i)$,
- reference: Lemma 3.1.

A.5.2 Fast Fourier transform and linear algebra.

Uses a combination of linear algebra and fast polynomial multiplication to determine the bottom linear recurrence relation.

- file: Bottom,
- command: ‘bottom/ms/linalg/fft‘, ‘bottom/ms/linalg/fft2‘,
- examples: Example 27 pp. 68 and Example 28 pp. 71,
- input: exponential generating function $t(x)$, M, m,
- output: exponential generating function of $\prod_{i=1}^{m} t(x\omega_m^i)$,
- reference: Section 5.2.

A.5.3 Symbolic differentiation and linear algebra.

This method uses a combination of symbolic differentiation and linear algebra.

- file: Bottom,
- command: ‘bottom/ms/linalg/sym‘,
- examples: Example 22 pp. 53,
- input: poly-exponential function $t(x)$, $2M$, m,
- output: exponential generating function of $\prod_{i=1}^{m} t(x\omega_m^i)$,
- reference: Section 4.3.

A.5.4 Using the recurrence polynomial and resultants.

This will use the resultant to determine the linear recurrence relation.

- file: Bottom,
- command: ‘bottom/ms/result‘,
- examples: Example 26 pp. 65,
- input: exponential generating function $t(x)$, m,
- output: exponential generating function of $\prod_{i=1}^{m} t(x\omega_m^i)$,
- reference: Section 5.1.

A.5.5 Factoring out common polynomials.

This factors out common polynomials to simplify the problem. This can be used in combination with any of the other methods.

- file: Bottom,
- command: ‘bottom/ms/factor‘,
- examples: Example 32 pp. 85,
- input: poly-exponential function $t(x)$, m,
- output: exponential generating function of $(\prod_{i=1}^{m} t(x\omega_m^i))$,
- reference: Section 4.7.

A.6 Top linear recurrence relation.

A.6.1 Naive method.

This code will naively use the formula in Lemma 3.1 to determine the top linear recurrence relation.

- file: Top,
- command: ‘top/ms/naive‘,

- examples: Example 13 pp. 30,
- input: poly-exponential functions $t(x)$, $s(x)$, m, q,
- output: exponential generating function of $(s(x)\prod_{i=1}^{m-1} t(x\omega_m^i))_m^q$,
- reference: Lemma 3.1.

A.6.2 Fast Fourier transform and linear algebra method.

This will use a combination of fast polynomial multiplication and linear algebra to solve the problem.

- file: Top,
- command: 'top/ms/linalg/fft',
- examples: Example 27 pp. 68,
- input: exponential generating function $t(x)$, $s(x)$, M, m, q,
- output: exponential generating function of $(s(x)\prod_{i=1}^{m-1} t(x\omega_m^i))_m^q$,
- reference: Section 5.2.

A.6.3 Symbolic differentiation and linear algebra.

This uses a combination of symbolic differentiation and linear algebra.

- file: Top,
- command: 'top/ms/linalg/sym',
- examples: Example 22 pp. 53,
- input: exponential generating function of $s(x), t(x)$, $\prod t(x\omega_m^i)$, m, q,
- output: exponential generating function of $(s(x)\prod_{i=1}^{m-1} t(x\omega_m^i))_m^q$,
- reference: Section 4.3.

A.6.4 Computing top linear recurrence relation with bottom.

This computes the top linear recurrence relation given the bottom linear recurrence relation.

- file: Top,
- command: ‘top/ms/linalg/know‘,
- examples: Example 29 pp. 75,
- input: exponential generating function of $s(x)$, $t(x)$, $\prod t(x\omega_m^i)$, m, q,
- output: exponential generating function of $(s(x)\prod_{i=1}^{m-1} t(x\omega_m^i))_m^q$,
- reference: Section 5.3.

A.6.5 Knowing probably linear recurrence relation.

This computes the initial values given the top linear recurrence relation, the bottom linear recurrence relation and the recursion formula.

- file: Top,
- command: ‘top/ms/know‘,
- examples: Example 29 pp. 75,
- input: exponential generating function of $s(x)$, $t(x)$, $\prod t(x\omega_m^i)$, m, q,
- output: exponential generating function of $(s(x)\prod_{i=1}^{m-1} t(x\omega_m^i))_m^q$,
- reference: Section 5.3.

A.6.6 Computing new recurrence polynomial using resultants.

This computes the new recurrence polynomial by using resultants.

- file: Top,
- command: ‘top/ms/result‘,
- examples: Example 26 pp. 65,
- input: exponential generating function $s(x)$, $t(x)$, m, q,

- output: exponential generating function of $(s(x)\prod_{i=1}^{m-1} t(x\omega_m^i))_m^q$,
- reference: Section 5.1.

A.6.7 Factoring out common polynomials.

This method will factor out common polynomials to simplify the problem. This can be used in combination with any of the other methods.

- file: Top,
- command: 'top/ms/factor',
- examples: Example 32 pp. 85,
- input: poly-exponential function $s(x)$, $t(x)$,
- output: exponential generating function of $(s(x)\prod_{i=1}^{m-1} t(x\omega_m^i))_m^q$,
- reference: Section 4.7.

A.7 Doing the calculation.

A.7.1 Normal method.

This is just the normal method, using only one processor.

- file: Normal,
- command: 'calcul/normal',
- examples: Example 13 pp. 30,
- input: linear recurrence relations, m, q, and how far to calculate.,
- output: the $mi+q$-th values ,
- reference: Theorem 3.1.

A.7.2 Multiprocessor, even load-balance method.

This will assume multiple, evenly balanced processors, which this algorithm will take advantage of with communication.

- file: Multi,
- command: ‘calcul/balanced‘,
- examples: Example 33 pp. 91,
- input: linear recurrence relations, m, q, and how far to calculate,
- output: the $mi + q$-th values,
- reference: Section 6.1.

A.7.3 Multiprocessor, uneven load-balance method.

This will assume multiple, unevenly balanced processors. This algorithm will balance, and utilize these processors with communication to perform calculations.

- file: Multi,
- command: ‘calcul/balancing‘,
- examples: Example 34 pp. 95,
- input: linear recurrence relation, m, q, and how far to calculate,
- output: the $mi + q$-th values,
- reference: Section 6.2.

Appendix B

Notation.

Symbol,	Meaning,	Page,
α, β,	elements of $\mathbb{C}$,	
γ,	Euler gamma function,	1,
λ, μ,	elements of $\mathbb{C}$ as $e^{\lambda x}$ or $(x-\lambda)$,	
τ,	golden ratio,	1,
ω_m,	root of unity,	11,
$\zeta(n)$,	Riemann zeta function.	1,
a_i, b_i, d_i,	variables in a linear recurrence relation,	6,
c_i,	variables in a recursion formula,	28,
$deg^d(f(x))$,		20,
$deg^P(f(x))$,		20,
$f(x)$, $g(x)$, $h(x)$,	functions in $\mathcal{R}$,	26,
$f_m^q(x)$,	multisectioned function,	11,
i, j, k,	indexes for sums, or products,	
$j^{(r)}$,	$j(j-1)(j-2)...(j-r+1)$	
m,	by what a function is multisectioned,	11,
n,	a fixed integer,	
$p_i(x)$, $q_i(x)$	polynomials in x,	
q	to what a function is multisectioned,	11,
r_i	an unrelated set of integers,	
$r(x)$, $s(x)$, $t(x)$	functions in $\mathcal{P}$,	5,

x	variable,	
y	variable of integration or resultant,	
$\mathbb{C}$	Complex numbers,	
$C_m^q(f_m^q(x))$,	Compression,	55.
G,	Catalan's constant,	1,
N	size of the linear recurrence relation in $\mathcal{P}$,	
$P^f(x)$,	Recurrence polynomial	8,
$\mathcal{P}$,	Poly-exponential functions,	5,
$\mathcal{P}_{R_1,R_2}$,		10,

Appendix D

Maple bugs and weaknesses.

This appendix includes some email corresponding between myself and Maple Software concerning bugs and weaknesses in their product. Some editing has been done on the letters for brevity as well as grammatical and spelling corrections.

D.1 Bug 7345 - expand/bigpow and roots of unity.

```
From kghare Thu Nov 26 17:14:46 1998
Subject: expand/bigpow
To: mapledev@daisy.uwaterloo.ca

Why is ‘expand/bigpow‘ being called in the second case?  It is noticeable
slower.

Kevin
-------

kernelopts(printbytes=false);

From kghare Mon Nov 30 15:14:08 1998
Subject: Re: expand/bigpow
To: mapledev@daisy.uwaterloo.ca

I found an easier example demonstrating that something is
wrong.  Noticed, I only changed which 5th root of unity
I was looking at.

> exp(2*Pi*I*2/5)^500;
                                           500
                              exp(4/5 I Pi)

> expand(%);
                                    1

> time();
                                  .079

> exp(2*Pi*I*3/5)^500;
                                            500
                             exp(- 4/5 I Pi)

> expand(%);
```

```
bytes used=1000132, alloc=786288, time=0.19
bytes used=2000888, alloc=1179432, time=0.40
bytes used=3001084, alloc=1441528, time=0.68
bytes used=4001256, alloc=1769148, time=1.00
<SNIP>
bytes used=115099316, alloc=18477768, time=87.06
bytes used=116099516, alloc=18543292, time=88.17
bytes used=117099900, alloc=18739864, time=89.30

                                        1

This amount of time, (and for that matter, memory requirements)
doesn't seem reasonable for a problem such as this.

Kevin
```

D.2 Bug 7357 - help for Euler.

Help for the Euler function was wrong.

```
From kghare Tue Dec  8 14:34:42 1998
Subject: Help page for Euler
To: mapledev@daisy.uwaterloo.ca

From the help page for the Euler function we have:

>euler - Euler numbers and polynomials
>
>Calling Sequence:
>     euler(n)
>     euler(n, x)
>
>Parameters:
>     n - a non-negative integer
>     x - an expression
>
>Description:
```

```
>- The function euler computes the nth Euler number, or the nth Euler
>  polynomial in x. The nth Euler number E(n) is defined by the exponential
>  generating function:
>
>
>        2/(exp(t)+exp(-t)) = sum(exp(n)/n!*t^n, n = 0..infinity)

This line should read

        2/(exp(t)+exp(-t)) = sum(E(n)/n!*t^n, n = 0..infinity)

and there should be some description of what E(n,x) is, the nth Euler
polynomial.

Kevin
```

D.3 Bug 7497 - the "process" package.

```
From kghare Thu Oct 15 13:20:35 1998
Subject: Process Package in maple
To: mapledev@daisy.uwaterloo.ca

To: Stefan Vorkoetter;
cc: Maple Dev

I am currently trying to use the "process" package in Maple R5.
For some reason, the new forked processes are having problems
reading the library.

I get the error messages:

Error, (in DoWork) `/maple/mapleR5/lib/process/block.m` is an incorrect or ou\
tdated .m file (rFfn)
> quit
bytes used=239656, alloc=262096, time=0.01
Error, (in DoWork) `/maple/mapleR5/lib/process/block.m` is an incorrect or ou\
```

```
tdated .m file (ot3d)
> Error, (in Multi2) invalid subscript selector

This appears to be true on both the CECM machines at Simon Fraser University,
and daisy, at SCG.  If you want to see a copy of the code,
it can be found in my daisy account at
~kghare/Multi2

If you don't have access to daisy, and are interested in seeing
the code, just contact me, and I will mail it to you.  (approx 236 lines)

If I have in my program,
unprotect(block);
block := ....
and simply copy the code in, then everything works fine.
Except that it is an ever-growing list of files that I need to
do this to. (binomial, convert/string, type/odd, fprintf, close, readline, ...)

Any suggestions as to what I might be doing wrong would be appreciated.
I am too unfamiliar with the package to decide if it is a bug, or
I am just using it wrong.

Thanks

Kevin

From kghare Tue Nov 10 17:17:53 1998
Subject: Process Package
To: mapledev@daisy.uwaterloo.ca

When using the "process" package in maple, there is something
strange going on with the libraries and/or kernel after a fork
command.  The child process does not seem to be able to access anything
in the library properly, and I get errors such as:

    |\^/|     Maple V Release 5 (Simon Fraser University)
```

```
> read Multi;
> Multi(3,6);
Error, (in DoWork) could not find ‘process/block‘ in the library
Error, (in DoWork) could not find ‘binomial‘ in the library
> quit
bytes used=227108, alloc=262096, time=Error, exponent too large
maple: unexpected end of input
> quit
bytes used=227208, alloc=262096, time=Error, exponent too large
maple: unexpected end of input
Error, (in Multi) could not find ‘process/block‘ in the library

This is making the code very annoying to use, as I have to use
work-arounds to get around this bug.  (I predefine anything that
the child process will need, so that the child process will not need to
access the library.)  This is in the released version of maple, so it
is not simply a problem of rmaple being a bit out of sync.  Further
it occurs both on the CECM machines (in particular "bb"), and on
the SCG machine (daisy), so it is not a problem with any particular
maple installation.

It would be nice if a patch or fix could be found for this, as I am
using this functionality in my research.

read Multi;
Multi(3,100);

Thanks

Kevin Hare
```

D.4 Bug with “process package” and bytes used message.

```
Subject: process[fork] and bytes used message
To: mapledev@daisy.uwaterloo.ca
Date: Wed, 27 Jan 1999 16:19:28 -0800 (PST)
```

When the process[fork] command is called, the options about printing bytes, or not printing bytes is ignored by either the child of the parent. (Probably the child.) Also, the printbytes message is not able to figure out the time, and returns an error message. This was done with the following scripts.

```
kernelopts(printbytes=false);
with(process):

A := proc()
    local pid;
    kernelopts(printbytes=false);

    pid := fork();

    if pid = 0 then # This is the child
        print("The child has run");
        quit;
    else # This is the parent
        print("The parent has run");
    fi;
    RETURN():
end;

A();
```

```
------------------------------------------------------------------
    |\^/|     Maple V Release 5 (Simon Fraser University)

> kernelopts(printbytes=false);
                                      true

> with(process):
> A := proc()
>     local pid;
>     kernelopts(printbytes=false);
```

```
>     pid := fork();
>     if pid = 0 then # This is the child
>         print("The child has run");
>         quit;
>     else # This is the parent
>         print("The parent has run");
>     fi;
>     RETURN():
> end;
A := proc()
local pid;
    kernelopts(printbytes = false);
    pid := fork();
    if pid = 0 then print("The child has run"); quit
    else print("The parent has run")
    fi;
    RETURN()
end

> A();
                              "The child has run"

                             "The parent has run"

bytes used=209100, alloc=196572, time=Error, (in A) exponent too large
> quit
> bytes used=209612, alloc=196572, time=Error, exponent too large
maple: unexpected end of input

> quit
bytes used=209184, alloc=196572, time=0.05
```

D.5 Bug with "process" package on xMaple.

```
Subject: process[fork] and xmaple interface
```

```
To: mapledev@daisy.uwaterloo.ca

When using the process[fork] command, I get more than one
thread of execution running.  As is standard, I must "quit"
all but one of these threads before returning control to
the command prompt level.  Unfortunately, if I am using
xmaple, any quit command, from either the child, or the parent
will result in the worksheet exiting.  Hence the following
procedure:

with(process);

A := proc()
    local pid;

    pid := fork();

    if pid = 0 then # This is the child
        print("The child has run");
        quit;
    else # This is the parent
        print("The parent has run");
    fi;
    RETURN():
end;

A();

This will run almost properly on the text based version (modulo the other
bug I just reported), but will terminate the worksheet if it is run under
xmaple (occasionally).

Kevin
```

D.6 Bug 7552 - factorial.

```
Subject: Kernel level factorial is slow, inefficient, and forgetful
To: bugkeeper@maplesoft.com

Below is a very rough version of a factorial function.  It is
written using interpreted maple, where as the built-in versions
is kernel level.  Despite the difference in speed of interpreted
code versus kernel level code, the interpreted version is considerably
faster.

    |\^/|     Maple V Release 5 (Simon Fraser University)

> Fac1 := proc(n)
>     local A;
>     if n < 100 then RETURN (n!)
>     else
>          A := ((n^10-45*n^9+870*n^8-9450*n^7+63273*n^6-269325*n^5+
>              723680*n^4-1172700*n^3+1026576*n^2-362880*n)*`procname`(n-10));
>         RETURN(A);
>     fi;
> end:
>
> tt := time(): Fac1(10000): time() - tt;
bytes used=1005196, alloc=982860, time=0.19
<SNIP>
bytes used=18202916, alloc=4259060, time=3.97
                                     4.013

> tt := time(): 10000!: time() - tt;
                                    11.516

Next, if we add some sort of memory to this function (for example,
here I remember every 100 th value), then the speed is greatly increased
for doing multiple calculations, (yet the memory requirements still
remain low).
```

```
> Fac2 := proc(n)
>     local A;
>     if n < 100 then RETURN (n!)
>     elif (n = 0) mod 10 then
>         A := ((n^10-45*n^9+870*n^8-9450*n^7+63273*n^6-269325*n^5+
>              723680*n^4-1172700*n^3+1026576*n^2-362880*n)*`procname`(n-10));
>         if (n=0) mod 100 then
>             `procname`(n) := A;
>         fi:
>         RETURN(A);
>     else
>         RETURN(`procname`(n-1)*n);
>     fi;
> end:
>
> tt := time():
> for i from 1 to 10000 by 19 do
> Fac2(i):
> od:
<SNIP>
bytes used=100348464, alloc=6945544, time=16.19
> time() - tt;
                                    16.263

>
> tt := time():
> for i from 1 to 10000 by 19 do
> i!:
> od:
bytes used=101348908, alloc=6945544, time=22.80
bytes used=102359904, alloc=6945544, time=115.56
bytes used=103367344, alloc=6945544, time=262.03
```

Killed as I didn't have the patients to wait. But it is clear that it is going to take more than 10 times the amount of time to finish. (I estimated the time that it would take at around 3000 seconds, but I don't know exactly.)

```
Kevin
```

D.7 Bug 5793 - Multi-argument forget does not work.

```
Subject: Forget forgets more than it should.

According to the help page for forget:

Calling Sequence:
     forget(f,...)
     forget(f,a,b,c,...)

Parameters:
     f      - any name assigned to a Maple procedure
     a, b, c, ... - (optional) specific argument sequence for the function f
     ...    - options

<SNIP>

- forget(f,a,b,c,...) causes the value of f(a,b,c,..) to be ``forgotten''. As
  with the one-argument case, the entry for the argument list a,b,c,... is
  removed from the remember table for f and also from the remember table for
  all functions whose names begin with f/.

<SNIP>

Yet this doesn't even work with the example given in the help page.

> f(x) := 456:
> f(y) := 12:
> f(x),f(y);
                                  456, 12

> forget(f,x);
> f(x),f(y);
```

```
                                  f(x), f(y)
```

```
It is forgetting too much.
```

```
Kevin
```

Appendix

CORRECTIONS AND UPDATES – 1st JANUARY, 2003

The book by K. Ohshika has been translated in english [Ohshi–02]. The main chapters are on Gromov's hyperbolic groups, on automatic groups, and on Kleinian groups.

I.B, and random walks on groups.

There is a nice introduction to random walks and diffusion on groups in [Salof–01], starting with a discussion on shuffling cards. A short exposition of Pólya's recurrence theorem can be found in [DymMc–72].

II.21 and VII.38, subgroup growth, and normal subgroup growth.

For further work concerning numbers of subgroups and normal subgroups of finite index in various groups, see among others [LiSMe–00] and [LarLu].

II.24, and a strong Schottky Lemma.

The classical Table-Tennis Lemma, or Schottky Lemma, is often used to show that a pair of isometries g, h of some hyperbolic space have *powers* g^n, h^n which generate a free group. There is a criterion for g, h to generate a free group in [AlFaN].

On free subgroups of isometry groups, see also [Woess–93] and [Karls].

II.25, II.33, and Möbius groups generated by two parabolics which are not free.

Let $\tilde{\Gamma}_z$ denote the subgroup of $SL(2,\mathbb{C})$ generated by $\begin{pmatrix} 1 & z \\ 0 & 1 \end{pmatrix}$ and $\begin{pmatrix} 1 & 0 \\ z & 1 \end{pmatrix}$, so that $\tilde{\Gamma}_z$ is free if $|z| \geq 2$ or if z is transcendental.

Grytczuk and Wójtowicz have shown that $\tilde{\Gamma}_{p/q}$ is *not* free for a set of rational values $z = p/q$ of the parameters which contains infinitely many accumulation points [GryWó–99].

II.28, and arithmeticity of lattices.

In $PSL(2,\mathbb{C})$, all arithmetic lattices which are generated by two elliptic elements and which are not co-compact have been determined [MacMa–01].

II.29$\frac{1}{3}$, more flowers for the herbarium of free groups.

Margulis has discovered a remarkable example of a free subgroup of the affine group of $\mathbb{R}^3$ acting *properly* on $\mathbb{R}^3$ [Margu-83]; an exposition appears in [Drumm–92].

II.29$\frac{2}{3}$, complement on groups with free subgroups.

We reproduce (most of) Problem 12.24 from the Kourovka Notebook.

Given a ring R with identity, the automorphisms of $R[[x]]$ sending x to $x(1 + \sum_{i=1}^{\infty} a_i x^i)$ form a group $N(R)$. We know that $N(\mathbb{Z})$ contains a copy of the free group F_2 of rank 2 (...). Does $N(\mathbb{Z}/p\mathbb{Z})$ contain a copy of F_2 ?

The answer is "yes": see [Camin–97]; it could be a challenge to find a table-tennis proof of this fact. For generalities on these "Nottingham groups" $N(R)$, see [Camin–00].

II.41, a misprint.

There is a misprint in the reference to [Bourb–75], which should be to Chapter VIII, § 2, Exercise 10.

II.41, and dense free subgroups of Lie groups.

The following result [BreGe] answers a question raised by A. Lubotzky and R. Zimmer: *if* Γ *is a dense subgroup of a connected semisimple real Lie group* G*, then* Γ *contains two elements which generate a dense free subgroup of* G. Also: in a connected non-solvable real Lie group of dimension d, any finitely generated dense subgroup contains a dense free subgroup of rank $2d$.

II.42, on Tits' alternative.

Let Γ be a subgroup of the group of homeomorphisms of the circle such that the action of Γ on the circle is minimal. Then, either the action is a conjugate of an isometric action, and therefore Γ contains a commutative subgroup of index at most 2, or Γ contains a so-called quasi-Schottky subgroup, which is in particular a non-abelian free subgroup [Margu–00]. A variation (possibly a simplification ?) of Margulis' original ideas appear in Section 5.2 of [Ghys–01].

For a group Γ of orientation preserving $\mathcal{C}^2$-diffeomorphisms of the circle, it is also known that the existence of an exceptional minimal set implies that Γ has non-abelian free subgroups [Navas].

On $Out(F_n)$, see also [BesFe–00].

Tits' alternative holds for automorphism groups of free soluble groups [Licht–95] and for linear groups over rings of fractions of polycyclic group rings [Licht–93], [Licht–99]. It also holds in a strong sense for subgroups of Coxeter groups [NosVi–02].

If Γ is a Bieberbach group, either both its automorphism group and its outer automorphism group are polycyclic, or both contain non-abelian free subgroups. See [MalSz] for precise criteria to decide which situation holds for a given Bieberbach group, in terms of the associated holonomy representation.

III.4, and examples of non-uniform tree lattices.

For the existence of such non-uniform lattices on uniform trees, see the work of L. Carbone [Carbo–01]. For tree lattices in general, see [BasLu–01].

III.6$\frac{1}{2}$, and further examples of finitely-genrated groups.

Let A be a commutative ring which is a finitely-generated $\mathbb{Z}$-module. Then the group A^* of invertible elements in A is a finitely-generated abelian group.

There is a proof in Section 4.7 of [Samue–67]; its main ingredient is Dirichlet's theorem, according to which the group of units in the ring of integers of a number field $\mathbb{K}$ is a direct product $F \times \mathbb{Z}^{r_1+r_2-1}$, where F is a finite group and r_1 [respectively $2r_2$] is the number of real [respectively complex] embeddings of $\mathbb{K}$ in $\mathbb{C}$.

More generally, if B is a commutative ring which is reduced (this means that 0 is the *only* nilpotent element) and finitely generated over $\mathbb{Z}$, then B^* is finitely generated [Samue–66].

III.18.iv, III.20, and residual finiteness.

On residual finiteness and topological dynamics: see also [Egoro–00].

A proof that finitely-generated linear groups are residually finite appears as Proposition III.7.11 in [LynSc–77].

III.21, on Baumslag-Solitar groups which are Hopfian.

For the equivalence between "$\Gamma_{p,q}$ Hopfian" and "p, q meshed" to hold, the definition should be

> two integers $p, q \geq 1$ are *meshed* if they have precisely the same prime divisors

and *not* the definition as it reads in [BauSo–62], or on page 57. I am grateful to E. Souche who pointed out this correction to me.

III.21, on actions of Baumslag-Solitar groups on the line.

For any p, q with $p > q \geq 1$, there exists a faithful action of the group $BS(p, q)$ on the line by orientation preserving real-analytic diffeomorphisms. In particular, $Diff_+^\omega(\mathbb{R})$ contains Baumslag-Solitar groups which are not residually finite [FarFr].

III.24, on maximal subgroups.

In "familiar" uncountable groups, maximal subgroups cannot be countable. More precisely, Pettis [Petti–52] has shown that, if G is a second category[1] nondiscrete Hausdorff group containing a countable everywhere dense subset, then any proper subgroup H of G lies in an uncountable proper sugroup H_+ of G; if H is countable, H_+ can be taken to be everywhere dense as well.

In their work on maximal subgroups of infinite index in finitely generated linear groups (exluding extensions of solvable groups by finite kernels), Margulis and Soifer have shown that such a group Γ contains a free (*infinitely* generated) subgroup F_∞ which maps *onto* any finite quotient of Γ; they deduce from this that any maximal subgroup of Γ which contains F_∞ is necessarily of infinite index. Soifer and Venkataramana have shown the following result: if Γ is an arithmetic subgroup of a non-compact linear semi-simple group G such that the associated simply connected algebraic group over $\mathbb{Q}$ has the so-called congruence subgroup property, for example if $\Gamma = SL(n, \mathbb{Z})$ with $n \geq 3$, then Γ contains a *finitely generated* free subgroup which maps onto any finite quotient of Γ [SeiVe–00].

III.24 and VIII.39. The Grigorchuk group has the following property: any maximal subgroup in it is of finite index [Pervo–00]. The same property holds for any group commensurable with Γ [GriWi].

[1] Recall that a topological space X is "second category" (= non-meager) if it is *not* the union of countably many subsets whose closures have empty interiors ("ensembles rares"). Baire's theorem shows that locally compact spaces and complete metric spaces are second category, indeed are Baire spaces (= spaces in which countable unions of closed subspaces with empty interiors have empty interiors).

III.B, an additional problem: does $SO(3)$ act non-trivially on $\mathbb{Z}$? (Ulam's problem).

I do not know which uncountable groups can act faithfully on a countable set. Of course, the group $Sym(\mathbb{N})$ of all permutations of $\mathbb{N}$ is itself uncountable, and it has received attention at least since [SchUl–33]. Here is a sketch to show that $\mathbb{R}$, viewed as a discrete group, acts faithfully on $\mathbb{N}$; in other and somehow biased words, this produces "a continuous flow on a discrete space". I am most grateful to Tim Steger for several helpful conversations on this material.

Choose a basis (e_t) of $\mathbb{R}$ as a vector space over $\mathbb{Q}$ which is indexed by the open interval $]0,1[$ of the line. Let C denote the countable set of pairs (a,b) of rational numbers such that $0 < a < b < 1$. For each $(a,b) \in C$, the map

$$\phi_{a,b} : \mathbb{R} \ni \sum_{t \in (a,b)} x_t e_t \longmapsto \sum_{t \in]a,b[} x_t \in \mathbb{Q}$$

is well-defined, $\mathbb{Q}$-linear and onto. Observe that, for any $x \neq 0$ in $\mathbb{R}$, there exists $(a,b) \in C$ such that $\phi_{a,b}(x) \neq 0$. Now $\mathbb{N}$ is in bijection with the disjoint union $\bigsqcup_{(a,b)\in C} \mathbb{Q}_{a,b}$ of copies of $\mathbb{Q}$ indexed by C. Define an action ϕ of $\mathbb{R}$ on this union which leaves each $\mathbb{Q}_{a,b}$ invariant and for which $x \in \mathbb{R}$ transforms $q \in \mathbb{Q}_{a,b}$ to $q + \phi_{a,b}(x)$. This ϕ is a faithful action. [Even if it is not important for our argument, observe that the product over $(a,b) \in C$ of the $\phi_{a,b}$ is a $\mathbb{Q}$-linear bijection from $\mathbb{R}$ onto a subspace of the vector space which is a direct product over C of copies of $\mathbb{Q}$.]

The group $\mathbb{R}/\mathbb{Z}$ is a direct sum of the torsion group $\mathbb{Q}/\mathbb{Z}$, which is countable, and a group isomorphic to $\mathbb{R}$ (a $\mathbb{Q}$-vector space of dimension the power of the continuum). It follows from the previous construction that there exists an injective homomorphism from $\mathbb{R}/\mathbb{Z}$ into $Sym(\mathbb{N})$.

In 1960, Ulam asked if the compact group $SO(3)$ of rotations of the usual space, viewed as a discrete group, can act on a countable set (see Section V.2 in [Ulam–60]). As far as I know, this is still open. Previous observations are possibly near what Ulam had in mind when writing his comments in Section II.7 of [Ulam–60].

III.38 and III.D, on finite quotients of the modular group.

For more on which finite simple groups are quotients of $PSL(2,\mathbb{Z})$, see the exposition of [Shale–01].

III.45, uncountably many finitely-generated groups with pairwise non-isomorphic von Neumann algebras.

Let Γ be a torsion-free Gromov-hyperbolic group which is not cyclic. Building up on results of Gromov, Ol'shanskii has shown that Γ has an uncountable family $(\Gamma_\iota)_{\iota \in I}$ of pairwise non-isomorphic quotient groups, all of which are simple and icc [Ol's–93]. N. Ozawa [Ozawa] has shown that, for any given separable factor M of type II_1, the set of those $\iota \in I$ for which the unitary group $\mathcal{U}(M)$ has a subgroup isomorphic to Γ_ι is a countable set. In particular, the set of von Neumann algebras of the groups Γ_ι (which are factors of type II_1) contains uncountably many isomorphism classes.

III.46, on groups with two generators.

It has been shown that two randomly chosen elements of a finite simple group G generate G with probability 1 as $|G| \to \infty$ (work of Dixon, Kantor-Lubotzky, Liebeck-Shalev, see [Shale–01]).

IV.1 and VI.1, on infinite generating sets and related word lengths.

Consider an integer $n \geq 2$, the group $\Gamma = SL(n, \mathbb{Z})$, and the infinite subset S of Γ consisting of those matrices of the form $I + kE_{i,j}$, with $k \in \mathbb{Z}$, $i, j \in \{1, \ldots, n\}$, $i \neq j$, and $E_{i,j}$ the matrix with all entries 0 except one 1 at the intersection of the ith row and the jth column.

As stated in Item III.2, the diameter of Γ with respect to the corresponding S-word length is finite as soon as $n \geq 3$.

IV.3.viii, on stable length: a correction.

The subadditivity

$$\tau(\gamma\gamma') \leq \tau(\gamma) + \tau(\gamma')$$

holds for *commuting* elements $\gamma, \gamma' \in \Gamma$ (as correctly stated by Gersten and Short).

For example, if γ, γ' are the two standard generators of the infinite dihedral group, then $\tau(\gamma\gamma') > 0$ and $\tau(\gamma) = \tau(\gamma') = 0$.

IV.24.i, and values of the indices for subgroups: a question.

Consider the following property of a group Γ: whenever two subgroups Γ_1, Γ_2 of finite indices are abstractly isomorphic, the indices $[\Gamma : \Gamma_1]$ and $[\Gamma : \Gamma_2]$ are equal.

Finitely generated free groups and fundamental groups of closed surfaces have this property, by an easy argument using Euler characteristics.

More generally, it would be interesting to know which groups have this property and which groups don't.

IV.25.vii, a quasi-isometry criterion for existence of lattices.

B. Chaluleau and C. Pittet [ChaPi–01] have answered one of the questions there and have shown:

Let N be a graded simply connected nilpotent real Lie group. If there exists a finitely-generated group which is quasi-isometric to N, then N has lattices.

IV.25, and examples of quasi-isometries.

(x) Say that a metric space X is *quasi-isometrically incompressible* if any quasi-isometric embedding from X into itself is a quasi-isometry. E. Souche [Souch] has shown that finitely generated nilpotent groups and uniform lattices in simple connected real Lie groups are quasi-isometrically incompressible, but that finitely-generated free groups and Baumslag-Solitar groups are not.

(xi) A finitely-generated group cannot be quasi-isometric to an infinite dimensional Hilbert space. Indeed, such a space has the following quasi-isometric-invariant property: for any positive number r, there exists a positive number R such that a ball of radius R contains infinitely many pairwise disjoint balls of radius r; and a finitely-generated group does not have this property.

IV.27, groups which are commensurable up to finite kernels.

Another terminology for commensurable up to finite kernels is *weakly commensurable* subgroups. See § 5.5 in [GorAn–93]; these authors also point out the following fact.

If M is a manifold on which some Lie group act transitively, then $\pi_1(M)$ contains a subgroup of finite index which is isomorphic to a discrete subgroup of a connected Lie group; if M is also compact, then $\pi_1(M)$ contains a subgroup of finite index which is isomorphic to a uniform lattice in some connected Lie group.

IV.29.v and VII.26, and the classification of lattices up to commensurability in some nilpotent Lie groups.

Y. Semenov has classified $\mathbb{Q}$-forms of some real nilpotent Lie algebras, and thus the commensurability classes of lattices in the corresponding nilpotent Lie groups [Semen]. It seems that the following question is open:

does there exist a finite dimensional real nilpotent Lie algebra of which the number k of $\mathbb{Q}$-forms (up to isomorphism) is such that $1 < k < \infty$?

IV.34 & 35, and commensurability. The following exercise is taken from [Gabor–02] and is clearly missing just before IV.34.

Exercise. (i) Show that two groups Γ_1, Γ_2 are commensurable if and only if they have commuting free actions on a set X such that both quotients $\Gamma_1\backslash X, \Gamma_2\backslash X$ are finite.

[Hint for one direction. Let Γ_j' be a subgroup of finite index in Γ_j, $j = 1, 2$, such that there exists an isomorphism $\varphi : \Gamma_1' \longrightarrow \Gamma_2'$. Set $\Delta = \{(\gamma_1, \gamma_2) \in \Gamma_1 \times \Gamma_2 \mid \gamma_1 \in \Gamma_1', \gamma_2 = \varphi(\gamma_1)\}$. Consider the natural actions of Γ_1 and Γ_2 on $(\Gamma_1 \times \Gamma_2)/\Delta$.

Hint for the other direction. Choose $x_0 \in X$. Consider the natural action of Γ_1 on $\Gamma_2\backslash X$ and the canonical projection $[x_0]_2$ of x_0 in $\Gamma_2\backslash X$. Let Γ_1' be the isotropy subgroup of Γ_1 defined by $[x_0]_2$ and set $\gamma_1 x_0 = \varphi(\gamma_1)x_0$. Check that φ is a well-defined group homomorphism $\Gamma_1' \longrightarrow \Gamma_2$ which is injective and whose image is of finite index in Γ_2.]

(ii) Assume that Γ_1, Γ_2 have commuting free actions on X such that both $\Gamma_1\backslash X, \Gamma_2\backslash X$ are finite, and let Γ_1', Γ_2' be as in the previous hints. Check that

$$\frac{[\Gamma_1 : \Gamma_1']}{[\Gamma_2 : \Gamma_2']} = \frac{|\Gamma_2\backslash X|}{|\Gamma_1\backslash X|}\,.$$

IV.36, on commensurability and torsion.

G. Levitt has observed that a group Γ with infinitely many torsion conjugacy classes can have a subgroup of finite index Γ_0 which is torsion-free.

Indeed, let first Γ_0 be the wreath product $\mathbb{Z} \wr \mathbb{Z} = (\oplus_{i\in\mathbb{Z}} \mathbb{Z}a_i) \rtimes \mathbb{Z}$, where the generator t of $\mathbb{Z}$ acts on the direct sum by a shift; this group is torsion-free. Then let Γ be the semi-direct product of Γ_0 with the automorphism ϕ of Γ_0 of order 2 defined by $\phi(a_i) = -a_i$ for all $i \in \mathbb{Z}$ and $\phi(t) = t$; and let $s \in \Gamma$ denote the element of order 2 which implements ϕ on the subgroup Γ_0. For $v, v' \in \oplus_{i\in\mathbb{Z}} \mathbb{Z}a_i$, the elements sv, sv' are on the one hand of order 2; on the other hand, they are conjugate in Γ if and only if there exist $\epsilon \in \{\pm 1\}$, $k \in \mathbb{Z}$, and $w \in \oplus_{i\in\mathbb{Z}} \mathbb{Z}a_i$ such that $v' = \epsilon t^k v t^{-k} + 2w$; it follows that the conjugacy classes in Γ of $s(a_1 + \cdots + a_n)$ are pairwise distinct ($n \geq 0$).

A. Erschler has shown that a torsion-free group can be quasi-isometric to a group having torsion of unbounded order [Ersch–b].

The main ingredient of the proof is the construction, for any finitely-generated group A, of another finitely generated group $W^\infty(A)$, using an iterated wreath product construction and an HNN-extension. On the one hand, if A, B are Lipschitz equivalent groups, then $W^\infty(A), W^\infty(B)$ are Lipschitz equivalent; on the other hand, if A is torsion-free and if B has torsion, then $W^\infty(A)$ is torsion-free and $W^\infty(B)$ has torsion of unbounded order. One example is provided by $A = \mathbb{Z}$ and $B = \mathbb{Z} \oplus (\mathbb{Z}/p\mathbb{Z})$.

IV.40, and groups quasi-isometric to abelian groups.

Some of Shalom's ideas are now available in [Shalo].

IV.41, on groups of classes of quasi-isometries.

J. Taback has studied the quasi-isometry groups of $PSL_2(\mathbb{Z}[1/p])$, for p prime. These quasi-isometry groups are all isomorphic to $PSL_2(\mathbb{Q})$, even though the groups are not quasi-isometric for different values of the prime p. For this and other results, see [Tabac–00].

IV.43, and quasi-isometries of Baumslag-Solitar groups.

For the results of K. Whyte quoted from [Whyte–a], see now [Whyte–01].

IV.46, and Lipschitz equivalence.

Here is a question of B. Bowditch. (Private communication, March 2000. See also Item 1.A' in [Gromo–93].) Consider a Penrose tiling of the plane with two prototiles D and K (dart and kite), more precisely a tiling $\mathbb{R}^2 = \bigsqcup_{j\in J} T_j$ with each T_j given together with an isometry onto either D or K. This defines a cell decomposition X of the plane, of which the 0-skeleton $X^{(0)}$ is a discrete subset of the plane.

Is $X^{(0)}$ Lipschitz equivalent to a lattice in $\mathbb{R}^2$?

IV.47.vi, on costs and ℓ^2–Betti numbers.

For a group Γ with cost $\mathcal{C}(\Gamma)$ and ℓ^2–Betti numbers $\beta_j^{(2)}(\Gamma)$, we have always

$$\mathcal{C}(\Gamma) - 1 \geq \beta_1^{(2)}(\Gamma) - \beta_0^{(2)}(\Gamma).$$

Moreover, for a large class of groups (including all groups for which both terms are known), the two terms are indeed equal. See [Gabor], in particular Corollary 3.22.

IV.50, geometric properties and weakly geometric properties.

Following [Ersch–b], it can be useful to be more precise in the terminology concerning a property $(\mathcal{P})$ of finitely generated groups. She suggests the following definitions.

Say $(\mathcal{P})$ is *geometric* if, for a pair (Γ_1, Γ_2) of finitely-generated groups which are quasi-isometric, Γ_1 has Property $(\mathcal{P})$ if and only if Γ_2 is commensurable to a group which has Property $(\mathcal{P})$.

Say $(\mathcal{P})$ is *weakly geometric* if, for a pair (Γ_1, Γ_2) of finitely-generated groups which are quasi-isometric, Γ_1 has Property $(\mathcal{P})$ if and only if Γ_2 is commensurable up to finite kernels to a group which has Property $(\mathcal{P})$.

An example of a property which is weakly geometric and which is not geometric is "being a lattice in $Spin(2,5)$"; see III.18.vi, III.18.x, and IV.42.

V.18, on the group of a remarkable simple closed curve.

It has been shown by Anna Erschler Dyubina that the group of V.18 is not finitely generated. Finding a proof is proposed as Problem 10 835 in the American Mathematical Monthly [DyuHa–00].

Problem. *Let Γ be the group defined by the presentation which has an infinite sequence $b_0, b_1, b_2, \ldots$ of generators and an infinite sequence $b_1 b_0 b_1^{-1} = b_2 b_1 b_2^{-1} = b_3 b_2 b_3^{-1} = \ldots$ of relations. Show that Γ is not finitely generated.*

We would like to add a comment and our solution. The nice solution of S.M. Gagola has appeared in the *Monthly*, November 2002.

Comment. In a short paper on wild knots, R.H. Fox discovered *A remarkable simple closed curve* (Annals of Math. **50**, 1949, pages 264–265) which is almost unknotted, a fact that Fox thinks "should be obvious to anyone who has ever dropped a stitch". The fundamental group Γ of the complement of this curve in 3-space has the presentation described above.

For other fundamental groups of complements of wild knots, see [Myers–00].

Our solution. Observe first that there is a homomorphism $\Gamma \longrightarrow \mathbb{Z}$ mapping b_k onto 1 for each $k \geq 0$; hence b_k is of infinite order in Γ for each $k \geq 0$. Observe also that there is a homomorphism σ from Γ onto the symmetric group $\langle x, y \mid x^2 = y^2 = (xy)^3 = 1 \rangle$ such that $\sigma(b_{2j}) = x$ and $\sigma(b_{2j+1}) = y$ for all $j \geq 0$; hence $b_k b_{k+1} \neq b_{k+1} b_k$ for all $k \geq 0$.

For each $n \geq 0$, there is a homomorphism $\phi_n : \Gamma \longrightarrow \Gamma$ such that $\phi_n(b_k) = b_{k+n}$ for all $k \geq 0$. Since the first relation of the presentation defining Γ can be written as $b_0 = b_1^{-1} b_2 b_1 b_2^{-1} b_1$ and since the other relations do not involve b_0, the group Γ has another presentation with generators b_k and relations $b_{k+1} b_k b_{k+1}^{-1} = b_{k+2} b_{k+1} b_{k+2}^{-1}$ for $k \geq 1$. Similarly, for each $n \geq 0$, the group Γ has a presentation with generators b_k and relations $b_{k+1} b_k b_{k+1}^{-1} = b_{k+2} b_{k+1} b_{k+2}^{-1}$ for $k \geq n$, so that ϕ_n is an automorphism of Γ.

Assume now by contradiction that Γ is finitely generated, and therefore generated by $b_0, b_1, \ldots, b_{n+1}$ for some $n \geq 0$. Using again the relations $b_{k+1}b_kb_{k+1}^{-1} = b_{k+2}b_{k+1}b_{k+2}^{-1}$, this time for $0 \leq k \leq n-1$, we see that Γ is generated by $\{b_n, b_{n+1}\}$. Thus Γ is also generated by $\{b_0, b_1\} = \phi_n^{-1}(\{b_n, b_{n+1}\})$, as well as by $\{b_1, b_2\} = \phi_1(\{b_0, b_1\})$.

For each $k \geq 0$, let $\tilde{\Gamma}_{k+1}$ the group abstractly defined by $k+2$ generators $b_0, \ldots, b_{k+1}$ and k relations $b_1b_0b_1^{-1} = \ldots = b_{k+1}b_kb_{k+1}^{-1}$. The same argument as above shows that $\tilde{\Gamma}_{k+1}$ has another presentation with 2 generators b_k, b_{k+1} and no relation, hence that $\tilde{\Gamma}_{k+1}$ is free of rank two. As b_0, b_1 do not commute in $\tilde{\Gamma}_{k+1}$, they generate a subgroup of $\tilde{\Gamma}_{k+1}$ which is free of rank two. As this holds for any $k \geq 0$, it follows that the group Γ, generated by b_0 and b_1, is itself free of rank two.

As Γ is free on $\{b_1, b_2\}$, there is a homomorphism $\psi : \Gamma \longrightarrow \mathbb{Z}$ such that $\psi(b_1) = 0$ and $\psi(b_2) = 1$, which is *onto*. On the other hand, as Γ is generated by b_0 and b_1, and as $\psi(b_0) = \psi(b_1^{-1}b_2b_1b_2^{-1}b_1) = 0 = \psi(b_1)$, we have $\psi(\Gamma) = \{0\}$. This is a contradiction and ends the proof. □

The group Γ has other straightforward non-finitenes properties. (i) It is not Hopfian, since it is isomorphic to its quotient by the relation $b_0 = 1$. (ii) It maps onto the Baumslag-Solitar group $\langle t, z \mid tzt^{-1} = z^2 \rangle$ by $b_{2n} \longmapsto zt^{-1}$ and $b_{2n+1} \longmapsto t^{-1}$.

V.20, and lattices in Lie groups.

Information on lattices in *complex* Lie groups can be found in [Winke–98].

V.21, and finiteness homological properties of $SL(n, \mathbb{F}_q[T])$.

The finiteness result according to which $SL(n, \mathbb{F}_q[T])$ is of type (F_{n-2}) and not of type (F_{n-1}) for $q \geq 2^{n-2}$ is due independently to H. Abels (as recorded in V.21) and P. Abramenko [Abram–96].

V.22, on commensurability and groups of automorphisms.

G. Levitt has drawn my attention to the fact that, given a group Γ and a subgroup Γ_0 of finite index, there can exist an infinity of automorphisms of Γ which coincide with the identity on Γ_0.

Indeed, let Γ be the infinite dihedral group and let Γ_0 be its infinite cyclic subgroup of index 2. Then the conjugations of Γ by elements of Γ_0 are pairwise distinct.

V.22, on large groups of automorphisms.

The automorphism group of a finitely-generated group is clearly countable. The automorphism group of a countable group need not be; an easy example is provided by an infinite direct sum of copies of any countable group not reduced to one element.

Here is another example, inspired from Ulam and using the notation of the addendum to III.B above. For each $(a, b) \in C$, let $\phi_{a,b} : \mathbb{R} \longrightarrow \mathbb{Q}$ be the

homomorphism defined there and let $\mathbb{Q}^2_{a,b}$ be a copy of $\mathbb{Q}$. The mapping

$$\psi_{a,b} \; : \; \begin{cases} \mathbb{R} & \longmapsto \; \mathrm{Aut}\left(\mathbb{Q}^2_{a,b}\right) \approx GL_2(\mathbb{Q}) \\ x & \longmapsto \qquad \begin{pmatrix} 1 & \phi_{a,b}(x) \\ 0 & 1 \end{pmatrix} \end{cases}$$

is a homomorphism of groups. Define Γ to be the direct sum, over $(a,b) \in C$, of the groups $\mathbb{Q}^2_{a,b}$; then the direct sum of the homomorphisms $\psi_{a,b}$ is an injection of $\mathbb{R}$ into $\mathrm{Aut}(\Gamma)$.

V.26, and some groups of Richard Thompson.

There are three groups, acting respectively on an interval, the circle, and the Cantor set, denoted by F, T, and V in [CanFP–96], and which appear in many different contexts. For T in the context of Teichmüller theory, see several articles by R.C. Penner, including [Penne–97]; for the isomorphism of Penner's group with T, see [Imber–97]. One interesting byproduct of this circle of ideas is that T can be generated by two elements α, β satisfying $\alpha^4 = \beta^3 = 1$, and other relations, such that the subgroup of T generated by α^2, β is the free product $\mathbb{Z}/2\mathbb{Z} * (\mathbb{Z}/3\mathbb{Z}) \approx PSL_2(\mathbb{Z})$; see [LocSc–97].

V.31, and efficiency.

A. Çevik gives in [Çevik–00] a sufficient condition for the efficiency of wreath products of efficient finite groups.

VI.9, an example of spherical growth series which is not monotonic.

On page 161, the last display, the coefficient of z^2 should be 8 not 6. This was pointed out to me by N.J.A. Sloane. Several growth series which appear in the the book appear also in his database of integer sequences: see

http://www.research.att.com/ njas/sequences/

on the web.

VI.19, on groups with the size of spheres not tending to infinity.

Groups in which the size of spheres does not tend to infinity are virtually cyclic (communicated by Anna Erschler Dyubina). More precisely:

Proposition. *If $\sigma(\Gamma, S; k) \leq C$ for infinitely many values of k, then Γ is virtually cyclic.*

Proof. Consider an arbitrary infinite finitely generated group, and let Φ be its inverse growth function, as in VII.32. First, it follows from the definition and from the obvious inequality $\beta(4k) > 2\beta(k)$ that $\Phi(2\beta(k)) \leq 4k$. Then, it follows from the first result quoted in VII.32 that, for an appropriate constant K, we have

$$\frac{\sigma(n)}{\beta(n-1)} \; \geq \; \frac{1}{8|S|\Phi(2\beta(n-1))} \; \geq \; \frac{1}{8|S|4(n-1)} \; \geq \; \frac{1}{Kn},$$

whence

$$\beta(n-1) \; \leq \; K\sigma(n)n$$

for all $n \geq 1$.

Assume now that $\sigma(n_j) \leq C$ for some constant C and a strictly increasing infinite sequence $(n_j)_{j\geq 1}$. Thus $\beta(n_j - 1) \leq KCn_j$ for any $j \geq 1$. By the strong form of Gromov's theorem (VII.29) on groups of polynomial growth, which is elementary for linear growth and which is due to Van den Dries and Wilkie [VdDW–84b], this implies that Γ is a group of linear growth and therefore a virtually cyclic group. □

VI.20, and the growth of braid groups for Artin generators.

For any integer $n \geq 2$, Artin's *braid group* on n strings has presentation

$$B_n = \left\langle \sigma_1, \ldots, \sigma_{n-1} \;\middle|\; \begin{array}{r} \sigma_i\sigma_{i+1}\sigma_i = \sigma_{i+1}\sigma_i\sigma_{i+1} \quad (1 \leq i \leq n-2) \\ \sigma_i\sigma_j = \sigma_j\sigma_i \quad (1 \leq i,j \leq n-1,\ |i-j| \geq 2) \end{array} \right\rangle$$

[Magnu–73] and is obviously a quotient of the *locally free group of depth* 1 with $n-1$ generators

$$LF_n = \langle f_1, \ldots, f_{n-1} \mid f_i f_j = f_j f_i \quad (1 \leq i,j \leq n-1,\ |i-j| \geq 2) \rangle$$

[Versh–90], [Versh–00], [VeNeB–00]. The value of the exponential growth rate of B_n for the generators σ_i is still unknown; however, Vershik and his co-authors have obtained partial results by comparing B_n with LF_n, more precisely by using the fact that LF_n appears both as a group of which B_n is a quotient and as a subgroup of B_n, the image of the injective homomorphism which maps f_i onto σ_i^2 for $i \in \{1, \ldots, n-1\}$.

For example, if ω_n^B, ω_n^{LF} denote respectively the exponential growth rates of B_n, LF_n for the generators discussed here, then

$$\lim_{n\to\infty} \omega_n^{LF} = 7 \qquad \text{and} \qquad \sqrt{7} \leq \omega_n^B \leq 7 \quad \text{for } n \text{ large enough.}$$

VI.B, early papers on growth of groups, and Dye's theorem on orbit equivalence for groups of polynomial growth.

Growth occurs in a paper by Margulis [Margu–67] published one year before those of Milnor ([Miln–68a], [Miln–68b]), where Margulis shows that if a compact three-dimensional manifold admits an Anosov flow, then its fundamental group has exponential growth. For a generalization to higher dimensions, see [PlaTh–72].

Also, between the mid fifties and 1968, some mathematicians in France were aware of the notion of growth of groups. Besides Dixmier (quoted on page 187), Avez had learned this from Arnold in 1965 [Avez–76].

We should also mention the following results of H. Dye. On the one hand, consider the compact abelian group $\prod_{j=0}^{\infty} C_j$, where each C_j is a copy of the group $\{0,1\}$ of order 2, with its normalised Haar measure μ. Let $T : G \longrightarrow G$ be the adding machine, defined by

$$T(x_0, x_1, x_2, \ldots) = (0, 0, \ldots, 1, x_{j+1}, x_{j+2}, \ldots)$$

where j is the smallest index such that $x_j = 0$, and

$$T(1,1,1,1,\ldots) \;=\; (0,0,0,0,\ldots).$$

Then T defines an ergodic action of $\mathbb{Z}$ by measure preserving transformations of the probability space (G,μ). On the other hand, consider any finitely generated group Γ acting by measure preserving transformations on a standard Borel space furnished with a non-atomic probability measure, the action being ergodic.

One of Dye's theorems is that, if Γ is of polynomial growth, then the action of Γ is orbit-equivalent to the odometer action of $\mathbb{Z}$ [Dye–63]; if $\Gamma \approx \mathbb{Z}$, this is already in [Dye–59]. See [Weiss–81] for an exposition, and [OrnWe–80], [CoFeW–81] for related results; in particular, Dye's theorem carries over to *amenable* countable groups.

VI.40, and the functions which are growth functions of semigroups.

Let M be a monoid generated by a finite set S and let $\beta(k) = \beta(M,S;k)$ denote the corresponding growth function (see VI.12). It is obvious that if $\beta(k)$ is unbounded, then $k \prec \beta(k)$; moreover,

$$k \prec \beta(k) \quad \text{and} \quad k \nsim \beta(k) \qquad \text{imply} \qquad k^2 \prec \beta(k)$$

as has been shown[2] by V.V. Beljaev (reported in [Trofi–80]).

Let $f, g : \mathbb{N} \longrightarrow \mathbb{N}$ be two functions such that $k^2 \prec f(k)$ and $g(k) \prec 2^k$. Then there exists a monoid M generated by a finite set S such that the sets

$$\{k \in \mathbb{N} \,|\, \beta(M,S;k) \leq f(k)\} \qquad \text{and} \qquad \{k \in \mathbb{N} \,|\, \beta(M,S;k) \geq g(k)\}$$

are both infinite.

VI.40, and the growth functions of Riemannian manifolds.

For further work after the paper of Grimaldi and Pansu quoted in VI.40, see [GriPa–01] and its bibliography.

VI.42, and growth of groups with respect to weights.

Growth with respect to generating sets and given weights are older than suggested by the references of Chapters VI and VII. In particular, in [PlaTh–76], Plante and Thurston define the growth of a countable group (*not* necessarily of finite type) with respect to a generating set (*not* necessarily finite) and a proper weight on it.

VI.42–43 and VII.35, on relative length functions and relative growth.

In the last line of page 176, read "relative length function" instead of "relative growth function". For relative growth of subgroups of solvable and linear groups, see [Osin–00].

VI.45, on word and Riemannian metrics.

See also [LubMR–00].

[2] This has been shown independently by several other mathematicians.

VI.56, on asymptotics of subadditive functions.

The correct conclusion of (i) should be that the sequence $\left(\frac{\alpha(k)}{k}\right)_{k\geq 1}$ either converges to $\inf_{k\geq 1}\frac{\alpha(k)}{k}$ *or diverges properly to* $-\infty$. (Since sequences appearing in the book are bounded below, the second case does not occur.)

VI.64, and groups of intermediate growth which are not residually finite.

Anna Erschler has shown that there exist uncountably many groups of intermediate growth which are commensurable up to finite kernel with the first Grigorchuk group, but which are not residually finite. She has also shown that there exist groups of intermediate growth which are not commensurable up to finite kernels with any residually finite group. See [Ersch–b].

VII.2, and a version of the Table-Tennis Lemma due to Margulis.

Proposition. *Let Γ be a group acting on a set X and let $a, b \in \Gamma$. Assume that there exists a non-empty subset U of X such that $b(U) \cap U = \emptyset$ and $ab(U) \cup a^2b(U) \subset U$. Then the semi-group generated in Γ by ab and a^2b is free; in particular, it is of exponential growth if Γ is finitely generated.*

Proof. Inside $U_\emptyset \doteqdot U$, the sets $U_1 = ab(U)$ and $U_2 = a^2b(U)$ are disjoint, since

$$ab(U) \cap a^2b(U) \;=\; a\Big(b(U)\cap U_1\Big) \;\subset\; a\Big(b(U)\cap U\Big) \;=\; \emptyset\,.$$

More generally, for each $n \geq 0$, let J_n denote the set of sequences of length n with elements in $\{1,2\}$; for each $\underline{j} = (j_1, \ldots, j_n) \in J_n$, define a subset $U_{\underline{j}} = a^{j_1}ba^{j_2}b\ldots a^{j_n}b(U)$ of U. For any $n \geq 1$ and $\underline{j}' \in J_{n-1}$, observe that the sets $U_{(1,\underline{j}')}$ and $U_{(2,\underline{j}')}$ are disjoint, since

$$U_{(1,\underline{j}')} \cap U_{(2,\underline{j}')} \;=\; a\Big(b(U_{\underline{j}'})\cap U_{(1,\underline{j}')}\Big) \;\subset\; a\Big(b(U)\cap U\Big) \;=\; \emptyset\,,$$

and that both are inside $U_{\underline{j}'}$. Thus, for two sequences $\underline{j}, \underline{j}' \in \bigcup_{n=0}^{\infty} J_n$, either the corresponding subsets $U_{\underline{j}}, U_{\underline{j}'}$ are disjoint, or one is strictly contained in the other; in other words, their inclusion order is that of the infinite rooted 2-ary tree (see Item VIII.1). The proposition follows. □

This version of the Table-Tennis Lemma was communicated by G.A. Margulis to the authors of [EsMoO–02], see VII.19 below.

VII.13, on tight growth of free groups and hyperbolic groups.

It is easy to show that, for any normal subgroup $N \neq 1$ of F_k and the canonical image $\underline{S}_k$ of S_k in Γ/N, the corresponding exponential growth rates satisfy the strict inequality $\omega(F_k/N, \underline{S}_k) < 2k-1$. G. Arzhantseva and I.G. Lysenok have shown the following generalization, which answers a question of [GrHa–97]. Let Γ be a non-elementary hyperbolic group, S a finite generating set and N an infinite normal subgroup of Γ; denote by $\underline{S}$ the canonical image of S in the quotient group Γ/N; then $\omega(\Gamma/N, \underline{S}) < \omega(\Gamma, S)$ [ArjLy].

VII.19, on uniformly exponential growth of solvable groups.

D. Osin has shown that any solvable group of exponential growth has uniformly exponential growth [Osin–a], thus solving Problem VII.19.B (see page 297); this has also been shown independently and shortly afterwards by J. Wilson (unpublished). More generally, Osin has shown that any elementary amenable group of exponential growth has uniformly exponential growth [Osin–b].

Also, D. Osin has shown that the uniform Kazhdan constant of an infinite Gromov hyperbolic groups is zero [Osin–c]

John Wilson has discovered *examples of groups which answer the main problem of Item VII.19* [Wilso]. More precisely, there exist groups which are isomorphic to their permutational wreath product with the alternating group on 31 letters. Let $\Gamma \approx \Gamma \wr A_{31}$ be any group of this kind; on the one hand, there exists a sequence $(S_n = \{x_n, y_n\})_{n \geq 1}$ of generating sets of Γ, with $x_n^2 = y_n^3 = 1$ for all $n \geq 1$, such that the limit of the corresponding exponential growth rates is 1, in formula $\lim_{n \to \infty} \omega(\Gamma, S_n) = 1$; on the other hand, for an appropriate choice of Γ, there exist non-abelian free subgroups in Γ, so that in particular Γ is of exponential growth.

VII.19, on uniformly exponential growth of linear groups.

It is a theorem of A. Eskin, S. Mozes and Hee Oh that, given an integer $N \geq 1$ and a field $\mathbb{K}$ of characteristic 0, a finitely generated subgroup of $GL(N, \mathbb{K})$ is of uniformly exponential growth if and only if it is not virtually nilpotent, namely if and only if it is of exponential growth (result of [EsMoO], announced in [EsMoO–02]).

In particular, this *solves Research Problem VII.19.C* (see page 297).

For other progress on uniformly exponential growth, see [BucHa-00], [GrHa–01a], and [GrHa–01b]. For an exposition on uniformly exponential growth, see [Harpe].

If constants measuring exponential growth often have uniform bounds in terms of the generating sets, other constants exhibit the opposite behaviour. For example, T. Gelander and A. Zuk have shown that, in many cases, Kazhdan constants depend in a crucial way on the chosen generating set [GelZu–02].

VII.29, group growth, and Gromov's theorem.

There is a brief survey on group growth and Gromov's theorem by D.L. Johnson [Johns–00].

Concerning polynomial growth for locally compact groups, V. Losert has published a second part to [Loser–87]: see [Loser–01].

VII.29, and growth of double coset classes.

Consider a *Hecke pair* (G, H), namely a group G and a subgroup H such that all orbits of the natural action of H on G/H are finite, or equivalently such that, for each $g \in G$, the indices of $H \cap gHg^{-1}$ in both H and gHg^{-1} are finite. It is a natural counting problem to estimate for each $g \in G$ the cardinality of the

H-orbit of gH in G/H, or equivalently the number of one-sided classes g_jH in the double class HgH.

The specific case of the pair $(SL(2,\mathbb{Z}[1/p]), SL(2,\mathbb{Z}))$, p a prime, appears in [BeCuH–02].

VII.34, and the growth of Følner sequences.

A question related to our Problem VII.34.A appears as Problem 14.27 in the Kourovka Notebook [Kouro–95], and has been answered in [Barda–01].

VII.38, and the growth of normal subgroups of finite index.

See [LarLu].

VII.39, growth of conjugacy classes, and growth of pseudogroups.

For growth of conjugacy classes in hyperbolic groups, see [CooKn–02] and [CooKn–b].

Growth of pseudogroups appears in connection with foliations in [Plant–75].

VII.40, and growth of infinitely generated groups.

See [PlaTh–76], and the above comment on Item VI.42.

VII.61, on the set of exponential growth rates.

Part of the problem was solved by Anna Erschler Dyubina, who has shown that *the set* Ω_2 *of exponential growth rates of* 2*-generated groups has the power of the continuum* (see [Ersch–02], [Ersch–a]).

VIII.7, and the adding machine.

The adding machine on the infinite 2-ary tree $\mathcal{T}^{(2)}$ can be economically (and recursively, compare VIII.9) defined as the element $\tau \in Aut(\mathcal{T}^{(2)})$ such that

$$\tau = a(1\,,\,\tau).$$

Observe that $\tau \neq 1$ since τ exchanges 0 and 1, and that τ is of infinite order since

$$\tau^2 = a(1,\tau)a(1,\tau) = (\tau,1)(1,\tau) = (\tau,\tau).$$

The simple and clever Proposition 20 of [Sidki–00] shows that an element $g \in Aut(\mathcal{T}^{(2)})$ is conjugate to τ if and only if it acts transitively on the set of 2^k vertices of the level $L^{(k)}$ for each $k \geq 0$.

Later, Sidki has shown that a solvable subgroup K of $Aut(\mathcal{T}^{(2)})$ which contains an element such as τ above is an extension of a torsion-free metabelian group by a finite 2-group. If furthermore K is nilpotent then it is torsion-free abelian [Sidki].

VIII.10.ii on automata and finitely generated groups.

This connexion is a very active subject of research; see among others [GriNS–00], [GriZu–a], [GriZu–b], and [Sidki-00].

VIII.31, a result of John Wilson.

At the end of this item, the "recent result" which is quoted was in fact essentially in John Wilson's Ph.D. thesis of 1971, as well as in [Wilso–72]. ("Essentially" in the sense that he did not use the words "branch groups".)

For these, [Grigo] contains comments and a sketchy proof, whereas details can be found in [Wilso].

VIII.32 and VIII.71, and elements of small lengths and large orders in the Grigorchuk group.

Proposition. *For any $n \in \mathbb{N}$, there exists $\gamma \in \Gamma$ such that*

$$\gamma^{2^n} \neq 1 \qquad \text{and} \qquad \ell(\gamma) \leq 2^n.$$

Proof (following a sketch of L. Bartholdi). Let $K = \langle abab \rangle^\Gamma$ be the normal subgroup of Γ of index 16 defined in VIII.30; recall that K is generated by

$$t = (ab)^2 \ , \quad v = (bada)^2 \ , \quad w = (abad)^2$$

and that $\psi^{-1}(K \times K)$ is a subgroup of K (the index is 4 by Exercise VIII.81, but we do not use this here). Let σ be the endomorphism of Γ defined in VIII.57. Since $\sigma(a) = aca$, $\sigma(b) = d$, $\sigma(d) = c$, and $\sigma(c) = b$, we have $\psi\sigma(a) = (d, a)$, $\psi\sigma(b) = (1, b)$, $\psi\sigma(c) = (a, c)$, $\psi\sigma(d) = (a, d)$. It follows that $\psi\sigma(x) = (1, x)$ for $x \in \{t, v, w\}$, and therefore for all $x \in K$.

Define inductively a sequence $(x_i)_{i \geq 0}$ by $x_0 = abab$ and $x_{i+1} = a\sigma(x_i)$. Since

$$\psi\left(a\sigma(x_i)a\sigma(x_i)\right) = (x_i, x_i),$$

the order of x_{i+1} is twice that of x_i. As x_0 is of order 8 by Proposition VIII.16, it follows that the order of x_i is 2^{i+3} for all $i \geq 0$.

On the other hand, denote by w_0 the word $abab$ representing x_0; for each $i \geq 0$, let w_{i+1} the word obtained from w_i by

- substitution of aca, d, b, c in place of a, b, c, d respectively,
- deletion of a if it appears as the first letter and addition of a as a prefix letter otherwise,

so that w_{i+1} represents x_{i+1}. Thus $w_1 = cadacad$ and, for each $j \geq 0$,

- w_{2j+1} is a word of length $2\ell\left(w_{2j}\right) - 1$ which begins with c and ends with a letter from $\{b, c, d\}$,
- w_{2j+2} is a word of length $2\ell\left(w_{2j+1}\right)$ which begins with a and ends with a letter from $\{b, c, d\}$;

in particular, $\ell(x_i) \leq \ell(w_i) < 2^{i+2}$ for all $i > 0$. The proposition follows (with $x = x_{n-2}$ for $n \geq 2$). □

VIII.67, and power series with finitely many different coefficients.

Here is a result of Szegö: a power series with finitely many different coefficients that converges inside the unit disk is either a rational function, or has the unit circle as natural boundary [Szegö–22].

VIII.88, complement on commensurability of finitely-generated subgroups.

It is a remarkable result of Grigorchuk and Wilson that any infinite finitely-generated subgroup of the Grigorchuk group Γ is commensurable to Γ [GriWi]. In other words, Γ has exactly two commensurability classes of finitely-generated subgroups: itself and $\{1\}$.

Here are a few examples of other groups for which all commensurability classes of finitely-generated subgroups are known; in case of torsion-free groups, we do not list the class of $\{1\}$.

(i) Free abelian groups $\mathbb{Z}^n$, with $\mathbb{Z}^j$ for $j \in \{1, \dots, n\}$.

(iii) The Heisenberg group $\begin{pmatrix} 1 & \mathbb{Z} & \mathbb{Z} \\ 0 & 1 & \mathbb{Z} \\ 0 & 0 & 1 \end{pmatrix}$, with $\mathbb{Z}$, $\mathbb{Z}^2$ and the group itself.

(iii) Non-abelian free groups F_n, with $\mathbb{Z}$ and F_2.

(iv) Virtually free groups, for example $PSL(2, \mathbb{Z})$, with finite subgroups, $\mathbb{Z}$ and F_2.

(v) The fundamental group Γ_g of a closed surface of genus $g \geq 2$, with $\mathbb{Z}$, F_2 and the group itself.

(vi) Olshanskii's "monsters" (see the reference in III.5, as well as [AdyLy–92]), in which any proper subgroup is cyclic.

VIII.87, on complex linear representations of the Grigorchuk group.

For each $k \geq 0$, let Γ_k denote as in VIII.35 the finite quotient of the Grigorchuk group which acts naturally on the level $L(k)$ of the binary tree. Choose some point in $L(k)$ and denote by P_k the corresponding isotropy subgroup of Γ_k. Then (Γ_k, P_k) is a *Gelfand pair,* and the natural linear representation of Γ_k on the space $\mathbb{C}^{L(k)}$ splits as a direct sum of $k+1$ pairwise inequivalent irreducible representations, of dimensions $1, 1, 2, 4, \dots, 2^{k-1}$ [BeHaG].

Isolating critical cases for reciprocals using integer factorization

Abstract

One approach to testing and/or proving correctness of a floating-point algorithm computing a function f is based on finding input floating-point numbers a such that the exact result $f(a)$ is very close to a "rounding boundary", i.e. a floating-point number or a midpoint between them. In the present paper we show how to do this for the reciprocal function by utilizing prime factorizations. We present the method and show examples, as well as making a fairly detailed study of its expected and worst-case behavior. We point out how this analysis of reciprocals can be useful in analyzing certain reciprocal algorithms, and also show how the approach can be trivially adapted to the reciprocal square root function.

1 Background

Suppose we have a floating-point algorithm computing a function that approximates a true mathematical function $f : \mathbb{R} \to \mathbb{R}$. For example, consider the following algorithm for the Intel® Itanium® architecture designed to compute a floating-point square root $\sqrt{a}$ using an initial reciprocal square root approximation followed by a sequence of fused multiply-adds. (In the actual implementation, the initial approximation instruction deals with special cases including $a = 0$.)

1.	$y_0 = \texttt{frsqrta}(a)$	
2.	$H_0 = \frac{1}{2} y_0$	$S_0 = a y_0$
3.	$d_0 = \frac{1}{2} - S_0 H_0$	
4.	$H_1 = H_0 + d_0 H_0$	$S_1 = S_0 + d_0 S_0$
5.	$d_1 = \frac{1}{2} - S_1 H_1$	
6.	$H_2 = H_1 + d_1 H_1$	$S_2 = S_1 + d_1 S_1$
7.	$d_2 = \frac{1}{2} - S_2 H_2$	$e_2 = a - S_2 S_2$
8.	$H_3 = H_2 + d_2 H_2$	$S_3 = S_2 + e_2 H_2$
9.	$e_3 = a - S_3 S_3$	
10.	$S = S_3 + e_3 H_3$	

If an algorithm is, like this one, implemented by composing basic floating-point operations (rather than, say, some more complicated analysis of bit-patterns), then the value computed can usually be represented as the result of rounding some approximation $f^*(x) \approx f(x)$, the value before the final rounding. In this case, the final S results from rounding the exact value $S_3 + e_3 H_3$.

The algorithm will therefore round correctly for all inputs x such that $f^*(x)$ and $f(x)$ round to the same number (for all the rounding modes under consideration). In the concrete square root example, this means that $\sqrt{a}$ and $S_3 + e_3 H_3$ should always round the same way.

A sufficient condition for equivalent rounding behavior is that the two values $f^*(x)$ and $f(x)$ should never be separated by a rounding boundary, i.e. a floating-point number (for directed rounding) or a midpoint (for round-to-nearest). That is, there is never a rounding boundary m with $f(x) \leq m \leq f^*(x)$ or $f^*(x) \leq m \leq f(x)$, unless $f^*(x) = f(x)$. (Not quite a necessary condition in the round-to-nearest mode since if one is exactly equal to the rounding boundary and the other on the "right" side, the correct result will be obtained.) This is usually hard to establish by analytic reasoning. However, it is usually easy to establish some sort of relative error bound ϵ such that:

$$|f^*(x) - f(x)| \leq \epsilon |f(x)|$$

Therefore, misrounding can occur only when

$$|f(x) - m| \leq \epsilon |f(x)|$$

It is therefore interesting for purposes of both testing and proving correctness to deliberately concoct test points x to make the relative distance from a rounding boundary $|f(x) - m|/|f(x)|$ as small as possible. Indeed, irrespective of the details of the algorithms we are concerned with, these test points might be expected to display greatest sensitivity to the accuracy of $f^*(x)$ and so show up errors most easily.

For some basic algebraic functions, such special x can be found analytically using number-theoretic techniques [14, 11], in such a way that the very worst examples (having the smallest relative distance from a rounding boundary) are isolated. For transcendental functions, this is more difficult, but one can still generate good cases by exploiting local linearity and solving congruences. For double-precision it is feasible, though costly, to isolate the very worst examples [6].

One use of the points so obtained is to test floating-point functions. Indeed, Parks [11] reports that such testing exposed a bug in a commercial microprocessor. A more ambitious goal, realized for square root algorithms by Cornea [1], is to isolate a sufficiently large set of points that the correct behavior of the algorithm on these, in conjunction with an analytical proof that covers all other cases, gives a complete correctness proof of the algorithm in all cases. For example, if we can prove analytically that for all floating-point numbers x we have:

$$|f^*(x) - f(x)| \leq \epsilon |f(x)|$$

and that some set S_ϵ contains all points x where $|m - f(x)| \leq \epsilon |f(x)|$ for some rounding boundary m, the correctness of the algorithm in all cases is equivalent to the correctness just for the points in S_ϵ. If such sets can be found easily and they are not too large, this gives a very effective methodology for proofs of algorithms. The goal of this paper is to show how to isolate such special cases for the reciprocal (and reciprocal square root) function and demonstrate their applicability in such correctness proofs of algorithms.

2 Critical cases for quotient and reciprocal

We will in what follows consider a single floating-point format with precision p, which contains all the floating-point numbers concerned and is also the destination format for the result. We also ignore the possibility of overflow and underflow in computation sequences. This keeps the presentation simpler and accords well with the intended applications where all input numbers are double-extended and additional exponent range (but not precision) is available for intermediate computations. The results that follow can straightforwardly be refined for mixed-precision applications.

It's instructive to examine the problem for the general case of quotients, and then contrast the restriction to the reciprocal. In general, we seek floating-point numbers x and y such that x/y lies close to some w that is either itself a floating-point number or a midpoint between two floating-point numbers. Without loss of generality, we can assume:

$$\begin{array}{ll} x = 2^{e_x} a & 2^{p-1} \leq a < 2^p \\ y = 2^{e_y} b & 2^{p-1} \leq b < 2^p \\ w = 2^{e_w} m & 2^p \leq m < 2^{p+1} \end{array}$$

where p is the floating-point precision and a, b and m, as well as the various e_i, are integers. Note that even values of m correspond to floating-point numbers and odd values correspond to midpoints. We are interested in how small the relative difference $|x/y - w|/|x/y|$ can become. This relative difference can be rewritten as:

$$\frac{|x/y - w|}{|x/y|} = |1 - wy/x| = |1 - 2^{-q} mb/a|$$

where $q = e_x - (e_w + e_y)$, and so

$$\frac{|mb - 2^q a|}{2^q a}$$

Given the ranges of the values a, b and m, we have

$$2^{2p-1} \leq mb < 2^{2p+1}$$

and

$$2^{q+p-1} \leq 2^q a < 2^{q+p}$$

It turns out that the only interesting cases are when $q = p$ or $q = p + 1$. For if $q \leq p - 1$ then $q + p \leq 2p - 1$ so we have

$$2^q a \leq 2^q (2^p - 1) < 2^{2p-1} \leq mb$$

(remember that the values a, b and m are integers so when $< 2^r$ they are actually $\leq 2^r - 1$) and so

$$\frac{|mb - 2^q a|}{2^q a} \geq 2^q / (2^q a) = 1/a > 2^{-p}$$

.

Similarly if $q = p + 2$ we have:

$$mb \leq (2^p - 1)(2^{p+1} - 1) < 2^{2p+1} \leq 2^{p+2} a < 2^{2p+2}$$

and therefore

$$\frac{|mb - 2^q a|}{2^q a} \geq (2^{p+1} + 2^p - 1)/(2^q a) > 2^{p+1}/2^{2p+2} = 2^{-(p+1)}$$

Finally, if $q \geq p + 3$ then $2^q a > 2mb$ and so

$$\frac{|mb - 2^q a|}{2^q a} > 1/2$$

In all these cases, the distance is at least $2^{-(p+1)}$. Therefore, when seeking cases where the distance is of order 2^{-2p} (for realistic p) we need only consider $q \in \{p, p + 1\}$. This

being the case, the denominator $2^q a$ is constrained to within a factor of 4, so the essential problem is to find how small

$$|mb - 2^q a|$$

can become for $q \in \{p, p+1\}$. Since the value is an integer, we can try to find small values by explicit consideration of the various possibilities in succession:

$$\begin{aligned}
mb &= 2^p a + 1 \\
mb &= 2^p a - 1 \\
mb &= 2^{p+1} a + 1 \\
mb &= 2^{p+1} a - 1 \\
mb &= 2^p a + 2 \\
mb &= 2^p a - 2 \\
mb &= 2^{p+1} a + 2 \\
mb &= 2^{p+1} a - 2 \\
mb &= 2^p a + 3 \\
&\dots
\end{aligned}$$

It seems that the number of possible solutions of these equations is too large for this to be a practical approach. On the other hand, if we fix any one of the values a, b and m, the problem becomes tractable. If we fix either m or b then the problem becomes a set of linear congruences (with additional range restrictions filtering the possible solution set), which are easy to solve. If we consider the special case of the reciprocal, then we fix $a = 2^{p-1}$. This problem is also tractable, as we shall see, but has a somewhat different character. We just need to consider

$$\begin{aligned}
mb &= 2^{2p-1} + \delta \\
mb &= 2^{2p} + \delta
\end{aligned}$$

for successive small integers δ. In fact, the situation is even better, because once again no small values can arise in the former case because of the range limitation, except for the trivial $mb = 2^{2p-1}$; the next case must be $(2^p + 1)2^{p-1} = 2^{2p-1} + 2^{p-1}$. So we need only be concerned with solutions to

$$mb = 2^{2p} + \delta$$

for integers $2^{p-1} \le b < 2^p$ and $2^p \le m < 2^{p+1}$. Indeed, for small δ, it is easy to see that the two upper bounds imply the lower ones.

3 Factorization distribution

Our approach to the problem of finding all solutions to $mb = 2^{2p} + \delta$ (with p and δ fixed) is quite straightforward. We find the prime factorization of $2^{2p} + \delta$, and consider all possible ways of distributing these prime factors into two parts m and b subject to the appropriate range limitation $m < 2^{p+1}$ and $b < 2^p$. In general, we will refer to a factorization $n = ab$ of n with $a < A$ and $b < B$ as an (A, B)-*balanced* factorization.

Consider, for illustration, the case $p = 6$ and $\delta \in \{\pm 1, \pm 2, \pm 3\}$. In each case we find the prime factorization of $2^{2p} + \delta$:

$$\begin{aligned}
2^{12} + 1 &= 17 \cdot 241 \\
2^{12} - 1 &= 3^2 \cdot 5 \cdot 7 \cdot 13 \\
2^{12} + 2 &= 2 \cdot 3 \cdot 683 \\
2^{12} - 2 &= 2 \cdot 23 \cdot 89 \\
2^{12} + 3 &= 4099 \\
2^{12} - 3 &= 4093
\end{aligned}$$

In the cases $2^{12}+1$, $2^{12}+2$, $2^{12}+3$ and $2^{12}-3$, the largest factor is already $> 2^{p+1} = 128$, so there is no possible distribution obeying the range restrictions. For $2^{12} - 2$ there is exactly one such distribution:

$$m \cdot b = 89 \cdot (2 \cdot 23) = 89 \cdot 46$$

Note that the 'symmetrical' distribution is not admissible because $89 > 2^p$. For $2^{12} - 1$, there are four possible distributions:

$$\begin{aligned}
m \cdot b &= (3^2 \cdot 13) \cdot (5 \cdot 7) = 117 \cdot 35 \\
m \cdot b &= (3 \cdot 5 \cdot 7) \cdot (3 \cdot 13) = 105 \cdot 39 \\
m \cdot b &= (7 \cdot 13) \cdot (3^2 \cdot 5) = 91 \cdot 45 \\
m \cdot b &= (5 \cdot 13) \cdot (3^2 \cdot 7) = 65 \cdot 63
\end{aligned}$$

Note that the corresponding m are all odd, and therefore represent midpoints. Thus, we can say that $|1/y - w| \ge 4/2^{12}|1/y|$ for any midpoint w except in the cases where y's significand b is in the set $\{35, 39, 45, 46, 63\}$; for $b = 46$ we get a $2/2^{12}$ relative distance and for 35, 39, 45 and 63 we get $1/2^{12}$. Since the above lists exhausts all m, even or odd, we see that $|1/y - w| \ge 4/2^{12}|1/y|$ for any floating-point number w, except for the special cases when y is a power of 2 and so its reciprocal is exactly representable (i.e. $1/y = w$).

4 Implementation

The implementation of the above idea is straightforward, given any reasonable programming language. We have used Objective CAML, a very high-level functional language that we have previously used extensively for implementation of theorem proving code:

`http://www.ocaml.org/`

This already has a multiprecision integer and rational function datatype available. It does not, however, have a built-in library for factoring numbers, and we did not want to write our own code for this operation — since the numbers can be as large as 2^{226} (for quad precision reciprocals), factorization is a non-trivial problem. We used the factoring code included in the PARI / GP system:

`http://www.parigp-home.de/`

The documentation says:

factorint$(n, \{flag = 0\})$: factors the integer n using a combination of the Shanks SQUFOF and Pollard Rho method (with modifications due to Brent), Lenstra's ECM (with modifications by Montgomery), and MPQS (the latter adapted from the LiDIA code with the kind permission of the LiDIA maintainers), as well as a search for pure powers with exponents≤ 10.

We are not experts in the topic of factorization, but have been quite impressed with how fast it usually factors numbers. Only for quad precision, when the numbers are of the order 2^{226}, does it start to slow down noticeably. Rather than a strict primality test, the factors are only subjected to a strong probabilistic primality test. Therefore, out of paranoia, we have developed our own code to certify primality, by constructing prime certificates in the style of Pratt [12], appealing to Lucas's theorem. That is, to certify that each p occurring in PARI/GP's factorization is prime, we show that there is a primitive root a modulo p such that $a^{p-1} \equiv 1 \pmod{p}$ but $a^{\frac{p-1}{q}} \not\equiv 1 \pmod{p}$ for any prime factor q of $p-1$. (The primitive root a is found randomly, and the factors q of $p-1$ are found by using PARI/GP's factorization recursively, certifying those factors as primes too.) This certification slows down the factorization process by a moderate amount, so we sometimes switch it off when experimenting.

Once we have the prime factors, we need to test all ways of distributing them over two numbers subject to range restrictions. As noted, we need only apply the upper range restrictions $m < 2^{p+1}$ and $b < 2^p$. Roughly, we just naively enumerate all possibilities. In order to cut off choice points as soon as possible, we start distributing from the largest prime factors, i.e. consider the prime factors $p_1^{\alpha_1} \cdot p_2^{\alpha_2} \cdot \cdots \cdot p_k^{\alpha_k}$ in decreasing order $p_1 > p_2 > \cdots > p_k$. We first consider all $\alpha_1 + 1$ ways of distributing $p_1^{\alpha_1}$ into two parts. If any of these distributions already violate the range restriction, they are abandoned. Otherwise, for each one, we consider the $\alpha_2 + 1$ ways of distributing $p_2^{\alpha_2}$, and so on. The algorithm is very straightforward to program recursively in OCaml.

It might be doubted whether such a naive distribution algorithm is acceptably efficient. At least it has been adequate to obtain some results quite quickly for the main precisions that interest us, $p \in \{24, 53, 63, 113\}$. We first look at some of these results and then turn to a detailed performance analysis.

5 Results

Table 1 presents a small sample of the results obtained using the methods outlined above. For each of the four major precisions $p = 24, 53, 64, 113$, we list the 66 floating-point significands whose reciprocals are closest either to floating-point numbers or midpoints. This distance, as a multiple of the corresponding 2^{-2p}, is given in the 'd' columns. When, as often happens, several reciprocals have the same 'd' value we order them in decreasing order, and cut the table off on that basis. The asterisk means that the distance is from a floating-point number (and hence may be unimportant if we are concerned only with round-to-nearest).

Larger lists for d up to a few thousand can be generated for all these precisions without requiring more than a few days of runtime on a modern machine. And of course, it is trivial to parallelize the task since it consists of a separate subtask for each d considered.

6 Applications

We can use the techniques set out above in the design and verification of algorithms for correctly rounded reciprocals. These might be substituted by the programmer, or by the compiler if it can recognize that in an expression a/b, the constant a is guaranteed to be 1. (This could be generalized to any power of 2.) For example, the following algorithm is normally used for double-extended precision division (precision $p = 64$) on Intel® Itanium® processors.

1.	$y_0 = \texttt{frcpa}(b)$	
2.	$d = 1 - by_0$	$q_0 = ay_0$
3.	$d_2 = dd$	$d_3 = dd + d$
4.	$y_1 = y_0 + y_0 d_3$	$d_5 = d_2 d_2 + d$
5.	$y_2 = y_0 + y_1 d_5$	$r_0 = a - bq_0$
6.	$e = 1 - by_2$	$q_1 = q_0 + r_0 y_2$
7.	$y_3 = y_2 + ey_2$	$r = a - bq_1$
8.	$q = q_1 + ry_3$

Table 1. Some numbers with reciprocals closest to numbers(*) and midpoints

As usual in algorithms of this kind, each operation uses a fused multiply-add (*not* a separate multiplication and addition), all steps but the last are performed in round-to-nearest mode with additional exponent range precluding the possibility of intermediate overflow or underflow, and the last operation is done in the intended rounding mode and target precision.

Embedded in this algorithm is the computation of a very accurate reciprocal approximation y_3. Originally, in the design of algorithms of this kind, the correctness of the final rounding of q was justified by a theorem whose precondition requires perfect rounding of y_3 [9], and only later was it noted by the present author that a relative error $y_3 = \frac{1}{b}(1+\epsilon)$ for $|\epsilon| < 2^{-p}$ suffices, which can be satisfied by a relatively weak error condition on y_2 and the analysis of a few special cases [3, 8]. However, if we are in a situation where $a = 1$ we might consider, instead of using the entire sequence, unpicking the algorithm for reciprocation to be used directly, since its latency is shorter by 1 operation, and it uses only 9 floating-point operations instead of 14:

1. $y_0 = \texttt{frcpa}(b)$
2. $d = 1 - by_0$
3. $d_2 = dd$ $\qquad$ $d_3 = dd + d$
4. $y_1 = y_0 + y_0 d_3$ $\qquad$ $d_5 = d_2 d_2 + d$
5. $y_2 = y_0 + y_1 d_5$
6. $e = 1 - by_2$
7. $y = y_2 + ey_2$

Now the question of whether y is always correctly rounded becomes critical. First we will consider round-to-nearest. The initial approximation returned by `frcpa` will satisfy $y_0 = \frac{1}{b}(1+\epsilon_0)$ for some $|\epsilon_0| \leq 2^{-8.886}$. A routine relative error analysis, assuming each rounding $rn(x)$ yields $x(1+\epsilon)$ for some $|\epsilon| \leq 2^{-64}$, shows that y^*, the value of y before the last rounding, satisfies

$$y^* = \frac{1}{b}(1+\epsilon)$$

where $|\epsilon| \leq 2^{-123.37}$. Therefore, the only cases where incorrect rounding can occur are those closer than this relative distance to a midpoint. The potentially failing significands b can be isolated by finding all $(2^{65}, 2^{64})$-balanced factorizations $mb = 2^{128} + d$ for integers $|d| \leq 24$ (since $24 + 1 > 2^{-123.37}/2^{-128}$) and m odd. The set of b values that we need to consider are the following 134 (ordered in decreasing size, not according to their closeness to a midpoint):

```

One can show by explicit computation that the algorithm works correctly on these values. It therefore rounds correctly on all values in round-to-nearest.

For directed rounding modes, the situation is less good. Once again the relative error condition gives rise to a set of test points, this time 227 of them. The algorithm works correctly on 220 of them, but not on floating-point numbers with one of the following 7 significands, the last of these representing exact powers of 2, for which the true result is exactly representable. Cognoscenti who perform a back-of-envelope calculation will not be surprised by the failure on exactly representable results, since correctness here would require y_2 already to be the correct result, which our relative error cannot quite guarantee.

```

0x8080402010080401 0x8000080000400001 0x8000000000000001
0x8000000000000000
```

This analysis indicates that the algorithm will produce correctly rounded results if the ambient rounding mode is known to be round-to-nearest, but will not always guarantee correct rounding in other rounding modes. Moreover, note that for the same reason, the 'inexact' flag will be incorrectly set in round-to-nearest mode in the special cases where b is a power of 2. (As noted, the penultimate approximation y_2 cannot be the exact reciprocal in such cases, for otherwise we would obtain $e = 0$ and correct rounding in all

modes.) However, if this is considered important, it would be easy to detect and fix the problem with special case code without affecting overall latency.

7 Feasibility study

Although the previous sections show that the method is usefully applicable to some real problems, it's worth analyzing how practical the approach is likely to be in general. In attempting to use the method, three potential practical problems might arise

- Too many special points are isolated for further analysis to be feasible
- The factorization of some of the numbers is not feasible
- The distribution of prime factors is not feasible

We will not analyze the feasibility of factorization, since we do not understand the details of its implementation. We will however make the empirical observation that all factorizations for precisions up to $p = 64$ seem to be very straightforward for PARI / GP, taking a fraction of a second, while those for $p = 113$ usually take several seconds and, exceptionally, minutes.

Average density of balanced factorizations

It is not difficult to see that "on average" we obtain a fairly modest number of balanced factorizations per value examined. First note that the number of (A, B)-balanced products of numbers $\leq n$ is the number of lattice points contained both within the rectangle $0 \leq x \leq A$, $0 \leq y \leq B$ and under the curve $xy = n$. We can get a good estimate by ignoring "edge effects" and just considering the plane area, integrating to obtain:

$$C(n) = n(1 + \ln(\frac{AB}{n}))$$

Differentiating with respect to n yields the expected density, i.e. the average number of (A, B)-balanced product representations of a number close to n:

$$D(n) = \ln(AB/n)$$

Of course, these gross averages do not reflect small-scale fluctuations. Nevertheless, the agreement is fairly good with some empirical results obtained by sampling. In the following table, we examine the density of $(2^p, 2^p)$-balanced products for several p, looking in each case at 31 regions close to $\frac{k+1/2}{32}2^{2p}$ for $0 \leq k \leq 31$ and sampling 1024 successive points in each. The final figures at the bottom give the mean value. This indicates how accurate the sampling process is on average; perfectly representative sampling would give exactly 1 here. (We avoid sampling at $\frac{k}{32}2^p$ because that would lead to strong correlations between the sets of numbers at different k.)

$\ln(2^{2p}/n)$	$p = 24$	$p = 53$	$p = 64$
4.1588	4.4785	4.6835	3.3300

1.0000	0.9660	1.0701	0.9755

So much for the average case. What about the worst case? This seems a more difficult question to address theoretically, but in the next section we will show how to obtain a pessimistic upper bound.

Feasibility of distribution algorithm

Although the final number of values produced depends on the number of balanced factorizations, the process by which the balanced factorizations are enumerated involves examination of many dead-end paths, so the runtime of the distribution process may be very large relative to the final number of possibilities produced. A reasonable, though pessimistic, bound on the runtime of the distribution algorithm for a value n is $d(n)$, the *total* number of divisors of n, regardless of balance. For even without early cutoffs owing to range limitations, the algorithm cannot examine, given

$$n = \Pi_{i=1}^{i=k} p_i^{\alpha_i}$$

more than

$$d(n) = \Pi_{i=1}^{i=k} (1 + \alpha_i)^n$$

possibilities, since each factor $p_i^{\alpha_i}$ can, without range cutoffs, be distributed in $1 + \alpha_i$ ways.

It is well known that the average number of divisors $d(n)$ of a number near n is approximately $d(n) = \ln(n)$. This can easily be derived using the same sort of argument as we used above for balanced products [2]. This suggests that on average, the distribution process will not have many cases to examine; even for quad precision, we have $n \leq 2^{230}$ and so $\ln(n) \leq 160$.

What about the worst case? The number of divisors of a number can be much larger than $\ln(n)$. In fact [2], *almost all* numbers (in a precise sense) have about $\ln(n)^{\ln(2)}$ divisors, with the larger overall average of $\ln(n)$ resulting from a small proportion of numbers with many more divisors. Asymptotically, it is known [2] that $d(n)$ has an upper limit of exactly $2^{\ln(n)/\ln(\ln(n))}$, or more precisely, that if $\epsilon > 0$ then $d(n) < 2^{(1+\epsilon)\ln(n)/\ln(\ln(n))}$ for all sufficiently large n, while $d(n) > 2^{(1-\epsilon)\ln(n)/\ln(\ln(n))}$ for infinitely many n.

This asymptotic limit needs refinement to be useful to us for the concrete ranges we are interested in. We can obtain a more refined estimate of the maximum $d(n)$ for all n below some limit N we are interested in as follows. The key to efficient search is to seek the *minimal* n with the *maximal* number of divisors possible for $n \leq N$. The minimality constraint forces strong patterns onto the prime factorization. Suppose that n has the following prime factorization:

$$n = \Pi_{i=1}^{i=k} p_i^{\alpha_i}$$

Let $p_i < p_j$ be two primes (not necessarily appearing with nonzero index in the above factorization) such that $p_i^{\beta} < p_j < p_i^{\beta+1}$ for some nonnegative integer β. Then it is easy to see that if n has the minimality property, the following relationships hold between the α's:

$$\beta\alpha_j \leq \alpha_i \leq (\beta + 1)\alpha_j + 2\beta$$

For if the first inequality failed we could get a smaller number with at least as many divisors by replacing $p_i^{\alpha_i} p_j^{\alpha_j}$ with $p_i^{\alpha_i+\beta} p_j^{\alpha_j-1}$, while if the second inequality failed we could likewise replace it with $p_i^{\alpha_i-(\beta+1)} p_j^{\alpha_j+1}$.

This observation includes the case where p_j is the first prime beyond those appearing in the factorization, and in this case $\alpha_i \leq 2\beta$. For example, if 17^{α} appears in the factorization, so must $3^{2\alpha}$ and $2^{4\alpha}$, while if no power of 17 appears in the factorization then the highest possible power of 2 appearing is 2^8, and the highest power of 3 is 3^6. Note in particular that the factorization of the minimal n must contain the first k consecutive primes without gaps, for some k.

These observations cut down the search space dramatically enough that we can easily perform an exhaustive search for the precise worst numbers up to quite large values, say 2^{3000}. The following table shows, for various values of p up to 230, the minimal $n \leq 2^p$ with the largest number of divisors possible in that range. For each such n, we show $\log_2(n)$ and $\log_2(d(n))$ (where $d(n)$ is the number of divisors of n), as well as the ratio with the expected limit superior $r(n) = \log_2(d(n))/(\ln(n)/\ln(\ln(n)))$ and the actual factorization of n.

p	$\log_2(n)$	$\log_2(d(n))$	$r(n)$	Factorization of that worst n
10	9.71	5.00	1.416	$2^3\ 3\ 5\ 7$

150	149.74	31.66	1.416	$2^9\ 3^5\ 5^3\ 7^2\ 11^2\ 13^2\ 17 \cdots 97$
160	159.79	33.14	1.408	$2^8\ 3^6\ 5^3\ 7^3\ 11^2\ 13^2\ 17 \cdots 101$
170	169.83	34.66	1.404	$2^9\ 3^5\ 5^3\ 7^2\ 11^2\ 13^2\ 17 \cdots 107$
180	179.99	36.14	1.398	$2^8\ 3^6\ 5^3\ 7^3\ 11^2\ 13^2\ 17 \cdots 109$
190	189.82	37.56	1.393	$2^9\ 3^5\ 5^4\ 7^2\ 11^2\ 13^2\ 17^2\ 19 \cdots 113$
200	199.88	39.02	1.388	$2^{10}\ 3^6\ 5^3\ 7^3\ 11^2\ 13^2\ 17^2\ 19 \cdots 127$
210	209.93	40.43	1.383	$2^{10}\ 3^6\ 5^3\ 7^3\ 11^2\ 13^2\ 17 \cdots 137$
220	219.87	41.83	1.379	$2^8\ 3^5\ 5^4\ 7^3\ 11^2\ 13^2\ 17^2\ 19 \cdots 139$
230	229.92	43.21	1.375	$2^{10}\ 3^5\ 5^3\ 7^3\ 11^2\ 13^2\ 17 \cdots 151$

We can see that even for double-extended precision, the number of factorizations that could possibly need to be examined is about 2^{28}. Although a fairly large number, this is definitely feasible. (And of course in practice such cases are exceptional and not all factorizations would be examined.) For quad precision, on the other hand, it is entirely possible for the search to be infeasible. We have not yet encountered this phenomenon in practice, however.

Note that $d(n)$ also gives an upper bound to the number of balanced factorizations. It is, of course, pessimistic, but testing on some of the values above suggests that the the number of balanced factorizations is a reasonable proportion (say 10%) of the total number of divisors. Naturally, it would be better to refine all these estimates to consider only numbers very close to the powers of 2, which is what we are really interested in.

The special numbers that we searched for above are particular cases of *highly composite numbers* [13]. For a detailed survey of the subject see [10], while Achim Flammenkamp's Web page seems to give a more efficient algorithm for generating HCNs:

`http://wwwhomes.uni-bielefeld.de/achim/highly.html`

The sequence of highly composite numbers is A002182 in Sloane's Encyclopedia of Integer Sequences.

8 Extension to reciprocal square root

It is interesting to note that a similar factor distribution technique can be used to attempt to find exceptional cases

for the reciprocal square root. In this case, we seek floating-point numbers or midpoints w and floating-point numbers y such that

$$\frac{|w - \frac{1}{\sqrt{y}}|}{|\frac{1}{\sqrt{y}}|}$$

is small. We can rewrite this as:

$$|\sqrt{y}(w - \frac{1}{\sqrt{y}})| = |w\sqrt{y} - 1|$$

In the critical cases where $w\sqrt{y} - 1$ is very small, then $w\sqrt{y} + 1$ is almost exactly 2 and so:

$$|w\sqrt{y} - 1| = \frac{|w^2 y - 1|}{|w\sqrt{y} + 1|} \approx \frac{|w^2 y - 1|}{2}$$

Once again, let us scale the values w and y to integers m and b:

$$\begin{array}{ll} y = 2^{e_y} b & 2^{p-1} \leq b < 2^p \\ w = 2^{e_w} m & 2^p \leq m < 2^{p+1} \end{array}$$

and then the distance we are interested in is then:

$$\frac{|m^2 b - 2^q|}{2^{q+1}}$$

where $q = -(2e_w + e_y)$. So we seek cases where $d = m^2 b - 2^q$ is as small as possible. Keeping in mind the range restrictions, we see that $2^{3p-1} \leq m^2 b < 2^{3p+2}$. As with simple reciprocals, it is impossible to come very close to the extremal powers of 2, but we do now need to consider two cases, $q = 3p$ and $q = 3p + 1$.

The reciprocal square root function is of some theoretical interest because it seems *prima facie* possible that $d = m^2 b - 2^q$ could be very small, perhaps even ± 1, yet no precisions where it is much smaller than 2^p have ever been found, and one might expect on naive statistical grounds that it is unlikely. (We only have 2^{2p} different choices of pairs m and b, and are scattering the resulting $m^2 b$'s somehow over an interval of size about 2^{3p}.) Li [7] proves that *assuming* the ABC conjecture from number theory holds, the distance is indeed of order 2^p for all sufficiently large p. Even if the ABC conjecture were proven, however, it's not clear whether it would be possible to constructivize the proof in order to obtain useful bounds for specific precisions. Iordache and Matula [4] observe that $d = 1$ is impossible in general, allowing the accuracy required to be lowered slightly, but add that 'trying to lower it is not an easy problem, even for a fixed p'. Although the present work does not touch the general case, and nor can it fully bridge the gap between expected and provable bounds, it *does* allow us quite easily to improve the provable bound for the typical p we are interested in by a reasonable factor.

We can take over the prime distribution function with little change. The only difference is that we now need to distribute the prime factors among $m^2 b$. This has the immediate consequence that only even powers of primes can be allocated to the m^2 part, and so any prime appearing to an odd power in the prime factorization of $2^q + d$ must be allocated at least once to b. This is almost always enough to render the distribution immediately impossible. We have made some searches for double-extended precision ($p = 64$) and quad precision ($p = 113$). For double-extended, we have shown that $d \leq 1024$ is impossible, and it would be easy to continue the search much further. For quad precision, the cost of factoring numbers is now a serious bottleneck, with a single number sometimes taking a day of CPU time and one of the factorizations for the $d = 6$ case apparently defeating factorization in a reasonable time. Nevertheless we have at least shown that $d < 6$ is impossible, which represents some improvement. For smaller precisions, it seems likely that other algorithms based on an (intelligent) exhaustive analysis of the whole space of significands would be more efficient. For example Lang and Muller [5] have performed a complete analysis of the double-precision case $p = 53$ (and found that the minimal distance is about 2^{-110}).

9 Conclusion

The methods described here allow reasonably effective isolation of the 'worst cases' for the reciprocal function. This opens the way to correctness proofs of reciprocal algorithms using the same kind of two-part approach used by Cornea [1] for square roots. In the absence of new theoretical advances, the method described may also be the best available means of improving the difficulty bounds on the reciprocal square root functions for larger precisions. Although our method has feasibility problems for the extreme case of quad-precision reciprocal square roots, it would be possible to explore alternative factoring algorithms. The numbers we are interested in factoring are very close (in relative terms) to powers of 2, so it is possible that algorithms such as the Special Number Field Sieve (SNFS) would give much better results.

Efficient Mesh Licensing

Stephen Toub
toub@fas.harvard.edu

Alexander Healy
ahealy@fas.harvard.edu

May 24, 2001

Abstract

We present an efficient mesh watermarking scheme whereby a vendor can embed purchaser-specific information (i.e. a user license) into a mesh upon the sale of the mesh. This watermark is robust to translation, rotation, uniform scaling, cropping and random perturbation of vertices (up to a threshold). Furthermore, since this method imposes only minor changes to the geometry of the model, it can be used in conjunction with ownership watermarks such as the technique presented in [2].

Introduction

The practice of *watermarking* geometric models involves a trade-off between several important properties: robustness (whether the model retains the watermark even after having been modified), information (how many bits can be encoded in the model), non-malleability (how secure the watermark is against forgery) and efficiency (how much preprocessing is required to embed the watermark and how much processing is required to recover it). In this work, we focus on the last two properties, non-malleability and efficiency, while still providing a modicum of robustness. We present an efficient mesh watermarking scheme whereby a vendor can embed purchaser-specific information (i.e. a user license) into a mesh upon the sale of the mesh. This watermark is robust to translation, rotation, uniform scaling, cropping and random perturbation of vertices (up to a threshold). The security of this watermark against forgery is grounded in the (conjectured) difficulty of computing discrete logarithms in a finite group, and, more generally, we illustrate a technique for representing a cryptographic/algebraic structure within the framework of polygonal meshes.

Previous Work and Motivation

Steganography (information-hiding) is of great interest to many content providers including those who provide digital audio and digital images. The watermarking techniques from these areas have been extended and modified so that polygonal meshes can be watermarked. We focus on two noteworthy examples:

In [5], Wagner presents a robust watermarking scheme that uses the lengths of edges in the mesh to hide a message. The watermark is preserved even after affine-transformations and cropping. However, the process of embedding the watermark is quite costly and can necessitate solving very large linear systems. This is impractical if we want to embed a different watermark each time a mesh is sold (e.g. if the watermark is to include the name of the purchaser). Hence, we would like a watermarking scheme which is allows the purchaser-specific information to be embedded very efficiently.

In [2], the authors present a watermarking scheme in which the message is hidden in the geometry (as opposed to the connectivity) of the mesh. This scheme is robust to arbitrary affine transformations and re-meshing. In order to ensure that the watermark non-invertible (i.e. to prevent false ownership claims), the authors suggest using a cryptographic hash of the ownership information to seed a random number generator that produces the watermark that will be embedded. This works if a given owner wants to show that he owns the mesh; however, if we are embedding purchaser-specific information into the mesh, this can be problematic. Consider the following simple scenario:

Alice sells a mesh to Bob with a watermark that says "This is Alice's mesh and Bob is licensed to use this copy." Now Bob gives the mesh to Carol. Alice

recognizes Carol's mesh, but she cannot determine that it was Bob that gave the mesh to Carol (illegally), unless she guesses that the watermark was "This is Alice's mesh and Bob is licensed to use this copy," and not "This is Alice's mesh and (anyone's name) is licensed to use this copy."

Hence, we would like a scheme in which we can guarantee that the watermark cannot be forged, but where we can recover the watermark text rather than just verifying it, i.e. where we do not have to know the watermarked information before it is recovered.

Encoding Information

In this section we are concerned with the problem of encoding a string of n bits into a mesh. In the next section we will address the issues of encrypting that string before it is embedded into the mesh. Let the original mesh be denoted by $\mathcal{O}$. From this mesh we will construct two meshes, $\mathcal{A}$ and $\mathcal{B}$, which have the same connectivity as $\mathcal{O}$, but where the vertices have been perturbed. In particular, for each vertex $v \in \mathcal{O}$, we compute the tangent plane at v, and we project the star of v onto the tangent plane. Let ϵ denote the length of the shortest edge incident to v in this projection. Next we randomly choose an angle $\theta \in [0, 2\pi)$, and a length $\ell \in (0, \frac{\epsilon}{\lambda}]$, where λ is a constant parameter ($\lambda = 8$ works well in practice). In mesh $\mathcal{A}$, the vertex corresponding to v is moved a distance ℓ in the direction θ on the tangent plane; in mesh $\mathcal{B}$, the vertex corresponding to v is moved a distance ℓ in the opposite direction.

Recall that n denotes the number of bits we wish to encode in the mesh. Now, we partition the vertices V of $\mathcal{O}$ into n sets, S_i, of size $\left\lfloor \frac{|V|}{n} \right\rfloor$ or $\left\lceil \frac{|V|}{n} \right\rceil$. To create a watermarked mesh, $\mathcal{W}$, with an n-bit text $T = b_1 b_2 \dots b_n$ embedded into it, we do the following: For each S_i, we choose the positions of the vertices in $\mathcal{W}$ from $\mathcal{A}$ if $b_i = 0$ and from $\mathcal{B}$ if $b = 1$. We can now interpret the effect of such an encoding in a more conventional setting: While we cannot assume that the S_i's will remain secret, we know that each vertex in $\mathcal{A}$ and $\mathcal{B}$ was produced by the exact same random process (recall that one vertex was perturbed by ℓ where as the other was perturbed by $-\ell$); therefore, to a third party who does not know the text T which is encoded in the mesh, there is no way for them to determine whether a given vertex (and hence a set of vertices) came from $\mathcal{A}$ or $\mathcal{B}$. In this way, this encoding is information-theoretically secure, provided that $\mathcal{A}$ and $\mathcal{B}$ are kept secret. In particular, it is analogous to encoding T as $T \oplus S$ for some randomly-generated secret key S.

To recover a message from such a watermarked mesh, $\mathcal{W}$, we need to realign the mesh and compare the locations of the vertices in each set S_i of $\mathcal{W}$ to the locations of the vertices in $\mathcal{A}$ and $\mathcal{B}$. If a majority of the vertices in a given set S_i are closer to the corresponding vertices in mesh $\mathcal{A}$, then bit i is taken to be a 0. Otherwise, bit i is taken to be a 1. The topic of realigning (or registering) the watermarked mesh is discussed in [2].

Finally, a note about efficiency: If we assume that the meshes $\mathcal{A}$ and $\mathcal{B}$ have been created as a preprocess, then the process of creating a mesh with an n-bit text T encoded into it simply involves choosing the positions for the vertices from either $\mathcal{A}$ or $\mathcal{B}$. Hence, this encoding process is $O(|V|)$, where V denotes the set of vertices of the mesh.

Encryption

In the above scheme, if the encoded message is known and the S_i's are known (this may be possible by comparing many encoded meshes) then such a watermark can be forged. In order to thwart such an attack, we will not encode the message M, but rather $E(M)$, where E is a private-key encryption function.

Since the messages we encode into the mesh are simply elements of $\{0,1\}^n$, it is natural to consider a message M as an element of $\mathbb{F}_{2^n}$, realized as $\mathbb{F}_2[x]/f(x)$ where $f(x)$ is an irreducible polynomial of degree n (since each polynomial in this quotient is easily represented a n-tuple of 0's and 1's, namely the coefficients of the polynomial). Furthermore, we choose n so that $2^n - 1$ is prime, i.e. a Mersenne prime. This ensures that the multiplicative group $\mathbb{F}_{2^n}^{\times}$, which has order $2^n - 1$, is cyclic of prime order, and hence every message is a multiplicative generator, except for the messages $0 \dots 00$ and $0 \dots 01$, which we assume will never be used. Although Mersenne primes are relatively rare, there are several reasonable values of n for this application, namely $n = 521, 607$ or 1279 (see sequence $A000043$ in [4]).

Now, we can use the following private-key encryption function, with secret key $s \in \{1, 2, \ldots, 2^n - 1\}$. Given a message $M \in \mathbb{F}_{2^n}^{\times}$, the encryption, of M is defined by $E(M) = M^s$.

Such a private-key encryption function is desirable because its security can be shown to be equivalent to solving the Diffie-Hellman problem and, in this case, also the discrete logarithm problem.

Problem 1 (Diffie-Hellman Problem). *Given a cyclic group, G, a generator $g \in G$, g^a and g^b for some unknown integers a and b, compute g^{ab}.*

Problem 2 (Discrete Logarithm Problem). *Given a cyclic group, G, a generator $g \in G$, and g^a, for some unknown integer a, compute a.*

It is conjectured that there is no efficient (i.e. polynomial-time) algorithm to solve these problems over various groups G, including $G = \mathbb{F}_{2^n}^{\times}$. Clearly, if one can solve the Discrete Logarithm Problem efficiently, then one can also solve the Diffie-Hellman problem efficiently, but the converse is not known to be true in general. Even so, in [1], Maurer shows that these two problems are computationally equivalent if $p - 1$ or $p + 1$ is sufficiently smooth for each prime factor p of $|G|$. Since we have chosen G to have prime order equal to $2^n - 1$, the only prime factor of $|G|$ is $2^n - 1$ and $(2^n - 1) + 1 = 2^n$ is 2-smooth; hence, the hypotheses of Maurer's result are met and the two problems are computationally equivalent.

This is of interest to us, since the following result relates the difficulty of forging an encryption $E(M)$ (given M, and without knowing the secret key s) to the difficulty of solving the Diffie-Hellman Problem.

Proposition 1. *Suppose an adversary has a polynomially-bounded number of pairs $(M_i, E(M_i))$, where the known plaintexts M_i, are randomly distributed over all possible messages in $\mathbb{F}_{2^n}$. Then, if the adversary can efficiently compute $E(M')$ for some known message M', then she can efficiently solve the Diffie-Hellman Problem in $\mathbb{F}_{2^n}^{\times}$.*

Proof. First we show that only one pair $(M_0, E(M_0))$ is necessary. This is simply because given such a pair, we can construct random pairs $(M_i, E(M_i))$, by computing $(M_0^r, E(M_0)^r)$ for a random $r \in [1, 2, \ldots, 2^n - 1]$. Clearly, $E(M_0)^r = (M_0^s)^r = (M_0^r)^s = E(M_0^r)$, and since any message M_0 is a generator, M_0^r is different for every r; hence a random choice of r yields a random pair $(M, E(M))$ where $M = M_0^r$. Thus, if the adversary can efficiently compute the ciphertext $E(M')$, given a polynomial number of random pairs $(M_i, E(M_i))$, then she can can efficiently compute $E(M') = M'^s$ given a single pair $(M_0, E(M_0))$. However, $M' = M_0^t$ for some t, since M_0 is a generator. Therefore, the adversary is able to efficiently compute $M'^s = (M_0^t)^s = (M_0)^{st}$ given a generator M_0, $M_0^s = E(M_0)$ and $M_0^t = M'$. This is exactly the statement of the Diffie-Hellman Problem, and the result follows. □

Corollary 1. *Suppose an adversary has a polynomially-bounded number of pairs $(M_i, E(M_i))$, where the known plaintexts M_i, are randomly distributed over all possible messages in $\mathbb{F}_{2^n}$. Then, if the adversary can efficiently compute $E(M')$ for some known message M', then she can efficiently solve the Discrete Logarithm Problem in $\mathbb{F}_{2^n}^{\times}$.*

Proof. By the previous proposition, we know that the adversary can efficiently solve the Diffie-Hellman Problem in $\mathbb{F}_{2^n}^{\times}$. By Maurer's result in [1], we know that the existence of an efficient algorithm to solve the Diffie-Hellman Problem in $\mathbb{F}_{2^n}^{\times}$ implies that there is an efficient algorithm for solving the Discrete Logarithm Problem in $\mathbb{F}_{2^n}^{\times}$. □

Unfortunately, this result depends on the known plaintexts, M_i, being random. It is possible, however, that an adversary would choose the M_i's deterministically in order to improve his chance of forging messages. To thwart such an attack, we recommend padding the messages with random bits before encoding them, i.e. given $M = m_1 m_2 \ldots m_k$, with $m_i \in \{0, 1\}$ let $M' = m_1 m_2 \ldots m_k r_{k+1} r_{k+2} \ldots r_n$ where the r_i are random bits, and compute $E(M')$. This will serve to randomize the plaintexts before they are encoded. The size of k, relative to n will determine the security of this encoding (and conversely how much information is encoded).

Application

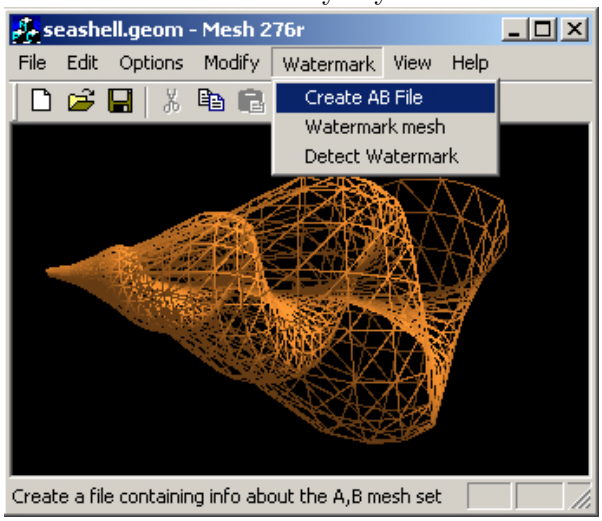
As we have noted before, this scheme only makes minor changes to the geometry of the model. For this reason, it could be used in conjunction with the watermarking scheme proposed in [2], as in the following example:

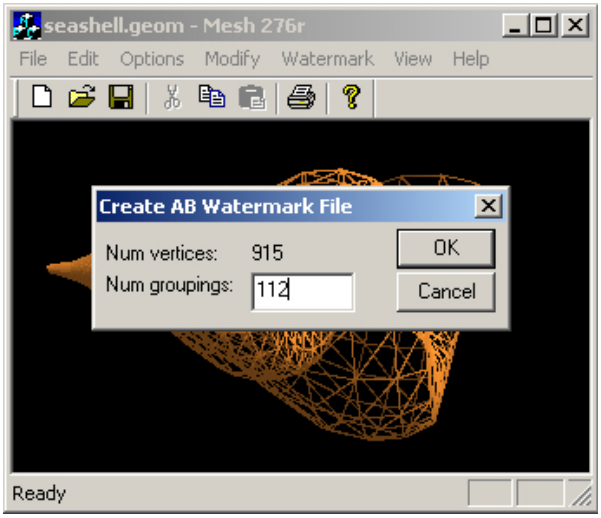
Meshmart licenses meshes that it owns to its customers. All of Meshmart's meshes are watermarked using Praun et al.'s scheme from [2]. Furthermore, each time a mesh is licensed to a customer, that customer's information is embedded using the scheme presented above. This way, Meshmart's meshes are always provided with both an ownership watermark and a license watermark, and so if Alice is found to have a mesh containing Meshmart's ownership watermark, but without a valid license watermark, she is culpable for mesh-fraud. Additionally, our method allows for the possibility that Alice's mesh will also retain its license watermark, revealing that Bob in fact purchased the mesh from Meshmart, and gave it (illegally) to Alice.

Implementation

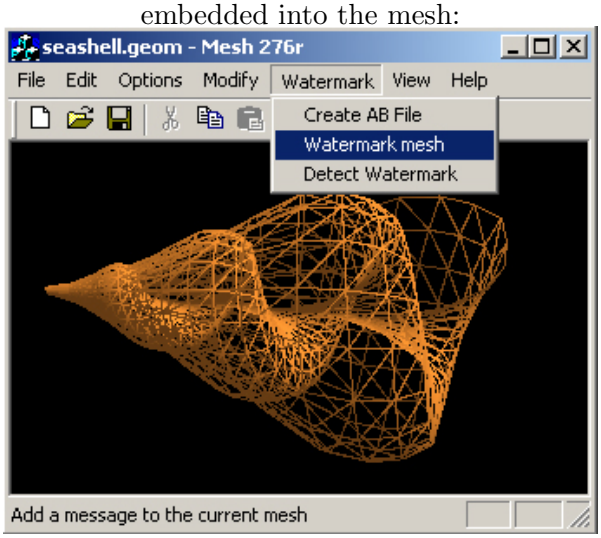
The accompanying implementation demonstrates the functionality of our proposed licensing scheme with triangular meshes. The application was written in C++, using OpenGL and our own mesh representation/manipulation library. Meshes are read and stored as .GEOM files. For simplicity, this application does not actually perform the encryption steps described above. Even so, exponentiation in $\mathbb{F}_{2^n}$ can be performed very quickly and so the difference in performance is negligible. The following screen-shots demonstrate the functionality of the system:

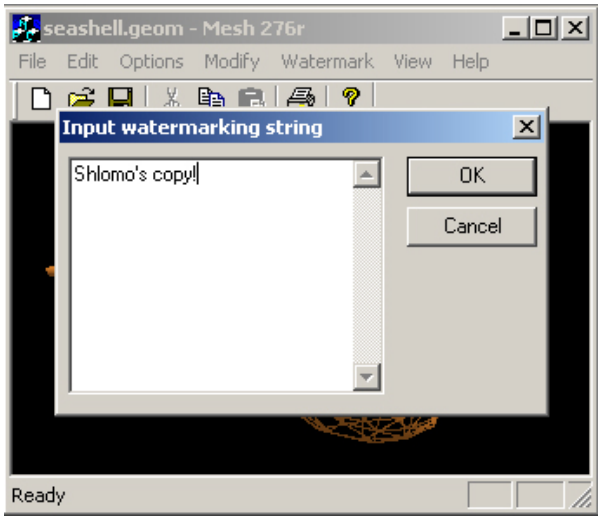
As a preprocess, a .MAB (Mesh A, B) file is created which stores the displacement information of the vertices and any key information:



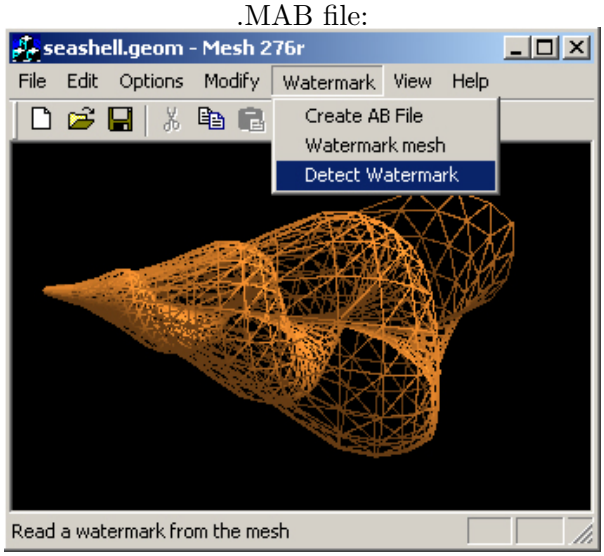


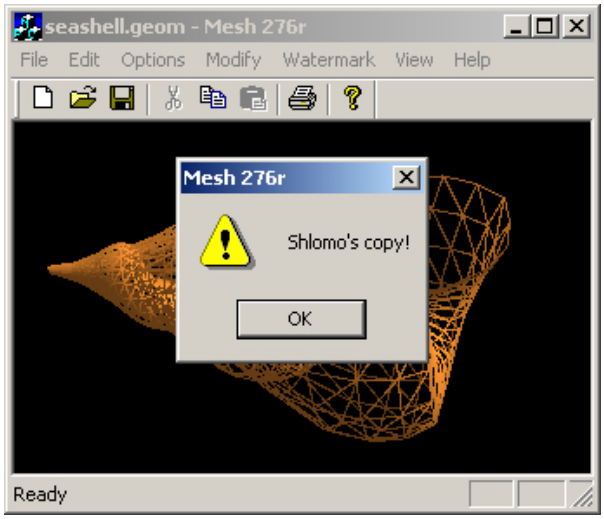
Using this .MAB file, a license/watermark can be embedded into the mesh:





Then the watermark can be recovered, using the .MAB file:





Conclusions and Future Work

We have presented an efficient watermarking scheme that incorporates algebraic cryptography in order to guarantee that the watermark cannot be forged. There are undoubtedly many cryptographic schemes that could be used in secure watermarking/licensing; however, the challenge lies in finding algebraic structures that are well-suited for embedding in meshes. For our purposes, $\mathbb{F}_{2^n}$ worked well, but there may be other encoding schemes which lend themselves to encoding elements of $\mathbb{Z}_N$ where N is the product of two primes as in the RSA and Rabin cryptosystems, or other useful algebraic structures.

Also, as it is presented here, our watermarks are robust to translation, rotation, uniform scaling, cropping, and random perturbations of vertices. It would be of interest to extend this encoding technique so that the watermarks are also robust to arbitrary affine transformations, or even projective transformations. However, this would almost certainly come at the expense of performance.

We have focused on the issues of efficiency and non-malleability in polygonal mesh watermarking. We have exhibited an efficient licensing scheme that is secure against forgery and which allows the licensing information to be recovered, and not just verified. This is particularly important when embedding purchaser-specific information into meshes if we want to find out which party broke the conditions of the license. Furthermore, this scheme can be used in conjunction with the robust watermarking technique in [2] in order to generate meshes with robust ownership watermarks and efficient user-license watermarks.

Tiling an m-by-n Area with Squares of Size up to k-by-k ($m \leq 5$)

Abstract Formulas for the number of tilings $T_{m,n}$ of an m-by-n rectangle with square tiles of size up to k-by-k, for $m \leq 5$ are derived. Two cases are considered: 1) tilings that use only squares of size 1-by-1 and 2-by-2, and 2) tilings that use squares of size up to k-by-k, where $k = \min\{m, n\}$. Using the idea of basic blocks (tilings that cannot be vertically split into smaller rectangles), a general recursive formula for the number of tilings is obtained. Explicit formulas are proved for the number of basic blocks of size m-by-k for $m = 3$ and $m = 4$ (both cases) and for $T_{3,n}$ for case 1. For $m = 5$, the number of basic blocks of size 5-by-k is determined recursively.

Keywords: Tiling of Rectangles, Square Tiles, Fibonacci Sequence, Jacobsthal Sequence

1. Introduction

The question to be discussed in this paper is a generalization of the problem of tiling a 1-by-n or 2-by-n rectangle with Cuisinaire rods ("c-rods"), color-coded rods of lengths 1 cm to 10 cm (1 cm = white, 2 cm = red). C-rods are used to help students with an intuitive understanding of concepts related to whole numbers, as well as geometry. In addition to their usefulness in K-8, the number of tilings of a rectangle of size 1-by-n with white and red c-rods is connected to the Fibonacci numbers. This connection can be used to give geometrical proofs of various relationships for this well-known sequence [1].

Extensions to the tiling question of a 1-by-n area with white and red c-rods have been investigated by a number of authors. Using the same types of c-rods, but covering a 2-by-n rectangle has been explored by Brigham et. al [2]. A generalization, allowing c-rods of length less than or equal to k for tiling 2-by-n and 3-by-n rectangles has been investigated by Hare [4,5] and by Hare and Chinn [6].

In this paper, the tiles used are squares, rather than c-rods. We will discuss two cases for tiling m-by-n rectangles, namely 1) to allow 1-by-1 and 2-by-2 tiles only; and 2) to allow tiles of size up to k-by-k, where $k = \min\{m,n\}$. The approach taken is based on basic blocks, comparable to the indecomposable blocks utilized in [2]. A recursive formula for the number of tilings based on basic blocks is derived (Lemma 1). In the case $m = 3$ with tiles of size up to 2-by-2, an explicit formula for the number of tilings results (Theorem 1). In all other cases, the recursive structure remains, but explicit formulas for the number of basic blocks are derived. The sole exception is the case $m = 5$, with tiles of size up to 5-by-5, where the number of basic blocks is given by a recursive formula (Theorem 6).

2. The Trivial Cases: m = 1 and m = 2

In the case of tiling a 1-by-n rectangle, there is only one possible tiling, namely the one where all the tiles are of size 1-by-1. When $m = 2$, 1-by-1 and 2-by-2 squares can be used for tiling. However, they cannot be mixed and matched in every possible fashion. If a 1-by-1 tile is used somewhere in the rectangle, then it has to be paired vertically with another 1-by-1 tile. Thus we get tilings that are sequences consisting of either two vertically stacked 1-by-1 tiles or the 2-by-2 tile. Due to the symmetry induced by the pairing of the two 1-by-1 tiles, tilings of size 2-by-n using squares have a one-to-one correspondence to tilings of a 1-by-n rectangle with white and red Cuisinaire rods (see Figure 1).

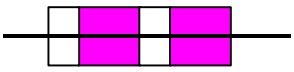

Figure 1

Formulas for the number of such tilings are well-known and can be found for example in [1]. A recursive relation is the basic idea for finding the number of these tilings. Rectangles of size 1-by-(n+1) are formed by either attaching a 1-by-1 rod to the left of a 1-by-n tiling, or by attaching a 1-by-2 rod to the left of a tiling of size 1-by-(n-1). In this manner, a recursion very much like the one for the Fibonacci numbers results, except that the initial conditions are "shifted". The generalization of this approach will be illustrated in the next section.

3. The Notion of Basic Blocks

When tiling rectangles with squares, the approach is similar. The basic idea is to form larger tilings by putting together tilings of smaller sizes in a specific way. The role of the 1-by-1 and 1-by-2 Cuisinare rods in the above example is now played by *basic* (or *indecomposable) blocks*. A basic block is a tiling that cannot be split (vertically) into two or more smaller rectangular pieces without cutting some of the squares. Figure 2 shows an example for tilings of size 4-by-3. The tiling on the left represents a basic block, whereas the second one does not qualify as a basic block, as it can be split into a 4-by-2 and a 4-by-1 rectangle.

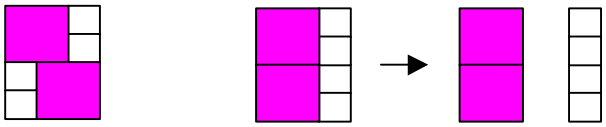

Figure 2

4. Notation

We now introduce some notation and conventions used throughout the paper. When talking about an m-by-n rectangle, m refers to the height and n refers to the width of the rectangle. Figure 3 shows the shadings which will be used for the different sizes of squares:

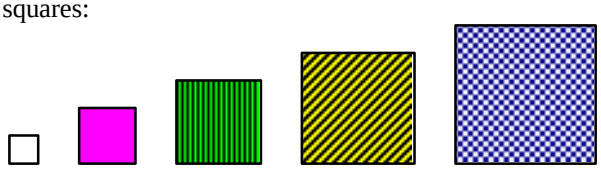

Figure 3

Furthermore, we let

$T_{m,n}$ = the number of tilings of an m-by-n rectangle with squares of size 1-by-1 and 2-by-2

$\tilde{T}_{m,n}$ = the number of tilings of an m-by-n rectangle with squares of size up to k-by-k, where $k = \min\{m, n\}$

$B_{m,n}$ = the number of basic blocks of size m-by-n using squares of size 1-by-1 and 2-by-2

$\tilde{B}_{m,n}$ = the number of basic blocks of size m-by-n using squares of size up to k-by-k, where $k = \min\{m, n\}$

F_m = the m^{th} Fibonacci number, with $F_1 = F_2 = 1$, and $F_m = F_{m-1} + F_{m-2}$

Note that $\tilde{T}_{m,n} = T_{m,n}$ and $\tilde{B}_{m,n} = B_{m,n}$ for $n = 1$ and $n = 2$.

5. The General Recursive Formula

The main idea is to combine a basic block of size m-by-k with a tiling of size m-by-(n-k) where $k \le n$. (We will always assume that the basic block is added from the left.) As all the tilings of size m-by-(n-k) are different, the newly created tilings are also different. On the other hand, each tiling starts with a basic block on the left (namely the first section that cannot be vertically separated). Thus, creating larger tilings by adding a basic block to the left of appropriate tilings will create all possible tilings. Double counting as shown in Figure 4 cannot happen, as the

second way to create the given tiling does not follow the algorithm. (The tiling added from the left is not a basic block.)

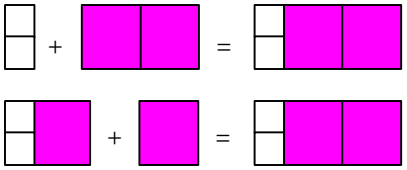

Figure 4

We will illustrate the general recursive formula for the case $m = 2$. The only basic blocks are of size 2-by-1 (two vertically stacked 1-by-1 tiles) and size 2-by-2 (the 2-by-2 tile), hence $B_{2,1} = B_{2,2} = 1$. We can create tilings of size 2-by-n in one of two ways: either by adding the basic block of size 2-by-1 to a tiling of size 2-by-(n-1) or by adding the basic block of size 2-by-2 to a tiling of size 2-by-(n-2). This leads to the recursive formula

$$T_{2,n} = B_{2,1}\, T_{2,\,n-1} + B_{2,2}\, T_{2,\,n-2} = T_{2,\,n-1} + T_{2,\,n-2}$$

The initial conditions are $T_{2,1} = 1$ and $T_{2,2} = 2$ (either a 2-by-2 tile or the tiling consisting of all 1-by-1 tiles). Therefore, the number of tilings of a 2-by-n rectangle is given by the shifted Fibonacci numbers, i. e. ,

$$T_{2,n} = F_{n+1}. \qquad (1)$$

In general, the number of tilings of size m-by-n can be created by combining a basic block of size m-by-k with a tiling of size m-by-(n-k), or it can consist of just a basic block of size m-by-n (if there are any). The same argument applies for tilings that allow squares of size up to k-by-k. If we define $T_{m,0} = \tilde{T}_{m,0} = 1$, then we get the following lemma:

Lemma 1: *The number of tilings of an m-by-n rectangle is given by*

$$T_{m,n} = \sum_{k=1}^{n} B_{m,k} T_{m,n-k} \quad \text{and} \quad \tilde{T}_{m,n} = \sum_{k=1}^{n} \tilde{B}_{m,k} \tilde{T}_{m,n-k} \ .$$

To make this formula useful, we need to determine the number of basic blocks of size m-by-k. We will first work on tilings that only use 1-by-1 and 2-by-2 squares, and then look at the general case.

6. Tilings with Squares of Size 1-by-1 and Size 2-by-2

6.1 Basic Blocks of Size m-by-1 and m-by-2

Before looking at specific values for m, we will state a fact that holds true independent of the value for m:

$$T_{m,1} = B_{m,1} = 1 \qquad \text{for all values of } m. \qquad (2)$$

(Each tiling consists of vertically stacked tiles of size 1-by-1.) Furthermore, we can easily derive a general formula for $B_{m,2}$.

The number of basic blocks of size m-by-2 is closely related to the number of tilings of size 2-by-m. The two types of tilings both cover the same size rectangle, viewed either vertically or horizontally. However, any basic block of width 2 must have at least one tile of size 2-by-2; therefore, the one tiling consisting of all 1-by-1 tiles has to be excluded. Together with (1), this leads to

$$B_{m,2} = T_{2,m} - 1 = F_{m+1} - 1. \qquad (3)$$

On the other hand, using a combinatorial argument (see [1]) for the number of ways to place either a 2-by-2 tile or two adjacent 1-by-1 tiles, one can also derive that

$$B_{m,2} = \sum_{r=1}^{\lfloor m/2 \rfloor} \binom{m-r}{r}. \qquad (4)$$

Combining (3) and (4) leads to a well-known formula for the Fibonacci numbers (see for example [3]).

6.2 The Case m = 3

The first step is to determine the number of basic blocks and the initial conditions for the recursive formula. As we only look at tiles of size 1-by-1 and 2-by-2, there are no basic blocks of size 3-by-*n* for $n > 2$. (To make basic blocks of larger size, there needs to be an interlocking mechanism, for which two 2-by-2 tiles are needed.) Thus, the only basic blocks for $m = 3$ are given in Figure 5, resulting in $B_{3,1} = 1$ and $B_{3,2} = 2$.

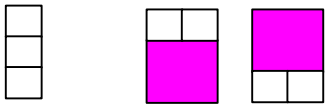

Figure 5

The general recursive formula (Lemma 1) reduces to

$$T_{3,n} = B_{3,1}\, T_{3,n-1} + B_{3,2}\, T_{3,n-2} = T_{3,n-1} + 2\, T_{3,n-2} \quad \text{for } n > 2, \quad (5)$$

with initial conditions $T_{3,1} = 1$ and $T_{3,2} = 3$ (the two basic blocks and the tiling consisting of only 1-by-1 tiles). However, this recursive formula has an explicit solution.

Theorem 1*: The number of tilings of a 3-by-n rectangle with squares of size 1-by-1 and 2-by-2 is given by*

$$T_{3,n} = \left(2^{n+1} - (-1)^{n+1}\right)/3$$

Proof:

The formula holds for the initial conditions:

$n = 1$: $T_{3,1} = \left(2^2 - 1\right)/3 = 1$

$n = 2$: $T_{3,2} = \left(2^3 + 1\right)/3 = 3$.

Furthermore, the recurrence relation (5) is identical to the recurrence for the Jacobsthal sequence (A001045 [7] or M2482 [8]), with $T_{3,1} = a(2)$ and $T_{3,2} = a(3)$. Thus,

$$T_{3,n} = a(n+1) = \left(2^{n+1} - (-1)^{n+1}\right)/3.$$

□

Table 1 lists the first ten values of $T_{3,n}$.

n	1	2	3	4	5	6	7	8	9	10
$T_{3,n}$	1	3	5	11	21	43	85	171	341	683

Table 1

6.3 The Case m = 4

Again we start by determining the number of basic blocks. Now the height of the blocks is large enough to allow for an interlocking effect (for $n \geq 3$) that creates basic blocks of any length. From equations (2) and (3) in Section 6.1 we know that $B_{4,1} = 1$ and $B_{4,2} = 4$. Figure 6 shows the four possible basic blocks of size 4-by-2.

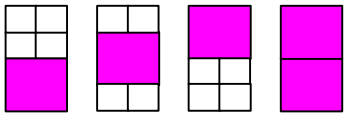

Figure 6

For $n > 2$, $B_{4,n} = 2$, as can be seen easily from the tilings shown in Figure 7.

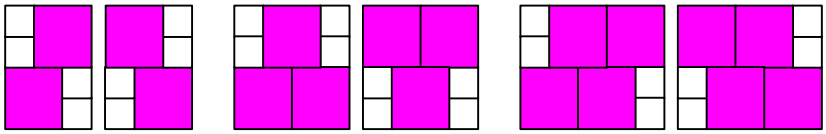

Figure 7

Since the 2-by-2 tiles have to be placed in an interlocking pattern to ensure the tiling forms a basic block, there are only two possibilities, depending on whether the leftmost 2-by-2 tile is located at the bottom or at the top. (A placement of the 2-by-2 tile in the middle position will only result in a basic block of width 2.) After the initial placement, there is only one way to extend the basic block for each of the two cases, giving exactly two basic blocks of size 4-by-*n*, $n > 2$.

Thus, we get the following result:

Theorem 2*: The number of tilings of a 4-by-n rectangle with squares of size 1-by-1 and 2-by-2 is given by the recursive formula*

$$T_{4,n} = T_{4,n-1} + 4T_{4,n-2} + 2\sum_{k=0}^{n-3} T_{4,k} \ ,$$

with $T_{4,0} = T_{4,1} = 1$, and $T_{4,2} = 5$.

Proof:
The recursive formula and re-indexing of the sum leads to the formula for $T_{4,n}$. The number of tilings of size 4-by-2 consist of the 4 basic blocks of that size and the tiling of all 1-by-1 squares.

□

Table 2 lists the first ten values of $T_{4,n}$.

n	1	2	3	4	5	6	7	8	9	10
$T_{4,n}$	1	5	11	35	93	269	747	2,115	5,933	16,717

Table 2

6. 4 The Case m = 5

This case differs from the cases for $m = 3$ and $m = 4$ in that the number of basic blocks is not as easily determined as before. Here we will develop a recursive formula for the number of basic blocks of size 5-by-n, for $n > 3$. From (3) we know that $B_{5,2} = 7$; the respective tilings are given in Figure 8.

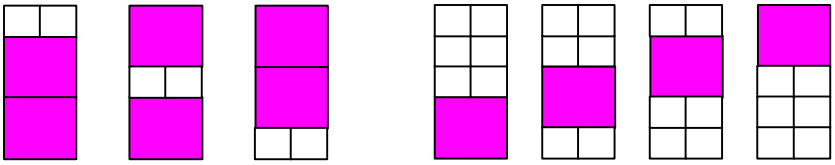

Figure 8

We now create basic blocks of size 5-by-(n+1) from those of size 5-by-n. We do this by placing a 2-by-2 tile over two vertically stacked tiles of size 1-by-1 in the rightmost column, and then filling up the remaining empty spaces in the new column with 1-by-1 tiles. Note the following: In order for a tiling to be a basic block of height 5, each vertical column must contain at least one 2-by-2 tile. In addition, any column but the leftmost and rightmost must contain two 2-by-2 tiles (to produce the interlocking effect).

Looking at the first three basic blocks in Figure 8, it is clear that they cannot be extended to basic blocks of size 5-by-3. For the other four basic blocks, there are two different possibilities, shown in Figure 9, depending on the structure of the rightmost column. If the 1-by-1 tiles are split into a single tile and a group of two tiles, then there is only one way to extend the basic block to the next larger size. If, on the other hand, there are three (vertically) stacked 1-by-1 tiles, then the 2-by-2 tile can be placed in two different ways. Thus, two of the basic blocks of size 5-by-2 produce one larger basic block of size 5-by-3, and the other two produce two basic blocks each.

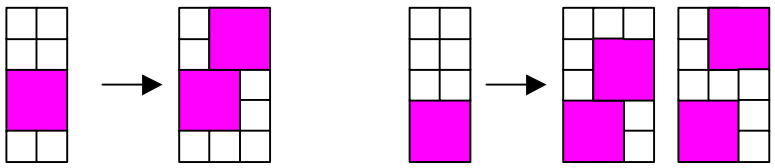

Figure 9

Altogether, we get a total of 6 basic blocks of size 5-by-3, grouped in Figure 10 according to their "ancestor" in Figure 8.

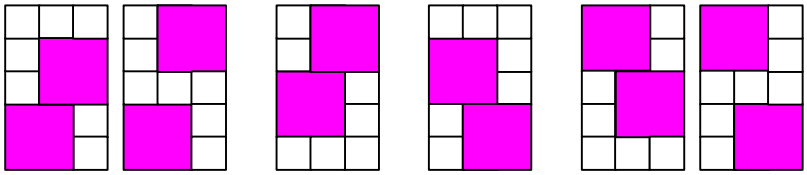

Figure 10

These are the only possible basic blocks of size 5-by-3, as exactly two 2-by-2 tiles in interlocking positions are needed. Let's look at this extension process in a little bit more detail. The difference between the two extensions of basic blocks shown in Figure 9 is the rightmost column. If we just look at this column, we can distinguish between two types:

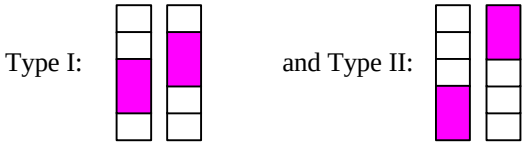

Figure 11

Each basic block of type I creates one new basic block of the next size, and those of type II produce two new basic blocks. But we also have to keep track of the type of the newly created blocks. Figure 12 shows what happens:

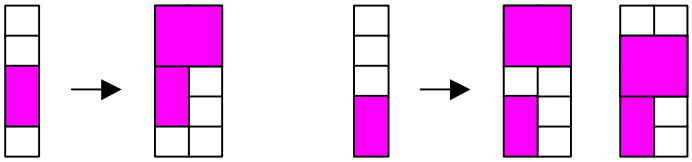

Figure 12

A type I block creates a type II block (as the single square and the 2-by-2 tile both get extended with 1-by-1 tiles to form a group of three consecutive 1-by-1 tiles). The same reasoning explains why one of the basic blocks created from a type II block also has to be of type II. (This is the one where the extending 2-by-2 tile is placed not adjacent to the existing 2-by-2 tile.) However, the second basic block created from a type II basic block is of type I. Altogether, we have the following lemma:

Lemma 2: *For n > 1, a type I basic block of size 5-by-n creates one type II basic block of size 5-by-(n+1); a type II basic block of size 5-by-n creates one type I and one type II basic block of size 5-by-(n+1).*

If we denote the number of basic blocks of type I and type II of size 5-by-*n* by $B_{5,n}^{I}$ and $B_{5,n}^{II}$, respectively, then we get the following formula for the number of basic blocks for $n > 2$ (as we have only type I and type II basic blocks):

$$B_{5,n} = B_{5,n}^{I} + B_{5,n}^{II} \qquad (6)$$

Now we can use Lemma 2 to determine formulas for the number of basic blocks of each type. Basic blocks of type I are created from basic blocks of type II only, hence

$$B_{5,n+1}^{I} = B_{5,n}^{II} \qquad (7)$$

On the other hand, basic blocks of type II are created from basic blocks of type I and type II. Each such block creates exactly one new block of type II. These blocks are all different, because their first *n*-1 columns were different. Therefore,

$$B_{5,n+1}^{II} = B_{5,n}^{I} + B_{5,n}^{II} = B_{5,n}. \qquad (8)$$

Combining (6), (7), and (8) results in the following formula for the number of basic blocks.

Lemma 3*: The number of basic blocks of size 5-by-m is given by*

$$B_{5,n} = 2 \cdot F_{n+1} \quad \text{for } n > 2,$$

with $B_{5,2} = 7, \text{and } B_{5,1} = 1.$

Proof:
For $n = 1$ and $n = 2$, the result is true by (2) and (3). Figure 10 shows that $B_{5,3} = 6 = 2 \cdot F_4$.

For $n = 4$, we recall that $B^I_{5,2} = B^{II}_{5,2} = 2$ (Figure 8). By Lemma 2, each of the two basic blocks of type I produces one type II basic block of size 5-by-3, and each of the two basic blocks of type II produces one basic block of type I and type II. Thus ,

$$B^I_{5,3} = 2 \quad \text{and} \quad B^{II}_{5,3} = 2 + 2 = 4 \ .$$

We now apply Lemma 2 once more to determine the number of basic blocks of type I and type II of size 5-by-4. Thus,

$$B^I_{5,4} = 4 \quad \text{and} \quad B^{II}_{5,4} = 4 + 2 = 6 \ .$$

This implies that $B_{5,4} = 4 + 6 = 10 = 2 \cdot F_5$.

For $n > 4$,

$$\begin{aligned} B_{5,n} &= B^I_{5,n} + B^{II}_{5,n} \\ &= B^{II}_{5,n-1} + B_{5,n-1} \qquad \text{by (7) and (8)} \\ &= B_{5,n-2} + B_{5,n-1} \qquad \text{by (8)} . \end{aligned}$$

As this is the recursion for the Fibonacci numbers, and the factor 2 carries through, the result follows.

This leads to the following recursive formula for the number of tilings of size 5-by-*n*:

Theorem 3*: The number of tilings of a 5-by-n rectangle with squares of size 1-by-1 and 2-by-2 is given by the recursive formula*

$$T_{5,n} = \sum_{k=1}^{n} B_{5,k} \, T_{5,n-k}$$

with

$$B_{5,n} = 2 \cdot F_{n+1} \quad \text{for} \quad n > 2,$$

where $B_{5,2} = 7$, $B_{5,1} = 1$, and $T_{5,1} = T_{5,0} = 1$.

Table 3 contains the first ten values for both $B_{5,n}$ and $T_{5,n}$.

n	1	2	3	4	5	6	7	8	9	10
$B_{5,n}$	1	7	6	10	16	26	42	68	110	178
$T_{5,n}$	1	8	21	93	314	1,213	4,375	16,334	59,925	221,799

Table 3

7. Tilings with Squares up to Size k-by-k, with k = min{n, m}

7.1 The Case m = 3 (Squares up to Size 3-by-3)

If we now allow tiles of size 3-by-3, only basic blocks of width larger than 2 can change. Obviously, there is one new basic block of size 3-by-3. However, as the 3-by-3 tile cannot be combined with any other tile to form an interlocking pattern due to height constraints, this is the only additional basic block. Thus, we have:

$$\tilde{B}_{3,1} = 1,\ \tilde{B}_{3,2} = 2,\ \text{and}\ \tilde{B}_{3,3} = 1.$$

Using the general recursive formula, we obtain the following result:

Theorem 4*: The number of tilings of a 3-by-n rectangle with squares of up to size 3-by-3 is given by*

$$\tilde{T}_{3,n} = \tilde{T}_{3,n-1} + 2\tilde{T}_{3,n-2} + \tilde{T}_{3,n-3}$$

with initial conditions $\tilde{T}_{3,0} = \tilde{T}_{3,1} = 1$ and $\tilde{T}_{3,2} = 3$ *as before.*

Even though there is only one additional basic block, the dynamics for the number of tilings changes quite dramatically. Table 4 gives the first ten values of $\tilde{T}_{3,n}$:

n	1	2	3	4	5	6	7	8	9	10
$\tilde{T}_{3,n}$	1	3	6	13	28	60	129	277	595	1,278

Table 4

7. 2 The Case m = 4 (Squares up to Size 4-by-4)

As in the case $m = 3$, the only changes in the number of basic blocks can occur for $n > 2$. Figure 13 shows the two additional blocks of width 3 and the one additional block of width 4.

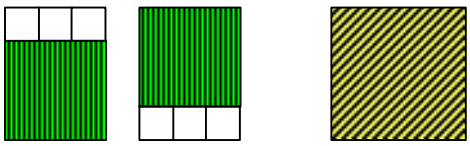

Figure 13

Neither the 3-by-3 nor the 4-by-4 tile can be used to make larger basic blocks through interlocking. Thus, these three are the only additional basic blocks, leading to:

$$\begin{aligned} &\tilde{B}_{4,1} = 1,\ \tilde{B}_{4,2} = 4,\ \tilde{B}_{4,3} = 2+2 = 4,\ \tilde{B}_{4,4} = 2+1 = 3, \\ &\text{and}\ \ \tilde{B}_{4,n} = 2 \quad \text{for } n > 4. \end{aligned} \tag{9}$$

We have the following result:

Theorem 5*: The number of tilings of a 4-by-n rectangle with squares of size up to 4-by-4 is given by*

$$\tilde{T}_{4,n} = \tilde{T}_{4,n-1} + 4\tilde{T}_{4,n-2} + 4\tilde{T}_{4,n-3} + 3\tilde{T}_{4,n-4} + 2\sum_{k=0}^{n-5}\tilde{T}_{4,k},$$

with $\tilde{T}_{4,0} = \tilde{T}_{4,1} = 1,\ \tilde{T}_{4,2} = 5,$ *and* $\tilde{T}_{4,3} = 13.$

Proof:
The result for $n > 3$ follows from the general recursive formula and a re-indexing of the sum. Furthermore, $\tilde{T}_{4,m} = T_{4,m}$ for $m = 0$, 1, and 2, since the same tiles are being used. Using the general recursive formula (Lemma 1) and (9) leads to

$$\tilde{T}_{4,3} = \sum_{k=1}^{3}\tilde{B}_{4,k}\ \tilde{T}_{4,n-k} = 1\cdot 5 + 4\cdot 1 + 4 = 13.$$

□

Table 5 displays the first ten values of $\tilde{T}_{4,n}$:

n	1	2	3	4	5	6	7	8	9	10
$\tilde{T}_{4,n}$	1	5	13	40	117	348	1,029	3,049	9,028	26,738

Table 5

7.3 The Case m = 5 (Squares up to Size 5-by-5)

In addition to the basic blocks made up from just 1-by-1 and 2-by-2 tiles, we now also allow 3-by-3, 4-by-4, and 5-by-5 tiles. Like in the case $m = 3$, the 4-by-4 and 5-by-5 tiles will only lead to basic blocks of their respective widths, as they cannot be extended in an interlocking fashion in combination with 2-by-2 tiles. Thus, any regular pattern for basic blocks will start for $n > 5$. We will first derive the number of basic blocks for $n \leq 5$.

Lemma 4: *The number of basic blocks of size 5-by-n, for $n \leq 5$, using tiles of size up to 5-by-5, are as follows:*

$$\tilde{B}_{5,1} = 1,\ \tilde{B}_{5,2} = 7,\ \tilde{B}_{5,3} = 13,\ \tilde{B}_{5,4} = 20,\ \text{and}\ \tilde{B}_{5,5} = 35.$$

Proof:
As the first additional basic blocks show up for $n = 3$, $\tilde{B}_{5,1} = B_{5,1} = 1,$ and $\tilde{B}_{5,2} = B_{5,2} = 7.$ For $n = 3$, we can now utilize 3-by-3 tiles, which can be placed in one of three positions, as shown in Figure 14.

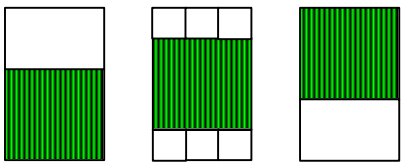

Figure 14

The first and third constellations are symmetrical, and the (white) 2-by-3 rectangle can be tiled in any way, i.e., in $T_{2,3} = 3$ ways. The second tiling in Figure 14 shows the only possibility if the 3-by-3 tile is placed in the middle position. Therefore, there are $2 \cdot 3 + 1 = 7$ basic blocks of size 5-by-3 using a 3-by-3 tile. Using Lemma 3, we have that $\tilde{B}_{5,3} = B_{5,3} + 7 = 13$.

If $n = 4$, then we get additional basic blocks formed by either using a 3-by-3 tile together with an interlocking 2-by-2 tile, or by using the 4-by-4 tile. If we use a combination of 2-by-2 and 3-by-3 basic blocks, then there are only four possible positions for the interlocking 2-by-2 and 3-by-3 tiles, as shown in Figure 15.

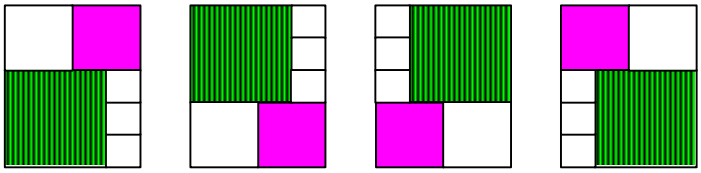

Figure 15

The (white) 2-by-2 square next to the interlocking 2-by-2 tile can be tiled in 2 ways (all 1-by-1 tiles or one 2-by-2 tile). Thus, there are altogether 8 basic blocks made up from 2-by-2 and 3-by-3 tiles. In addition, we can use a 4-by-4 tile, which will lead to 2 basic blocks of size 5-by-4. Altogether, $\tilde{B}_{5,4} = B_{5,4} + 8 + 2 = 10 + 10 = 20.$

Finally, for $n = 5$, the additional basic blocks are either made from a combination of 2-by-2 and 3-by-3 tiles or consist of the 5-by-5 tile. In the former case, we need one 3-by-3 tile and two 2-by-2 tiles to create an interlocking structure. There are six possibilities to place the 3-by-3 tile: two of these allow for exactly one placement of the 2-by-2 tiles, whereas the other four allow for two different placements each. Figure 16 shows the different possible positions of these tiles.

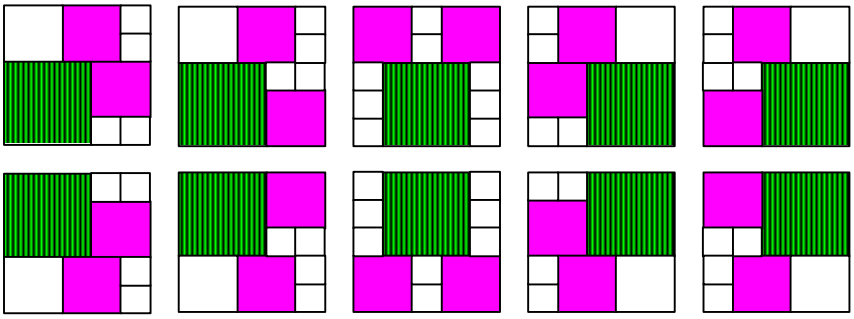

Figure 16

All but the two middle basic blocks in Figure 16 still contain a (white) 2-by-2 square that can be tiled in two ways. Thus, there are $8 \cdot 2 + 2 = 18$ basic blocks containing both 2-by-2 and 3-by-3 tiles. Altogether, using Lemma 3, $\tilde{B}_{5,5} = B_{5,5} + 18 + 1 = 16 + 19 = 35$.

Now that we have established the number of basic blocks for $n \leq 5$, we will look at a mechanism to create basic blocks of size 5-by-(n+1) from basic blocks of size 5-by-n. We will use an approach similar to the one used in Section 6.4. However, since tiles of size 3-by-3 can be used in the extension, we need to look at the **two**, instead of just one, rightmost columns of a basic block. Lemma 5 establishes the possible configurations for the last two columns of a basic block.

Lemma 5*: For n > 5, the last two columns of basic blocks of size* 5*-by-n must be of one of the five types shown in Figure* 17.

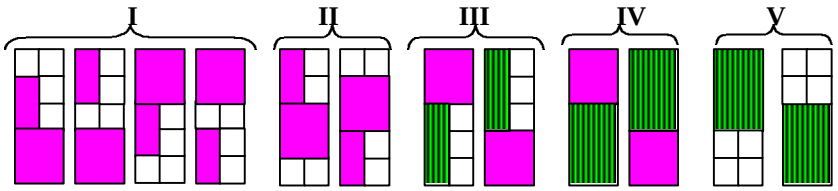

Figure 17

Proof:
The last two columns must contain a 2-by-2 or a 3-by-3 tile in order to ensure the tiling is a basic block. If the last two columns contain only 1-by-1 and 2-by-2 tiles, then the second to last column must contain two 2-by-2 tiles, and the last one can have only one 2-by-2 tile (due to the interlocking nature). The rest of the column is filled by three 1-by-1 tiles, which can be either grouped together (type I) or split into a pair of 2 and a single one (type II).

If both of the last columns are covered with a 3-by-3 tile (which necessarily is either on the top or bottom to allow for an interlocking extension), then the remaining 2-by-2 rectangle can be tiled with either a 2-by-2 tile (type IV) or four 1-by-1 tiles (type V). If the 3-by-3 tile only covers the next to last column, then it must be paired with a 2-by-2 tile in an interlocking fashion. The only such possibility is given by type III.

▭

We can now establish how basic blocks of size 5-by-(n+1) can be created from basic blocks of size 5-by-n. We will denote the number of basic blocks of size 5-by-n which are of type I by $\tilde{B}^{I}_{5,n}$ (and likewise for the other four types).

Lemma 6: *The number of basic blocks of size 5-by-(n+1) for* $n \geq 5$ *is given by*

$$\tilde{B}_{5,n+1} = \tilde{B}^{I}_{5,n+1} + \tilde{B}^{II}_{5,n+1} + \tilde{B}^{III}_{5,n+1} + \tilde{B}^{IV}_{5,n+1} + \tilde{B}^{V}_{5,n+1}$$

where

$$\begin{aligned} \tilde{B}^{I}_{5,n+1} &= \tilde{B}^{I}_{5,n} + \tilde{B}^{II}_{5,n} + \tilde{B}^{III}_{5,n} \\ \tilde{B}^{II}_{5,n+1} &= \tilde{B}^{I}_{5,n} + \tilde{B}^{III}_{5,n} \\ \tilde{B}^{III}_{5,n+1} &= \tilde{B}^{V}_{5,n} \\ \tilde{B}^{IV}_{5,n+1} &= \tilde{B}^{II}_{5,n} \\ \tilde{B}^{V}_{5,n+1} &= \tilde{B}^{II}_{5,n} \end{aligned} \qquad (10)$$

and $\tilde{B}^{I}_{5,5} = 14,\ \tilde{B}^{II}_{5,5} = 10,\ \tilde{B}^{III}_{5,5} = 2,\ \tilde{B}^{IV}_{5,5} = \tilde{B}^{V}_{5,5} = 4.$

Proof:
Extensions can be made by using either 2-by-2 or 3-by-3 tiles. A 2-by-2 tile will replace two adjacent 1-by-1 tiles in the last column. A 3-by-3 tile will replace a 2-by-2 tile and two 1-by-1 tiles that are adjacent to the 2-by-2 tile. After the interlocking tile has been placed, the remainder of the new last column is filled with 1-by-1 tiles. This may result in a set of four 1-by-1 tiles, which can be replaced by a 2-by-2 tile to form another basic block. We will show the possible extensions only for half of the configurations in Figure 17, as the remaining ones are symmetric (vertically reflected).

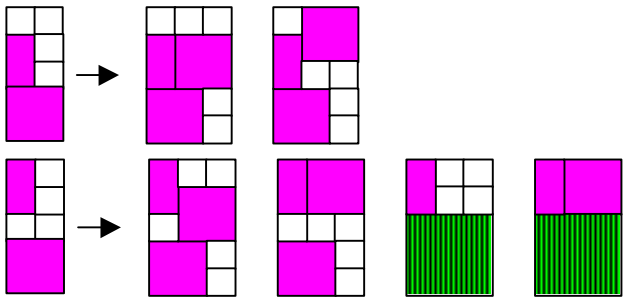

Figure 18

Type I: There are two ways to extend type I blocks with a 2-by-2 tile, leading to either a type I or a type II block of the next larger size. For the second type I block, two extensions with a 3-by-3 tile are also possible as shown in Figure 18.

Type II: In this case, an extension with a 2-by-2 tile is possible in only one way, creating a block of type I. In addition, an extension with a 3-by-3 tile is possible, just like in the case of the second basic block of type I, creating one block each of type IV and V. However, if we look at these two extensions in Figure 19 and compare them to those in Figure 18, we see that they create identical columns. The differences that existed before in the basic blocks of smaller size have now been erased. To avoid double counting, we will think of these extensions as coming from the type II blocks (then the two type I blocks create the same extension types).

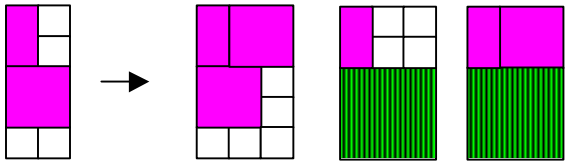

Figure 19

Thus, we can summarize what happens for type I and type II basic blocks:

Each type I block produces one type I and one type II block.
Each type II block produces one each of type I, type IV and type V.

Type III: A type III block can only be extended with a 2-by-2 tile, and there are two possible ways to do so, as shown in Figure 20. No extensions with 3-by-3 tiles are possible.

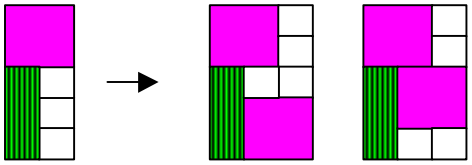

Figure 20

Type IV: This type has no extension.

Type V: There is only one way to extend a type V block, resulting in a type III block as shown in Figure 21.

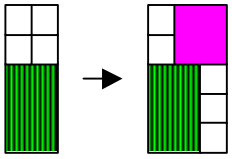

Figure 21

We summarize these three cases:

Each type III block produces one type I and one type II block.
A type IV block does not produce any extension.
Each type V block produces one block of type III.

Thus, type I basic blocks of size 5-by-(n+1) are created by each of the type I, type II, and type III basic blocks of size 5-by-n. This results in:

$$\tilde{B}^{I}_{5,n+1} = \tilde{B}^{I}_{5,n} + \tilde{B}^{II}_{5,n} + \tilde{B}^{III}_{5,n}$$

Likewise, one derives the other four equations. As any extensible basic block of size 5-by-(n+1) has to be of one of these types for $n \geq 5$, the total number of basic blocks of size 5-by-(n+1) is the sum of the basic blocks of the types I - V.

Finally, we need to verify the initial conditions. Figure 16 shows the basic blocks containing 3-by-3 tiles. We only need to look at the basic blocks in the top row, as the bottom row contains basic blocks that are vertically reflected. Recall also that all but the middle basic block have two possibilities for tiling the (white) 2-by-2 area. The first basic block is of type II in both cases, the second is of type I in both cases, the third is of type III, and the fourth and fifth are either of type IV or type V. For the 18 possible basic blocks indicated in Figure 16, we get (as we double the above count): Type I: 4, type II: 4, type III: 2, type IV: 4, and type V: 4. Now we have to look at basic blocks of size 5-by-5 containing only 1-by-1 and 2-by-2 tiles. By Theorem 3, there are 16 such basic blocks. Figure 22 shows 8 of these, with the remaining 8 being symmetrical (vertical reflection).

The first, second, and seventh are of type II; the other ones are of type I. Thus, we have 6 additional blocks of type II and 10 additional basic blocks of type I. Altogether, this leads to $\tilde{B}^{I}_{5,5} = 14$, $\tilde{B}^{II}_{5,5} = 10$, $\tilde{B}^{III}_{5,5} = 2$, $\tilde{B}^{IV}_{5,5} = 4$, and $\tilde{B}^{V}_{5,5} = 4$. (This gives 34 of the 35 basic blocks of size 5-by-5; the remaining one is the basic block consisting of the 5-by-5 tile itself.)

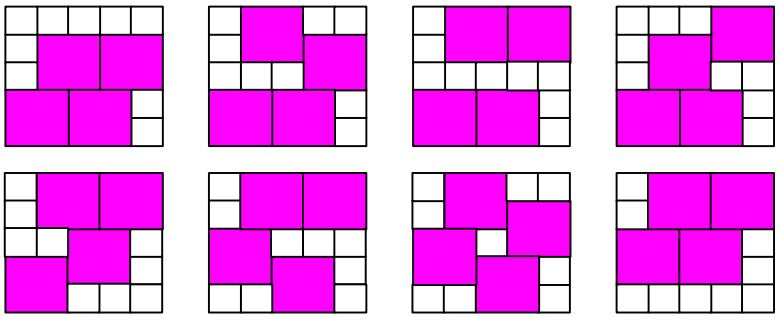

Figure 22

Finally, we can compute the number of tilings using the general recursive formula:

Theorem 6: *The number of tilings of a 5-by-n rectangle with squares of size up to 5-by-5 is given by*

$$\tilde{T}_{5,n} = \sum_{k=1}^{n} \tilde{B}_{5,k} \tilde{T}_{5,n-k} \ ,$$

where

$$\tilde{B}_{5,k} = \tilde{B}_{5,k-1} + \tilde{B}_{5,k-2} + \tilde{B}_{5,k-3} \quad \text{for } n > 8$$

with $\tilde{B}_{5,1}=1, \tilde{B}_{5,2}=7,\ \tilde{B}_{5,3}=13,\ \tilde{B}_{5,4}=20,\ \tilde{B}_{5,5}=35,\ \tilde{B}_{5,6}=66,\quad \tilde{B}_{5,7}=118,\ \tilde{B}_{5,8}=218,$ and $\tilde{T}_{5,0}=\tilde{T}_{5,1}=1$.

Proof:
Using (10) of Lemma 6, we can express the number of basic blocks of type I and III in terms of the number of basic blocks of type II:

$$\tilde{B}^{I}_{5,n+1}=\tilde{B}^{II}_{5,n+1}+\tilde{B}^{II}_{5,n}, \text{ and } \tilde{B}^{III}_{5,n+1}=\tilde{B}^{II}_{5,n-1}. \qquad (11)$$

Summing over all types,

$$\begin{aligned}\tilde{B}_{5,n+1}&=\left(\tilde{B}^{II}_{5,n+1}+\tilde{B}^{II}_{5,n}\right)+\tilde{B}^{II}_{5,n+1}+\tilde{B}^{II}_{5,n-1}+\tilde{B}^{II}_{5,n}+\tilde{B}^{II}_{5,n}\\&=2\cdot\tilde{B}^{II}_{5,n+1}+3\cdot\tilde{B}^{II}_{5,n}+\tilde{B}^{II}_{5,n-1}\end{aligned} \qquad (12)$$

Using (10) in combination with (11), we can derive a recursive formula for $\tilde{B}^{II}_{5,n+1}$:

$$\tilde{B}^{II}_{5,n+1}=\tilde{B}^{I}_{5,n}+\tilde{B}^{III}_{5,n}=\left(\tilde{B}^{II}_{5,n}+\tilde{B}^{II}_{5,n-1}\right)+\tilde{B}^{II}_{5,n-2}. \qquad (13)$$

Substituting (13) into (12) for each of the terms, followed by a suitable grouping of the resulting terms leads to the recursive equation for $\tilde{B}_{5,n+1}$:

$$\begin{aligned}\tilde{B}_{5,n+1}&=2\cdot\left(\tilde{B}^{II}_{5,n}+\tilde{B}^{II}_{5,n-1}+\tilde{B}^{II}_{5,n-2}\right)+3\cdot\left(\tilde{B}^{II}_{5,n-1}+\tilde{B}^{II}_{5,n-2}+\tilde{B}^{II}_{5,n-3}\right)\\&\quad+\left(\tilde{B}^{II}_{5,n-2}+\tilde{B}^{II}_{5,n-3}+\tilde{B}^{II}_{5,n-4}\right)\\&=\left(2\cdot\tilde{B}^{II}_{5,n}+3\cdot\tilde{B}^{II}_{5,n-1}+\tilde{B}^{II}_{5,n-2}\right)+\left(2\cdot\tilde{B}^{II}_{5,n-1}+3\cdot\tilde{B}^{II}_{5,n-2}+\tilde{B}^{II}_{5,n-3}\right)\\&\quad+\left(2\cdot\tilde{B}^{II}_{5,n-2}+3\cdot\tilde{B}^{II}_{5,n-3}+\tilde{B}^{II}_{5,n-4}\right)\\&=\tilde{B}_{5,n}+\tilde{B}_{5,n-1}+\tilde{B}_{5,n-2}.\end{aligned}$$

This formula is valid for $n > 8$, since the recursions for the subtypes are only valid for $n > 5$. For $n \le 5$, the initial conditions for $\tilde{B}_{5,n}$ follow from Lemma 4. Equation (10) can be used together with the initial values given in Lemma 6 to compute the number of subtypes for n = 6, 7 and 8. Summing over all subtypes gives

$$\tilde{B}_{5,6}=26+16+4+10+10=66,\ \tilde{B}_{5,7}=46+30+10+16+16=118 \text{ and } \tilde{B}_{5,8}=86+56+16+30+30=218.$$

□

Table 6 shows the values of $\tilde{B}_{5,n}$ and $\tilde{T}_{5,n}$ for $n \le 10$.

n	1	2	3	4	5	6	7	8	9	10
$\tilde{B}_{5,n}$	1	7	13	20	35	66	118	218	402	738
$\tilde{T}_{5,n}$	1	8	28	117	472	1,916	7,765	31,497	127,707	517,881

Table 6

8. Conclusion

The approach used in this paper for generating basic blocks in the case where tiles of size up to *k*-by-*k* are allowed becomes quite complex as *m* increases (since more and more columns need to be taken into account for determining the different types). Therefore, results for $m > 5$ will most likely require a different approach.

However, in the case where only 1-by-1 and 2-by-2 tiles are used, the extension of basic blocks follows a more regular pattern. There is a good chance that combinatorial formulas for the number of basic blocks, similar to the one for $B_{m,2}$, may be derived. A first step is the implementation of an algorithm for generating and counting the basic blocks of the next larger size and to look for patterns in the resulting sequences.

Acknowledgement

I would like to thank Phyllis Chinn, who introduced me to this research question at a PROMPT (Professors Rethinking Options for Mathematics for Pre-service Teachers) workshop, sponsored by NSF grant TPE 92-53321. Thanks also to Daphne Liu, who was always willing to read new drafts of this paper. Finally, I would like to thank Neil Calkin, who has introduced me to the online check for integer sequences [7] and given me ideas for future work on this problem.

MuPAD-Combinat, an open-source package for research in algebraic combinatorics

F. Hivert, N. M. Thiéry

23rd September 2003

Abstract

In this article we give an overview of the MuPAD-Combinat open-source algebraic combinatorics package for the computer algebra system MuPAD 2.0.0 and higher. This includes our motivations for developing yet another combinatorial software, a tutorial introduction with lots of examples, as well as notes on the general design. The material presented here is also available as part of the MuPAD-Combinat handbook; further details and references on the algorithms used can be found there. The package and the handbook are available from the web page, together with download and installation instructions, mailing-lists, and so on:

http://mupad-combinat.sourceforge.net

Contents

1 Introduction

`MuPAD-Combinat` is an open-source algebraic combinatorics package for the computer algebra system MuPAD 2.0.0 and higher. The main purpose of this package is to provide an extensible toolbox for computer exploration. The development started in spring 2001, and the package currently contains functions to deal with usual combinatorial classes (partitions, tableaux, decomposable classes, ...), Schubert polynomials, characters of the symmetric group, and weighted automata. It supplies the user with tools for constructing new combinatorial classes and combinatorial algebras and, as an application, provides some well-known combinatorial algebras like the algebra of symmetric functions and various generalizations. This represents about 65000 lines of MuPAD and C++ code together with 350 pages of doc, written by 3 main developers and altogether about 20 contributers. The core of the package is integrated in the official library of MuPAD since version 2.5.0.

The purpose of this paper is to present the package for people that can be interested as more or less advanced users but also for people who may contribute code.

After a presentation of our motivation to write such a package, we propose a guided tour to the package. Though this tour suppose some familiarities with the MuPAD computer algebra system, the first part describe the combinatorial feature of `MuPAD-Combinat` and is intended for users. It does not suppose strong programming knowledge. The second part of the tour devoted to the building of new combinatorial algebras, is a little bit more advanced.

After that, the paper goes on with some design notes for the `MuPAD-Combinat` package. This third part of the paper deals much more with programming technics, and may interest people who wants to understand inner mechanisms of the package. Note that this part is not only written for peoples who want to contribute but also to people who want to know the internal mechanism of `MuPAD-Combinat`, for example to compare it with similar package. It requires strong knowledge about programming but not necessarily about the MuPAD language itself. In particular we discuss the advantage of using typing mechanism and object oriented features rather that just manipulating expressions which is the usual mechanism of similar packages. As such, it may interest people wanting to have comparable feature in a different language.

1.1 A need for a toolbox for computer exploration in algebraic combinatorics

While doing research in (algebraic) combinatorics, computer exploration can be of great help. In its simplest form, when looking for the generating series of a combinatorial class, one can try to compute its first terms; those may give a

hint on a recurrence relation or a general formula; at least, they can be sent to the *Online Encyclopedia of Integer Sequences* [Se03] for comparison with other well known sequences. In general, using a computer allows for studying large scale examples (in combinatorics, the size of the examples usually grows very quickly!). This can help to suggest conjectures, check them for likeliness, or find counter-examples.

The first author is interested in symmetric functions and their generalizations in connection with representation theory. The problem is basically to find interesting bases together with product and change of basis rules (analogues of Littlewood-Richardson rules). His results were mainly obtained by computer exploration, using some `Maple` [CGG+88] routines extending the `ACE` [Vei98] package. Similarly, the second author had developed a library for computing within invariant rings of permutation groups, in order to study certain invariant rings related to graph theory. The common point of those tools was that they essentially consisted of basic combinatorial routines together with mechanics to compute within certain combinatorial algebras.

By a combinatorial algebra, we mean a vector space, with a basis indexed by combinatorial objects, and endowed with a product that obeys some combinatorial rule. Think of the algebra of the n-th symmetric group: the basis is indexed by permutations, while the product is given by the usual product of permutations. Such combinatorial algebras appear in many situations (references). One often needs to run computations within such algebras, for example for finding idempotents, or better understanding the algebraic structure.

A typical computation is to find the elements c in a given combinatorial algebra satisfying certain properties (say $c^2 = c$):

1. Provide the product rule on basis elements (unless the algebra is already implemented);

2. Produce a system of equations characterizing those elements c by running appropriate computations in the algebra;

3. Solve this system of equations;

4. Interpret the result.

This simple example highlights what the platform for computer exploration should essentially provide: in the first step it helps to have right under hand a wide toolbox of basic combinatorial routines; in the second step, the system should take care of all the linear bookkeeping to allow for manipulating elements of the algebra; the third step requires all the usual computer algebra tools (linear algebra, Gröbner bases, integration, solvers, ...).

1.2 Review of preexisting software

We now review some related algebraic combinatorics software, and describe to which extent they did or did not fit our needs. We do not seek completeness, but rather want to present the background that motivated the definition of the specifications for `MuPAD-Combinat`. For a complete list of related software, we refer to `http://www.mat.univie.ac.at/~slc/divers/software.html`.

One of the first, and most famous, package for algebraic combinatorics is J. Stembridge's `SF` library for `Maple` [CGG+88] which allows to compute with symmetric functions.

A more ambitious package for `Maple` [CGG+88], called `ACE` [Vei98], was developed in Marne-la-Vallée, mostly by S. Veigneau. It provides a wide range of combinatorial routines and implements several classical combinatorial algebras (symmetric functions, quasi-symmetric function, non commutative symmetric functions, Schubert polynomials, ...) using state of the art algorithms. Being a library for a computer algebra system that is widely used in the community helped it to spread (there are about 100 known users), and allowed to combine it with the many other existing combinatorics package for the same system. On the other hand it suffered from the poor programming language of `Maple` [CGG+88], and the continuous incompatibilities with the new versions of `Maple` [CGG+88]made its maintenance tricky. Also, it appeared with time that the overall design made it difficult to extend in particular for defining new combinatorial algebras. Altogether, the development essentially stalled in 1999 when S. Veigneau left for industry after his PhD thesis.

μ-`EC` [Pro99], also developed in Marne-la-Vallée by V. Prosper, was an attempt to translate `ACE` [Vei98] for the computer algebra system MuPAD. The goal was mainly to try if the programing language was more adapted to the needs, and in particular to incorporate Symmetrica (see below) into the system, via a dynamic module. However, it suffered from the same design and development model limitations than ACE and the development also stalled when V. Prosper left for industry after his PhD thesis in 2000.

A. Kohnert leads the development of `Symmetrica` [KKL], a collection of `C` routines to compute with symmetric functions and Schubert polynomials, ordinary, modular, and projective representations of the symmetric group, and Hecke algebras of type A. The underlying programming language allows very substantial speed improvements compared to equivalent algorithms written, say, in `Maple` [CGG+88]. The object oriented design definitely helps for maintaining and extending it. On the other hand, it does not provide support for easy definition of new combinatorial algebras, and can't be straightforwardly combined with other computer algebra tools. The remaining drawbacks, coming from the programming language, are partly matters of personal taste. There is a steep learning curve for non everyday programmers, which makes it difficult to attract new user. We also find the development cycle to be too long in a low-level pro-

graming language. Finally, not having an interpreter makes it quite unpractical for interactive computer exploration (this could be circumvented by using a `C` interpreter like `CINT`).

B. Weybourne also wrote an interactive program called `Schur` for calculating properties of Lie groups and symmetric functions, with a view toward physics. As for `Symmetrica`, it can't be easily combined with other computer algebra tools, and does not provide support for easy definition of new combinatorial algebras.

To some extent, the systems `GAP` [GAP99] and `Magma` [`?`, `?`] allow for defining new combinatorial algebras, and provide a wide set of tools from group theory and algebra that are useful for algebraic combinatorics. We discuss them further later on in the choice of the underlying system.

Finally, one should mention the `Maple` [CGG+88] library for Gröbner basis computations by F. Chyzak which allows to easily implement those combinatorial algebras that fit within the more specific framework of Ore-algebras.

1.3 Specifications

As argued in the former sections our goal is to have a flexible and easy to use toolbox for computer exploration in algebraic combinatorics. This means two distinguished and closely interfaced set of packages: A first for combinatorics a second for algebra.

The combinatorial part should provide the basic routines to deals with various combinatorial objects. As such, it has to be a large collection of many various relatively small functions to count, list, manipulate combinatorial objects. Most of the required combinatorial utilities are quite common (say, list all the partitions of a given integer, ...); however, there are so many potential common utilities that a combinatorial package will never be able to provide all of them, or at least not in an optimized form.

In our minds, such a package is written when needed in research. So the main goal here is to share the code. Thus it must be easy to add some functions in the package, and each functions should have a natural and easy to find place in the package. Such a package should make it easy to integrate new utilities by providing a well designed framework. Ideally, the package should act as a repository where users would include their utilities while they develop them for their own needs. Furthermore, the package should provide versatile tools that makes it easy to define new combinatorial classes, new algebras, and so on.

The algebraic part should be a sort of mecano build on top of the combinatorial part. On the contrary to other package like `ACE` [Vei98] ore `Symmetrica` [KKL], we wanted to have a unspecialized, very flexible and extensible package to build algebraic objects. Standard algebras such as symmetric functions are given as examples rather than as goal. We believe than what is needed is more a toolbox than a set of polished implementation of various algebras. So the package should

take care about all tedious part of computations such has parsing, extracting coefficients, converting to vector notations, ... Hence, the writer can concentrate on the specific part of his problem which is, most of the time in our experience, in combinatorics.

Moreover, the system should allows to ask very natural question such as for example the rank of a set of vector or which element in a combinatorial algebra are idempotents. In such computations, one builds large systems of equation, linear or not. To solve such systems, one often needs general computer algebra tools, like linear algebra, integration, Gröbner basis, and so on. Interfacing with such tools should be as seamless as possible. So we choose to use a generic computer algebra system. But as the size of the equation system may be very large, we often needs more specialized packages. thus we need to be able to interface as easily as possible our package with other one such as `gb`, `alp`, ...

Has a guideline for choosing what has to be done, we decided to take to following rules:

Our ultimate goal is to do research, not to write software. However, to do this research, we need the appropriate tools. Hopefully, in the middle term, sharing those tools and the associated development time with others is a way for us to save time for more research. So the goal is to share as much and as earlier as possible pieces of codes. This implies that, the development cycle ought to be short.

Genericity, flexibility, rapid prototyping, and speed of development are at a premium. Of course, efficiency is desirable but constant time factors are not necessarily so important (anyway, most of the time, the size of the studied objects grows exponentially). Optimizations are usually only really required in very specific parts (underlying linear algebra, ...); only those parts need to be optimized, after a careful analysis with a profiler. Of course, ideally, the code should be written in such a way to leave room for such specializations and optimizations. All of this speaks for a high-level language that allows to write code that sticks as much as possible to the mathematical way of thinking. Of course, this does not preclude the use of some modules written in a low-level language like C for the critical sections, when there is a clear need for it.

Following the goal to share work as possible, the package should allow different levels of use:

- Occasional usage, as a mere calculator using only predefined utilities.
- Regular usage, programming of little utilities, definition of simple new combinatorial classes and algebras;
- Intensive usage, programming of complete libraries for new combinatorial classes and algebras;

- Core hacking, implementation of generic algorithm, writing of external modules (say in C) for optimized speed, ...

And finally, being integrated in a well-known and widely available system helps so that the user can work in his usual environment; this is particularly important for the first two levels of usage above. Moreover, this is a critical problem to share code.

1.4 Structure of this document

Apart from the preceding introduction this paper is divided in two sections. The First section is a guided tour trough `MuPAD-Combinat`. After a general example of usage, we describe step by step the structure of a combinatorial class, together with two generic tools to deals with constrained list of integers and grammar described decomposable objects. We gives then some examples, how to define new combinatorial classes. The next two subsection are devoted to combinatorial algebras, predefined and new one. This first part ends with a summary of what is now provided in the package and what should be in the short term. Note that the version of this document included in the `MuPAD-Combinat`documentation provides exercises throughout the guided tour.

The second section is devoted to the design of the package. First we discuss about some very basic conventions such as naming. Then we deals with combinatorial objects and how they can be represented in a computer algebra system. We describe our solution to have a unified interface for various combinatorial classes on the to of which we will build algebraic object. In particular, inheritance allows here to standardize and reuse code. Finally, we deals with combinatorial algebras. We describe the advantage of typing objects rather that using expressions. Then we concentrate on the description of several implementation of free module and how the system take care of linearity. We ends by the description of combinatorial algebra with different bases and the way the system deals with the conversion between these different bases.

The suggested order of reading is to browse quickly through the guided tour (Section **??**), and the design notes (Section **??**, essentially the beginning of subsections **??** *Representing combinatorial objects and classes* and **??** *Representing combinatorial algebras*), and then to read those two sections in detail with a computer under hand to experiment with the examples.

2 A guided tour through MuPAD-Combinat

The main purpose of this package is to provide tools for manipulating combinatorial (Hopf) algebras. To setup the stage, we start this guided tour by presenting a few sample computations with two examples of such algebras. Then, we proceed

by illustrating with many examples the predefined combinatorial objects and how to define new ones and the predefined combinatorial algebras and how to define new ones. We conclude this tour by a summary of the current features.

2.1 Two examples of combinatorial algebras

We load the MuPAD-Combinat package, and define a shortcut for the algebra of symmetric functions [Mac95]:

```
>> package("Combinat", Quiet):
   S := examples::SymmetricFunctions():
```

We consider the three first elementary symmetric polynomials in the variables {x1,...,x6}:

```
>> alphabet := [ x1, x2, x3, x4, x5, x6]:
   e1 := expand(S::e([1])(alphabet));

                    x1 + x2 + x3 + x4 + x5 + x6

>> e2 := expand(S::e([2])(alphabet));

 x1 x2 + x1 x3 + x1 x4 + x2 x3 + x1 x5 + x2 x4 + x1 x6 +

    x2 x5 + x3 x4 + x2 x6 + x3 x5 + x3 x6 + x4 x5 + x4 x6 +

    x5 x6

>> e3 := expand(S::e([3])(alphabet))

 x1 x2 x3 + x1 x2 x4 + x1 x2 x5 + x1 x3 x4 + x1 x2 x6 +

    x1 x3 x5 + x2 x3 x4 + x1 x3 x6 + x1 x4 x5 + x2 x3 x5 +

    x1 x4 x6 + x2 x3 x6 + x2 x4 x5 + x1 x5 x6 + x2 x4 x6 +

    x3 x4 x5 + x2 x5 x6 + x3 x4 x6 + x3 x5 x6 + x4 x5 x6
```

Computing the product of two such polynomials yields a huge polynomial which is not quite practical to manipulate:

```
>>   expand(e2*e3)
```

```
 10 x1 x2 x3 x4 x5 + 10 x1 x2 x3 x4 x6 + 10 x1 x2 x3 x5 x6 +

    10 x1 x2 x4 x5 x6 + 10 x1 x3 x4 x5 x6 + 10 x2 x3 x4 x5 x6 +

                  2
    3 x1 x2 x3 x4  + ... (one page of output)

         2   2
    x1 x2  x3  + ... (another page of output)
```

Instead, if we use the symmetries, the previous product can be expressed as compactly as:

```
>>   S::m( S::e([2]) * S::e([3]) );

       10 m[1, 1, 1, 1, 1] + 3 m[2, 1, 1, 1] + m[2, 2, 1]
```

Here, `m[2, 1, 1, 1]` denotes the monomial symmetric function $m_{2,1,1,1}$ obtained by summing all the monomials with one variable elevated to the power 2 and three variables to the power 1.

Now, we are working in an algebra whose basis is indexed by partitions, and we want to compute efficiently in this algebra. As another typical example, we are currently working on the so-called Loday-Ronco algebra [LR98], which is in particular of interest for theoretical physicists [BF, ?, ?]. It is implemented as a combinatorial algebra having binary trees as basis.

```
>> LRA:= (examples::LodayRoncoAlgebra())::p:
```

For example, take the two following trees:

```
>> t1 := LRA(combinat::binaryTrees::unrank(6, 4))

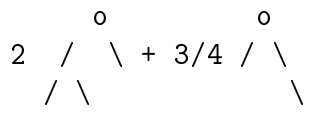
                                o
                               / \
                                  \
```

```
>> t2 := LRA(combinat::binaryTrees::unrank(26, 5))

                                  o
                                 /  \
                                / \
```

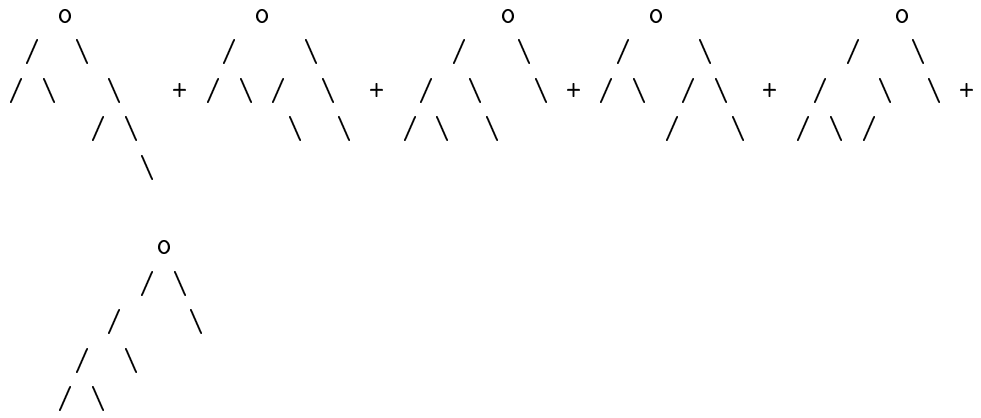
You can make a formal linear combination of them:

```
>> t3 := 2*t2 + 3/4*t1
```



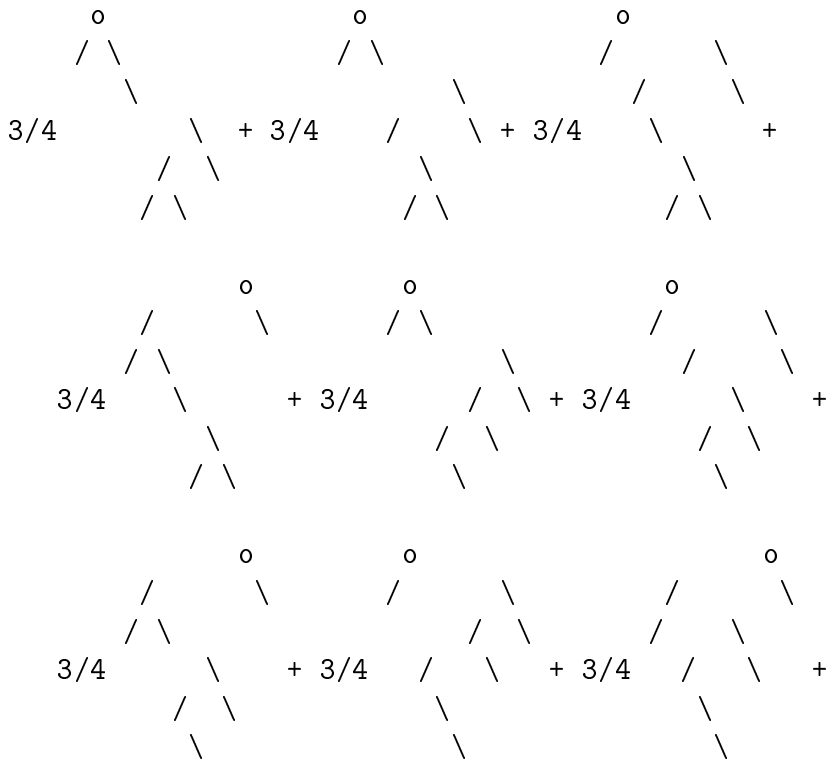
or take their product:

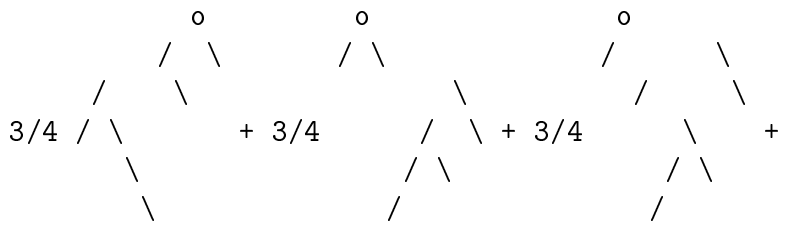
```
>> t2*t1
```

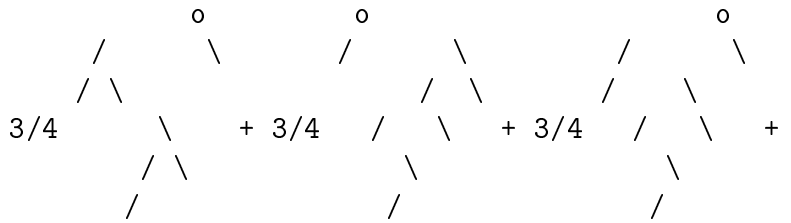


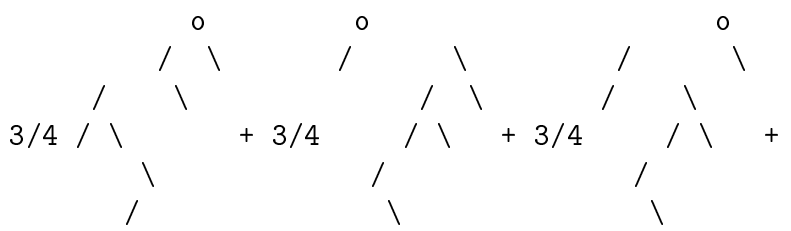
Here is a more complicated product in this algebra:

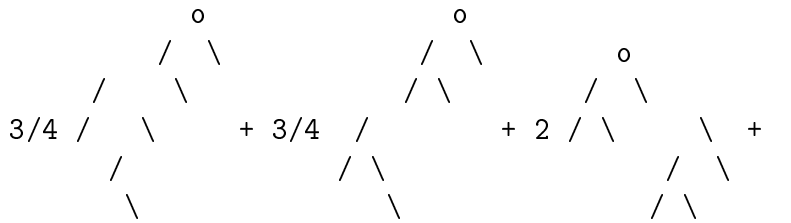
```
>> t3*t2
```

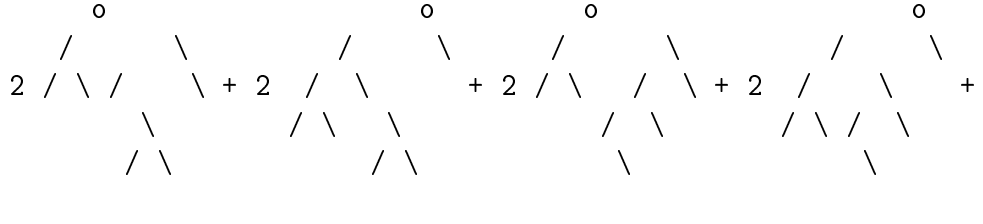


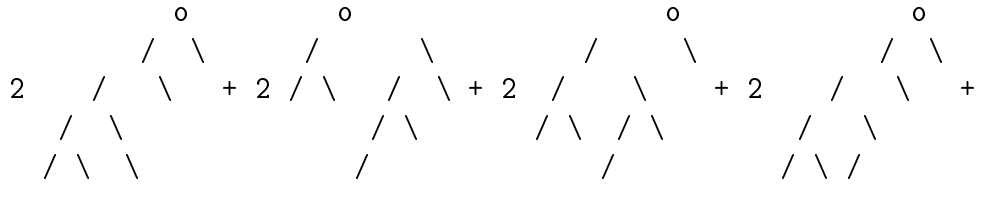












```
    2    /
       /  \
      / \
```

2.2 MuPAD-Combinat, step by step

We now describe in more details how all of this works. In the following, we assume that the package `MuPAD-Combinat` has been loaded into MuPAD and, for shortening the notations, that the library combinat has been exported. We also assume that the reader is somewhat familiar with the MuPAD syntaxwe refer to the MuPAD tutorial for details. Technicalities can be safely ignored in a first reading; they will be better understood after the explanations in the design notes.

```
>>   package("Combinat", Quiet):
     export(combinat):
```

Using predefined combinatorial functions and classes

We start by some sample applications at random. We compute the first terms of the famous Catalan sequence, we generate the Cartesian product of three lists, we compute all permutations of the numbers $1, 2, 3$, and we ask for all sub-words of the word `[a, b, c, d]`:

```
>> catalan(i) $ i = 0..10

         1, 1, 2, 5, 14, 42, 132, 429, 1430, 4862, 16796

>> cartesianProduct::list([1,2,3],[a,b],[i,ii,iii])

 [[1, a, i], [1, a, ii], [1, a, iii], [1, b, i], [1, b, ii],

    [1, b, iii], [2, a, i], [2, a, ii], [2, a, iii], [2, b, i],

    [2, b, ii], [2, b, iii], [3, a, i], [3, a, ii],

    [3, a, iii], [3, b, i], [3, b, ii], [3, b, iii]]

>> permutations::list([1, 2, 3])

 [[1, 2, 3], [1, 3, 2], [2, 1, 3], [2, 3, 1], [3, 1, 2],

    [3, 2, 1]]

>> subwords::list([a,b,c,d])
```

```
 [[], [a], [b], [c], [d], [a, b], [a, c], [a, d], [b, c],

    [b, d], [c, d], [a, b, c], [a, b, d], [a, c, d], [b, c, d],

    [a, b, c, d]]
```

We turn now to various *combinatorial classes*; in short a combinatorial class is a set of related combinatorial objects, like the set of all integer partitions. For each such class, there is a sub-library of `combinat`. We can use the library `combinat::partitions` to list all the integer partitions of 5:

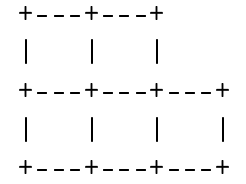
```
>> partitions::list(5)

 [[5], [4, 1], [3, 2], [3, 1, 1], [2, 2, 1], [2, 1, 1, 1],

    [1, 1, 1, 1, 1]]
```

Let us draw the partition `[3,2]` using boxes (French or Cartesian notation):

```
>> partitions::printPretty([3, 2])
```



Now, we can fill those boxes with the numbers `1,2,3,4,5` so that the numbers are increasing along rows and columns to obtain so-called *standard tableaux*. Here are all the standard tableaux of shape `[3,2]`:

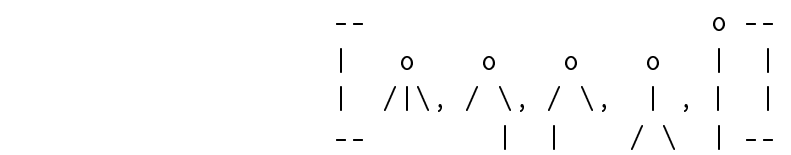
```
>> map(tableaux::list([3, 2]), tableaux::printPretty)
```

```
 -- +---+---+      +---+---+      +---+---+      +---+---+
|  | 4 | 5 |      | 3 | 5 |      | 2 | 5 |      | 3 | 4 |
|  +---+---+---+  +---+---+---+  +---+---+---+  +---+---+---+
|  | 1 | 2 | 3 |, | 1 | 2 | 4 |, | 1 | 3 | 4 |, | 1 | 2 | 5 |,
 -- +---+---+---+  +---+---+---+  +---+---+---+  +---+---+---+

    +---+---+     --
    | 2 | 4 |      |
    +---+---+---+  |
    | 1 | 3 | 5 |  |
    +---+---+---+ --
```

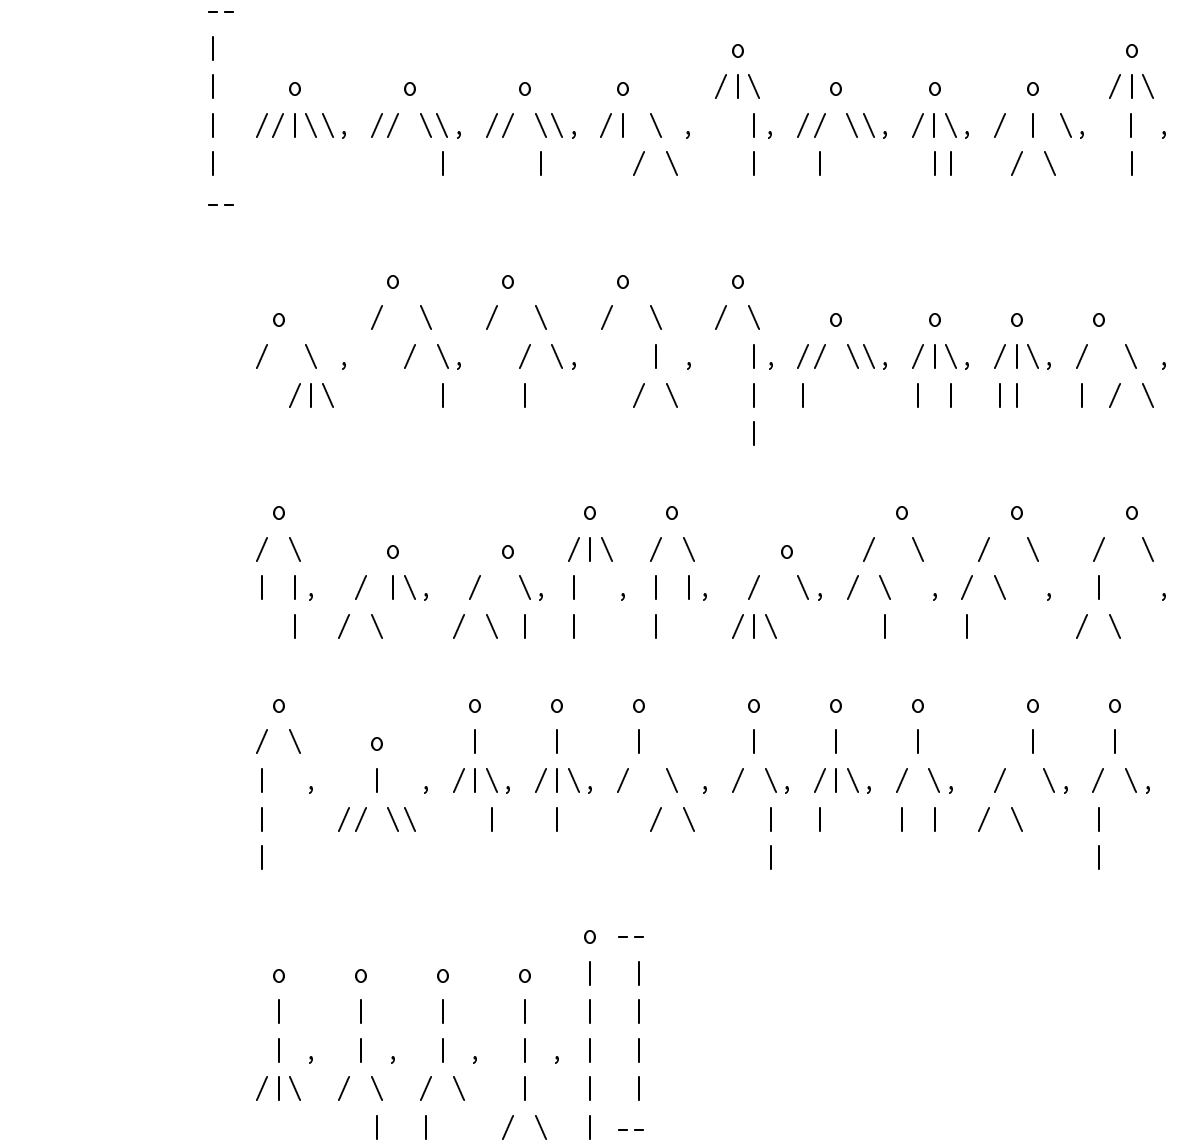
Ordered trees are another typical combinatorial class. Here are all the trees on four nodes:

```
>> trees::list(4)
```



and here are a lot of trees:

```
>> trees::list(6)
```



All the sub-libraries of `combinat` share a standardized interface. Let us look in more detail at the library `combinat::partitions`. We can count partitions:

```
>> partitions::count(i) $ i = 0..10
```

```
              1, 1, 2, 3, 5, 7, 11, 15, 22, 30, 42
```

list them under some extra conditions (here we list the partitions of 5 whose length is between 2 and 3):

```
>> partitions::list(5, MinLength = 2, MaxLength = 3);
```

```
             [[4, 1], [3, 2], [3, 1, 1], [2, 2, 1]]
```

or compare them (lexicographically):

```
>> bool(partitions::_less([3, 1], [2, 2]))
```

```
                                FALSE
```

An important feature of `MuPAD-Combinat` are the so-called *generators*, which allow to run through huge lists of combinatorial objects without expanding the full lists into memory. Technically, a generator is a function `g` such that each call `g()` returns either a new object, or FAIL if no more objects are available. Let us build a generator for the partitions of 4:

```
>> g := partitions::generator(4):
```

Here is the first partition of 4:

```
>> g()
```

```
                                  [4]
```

Here is the second partition of 4:

```
>> g()
```

```
                               [3, 1]
```

And here are the remaining ones:

```
>> g(), g(), g(), g()
```

```
              [2, 2], [2, 1, 1], [1, 1, 1, 1], FAIL
```

Generators become handy when you want to work with the 53174 partitions of 42:

```
>> g := partitions::generator(42):
   g(), g(), g(), g(), g(), g()
```

```
[42], [41, 1], [40, 2], [40, 1, 1], [39, 3], [39, 2, 1]
```

Most of the sub-libraries of `combinat` provide such generators.

Whenever possible (i.e. when it does not harm the computational complexity), we focus on providing the user with generic tools that cover many kinds of applications. For example, the libraries for partitions, integer vectors, and compositions share a very similar interface:

```
>> integerVectors::list(10, 3, MinPart = 2, MaxPart = 5, Inner = [2, 4, 2])
```

(Note: `Inner = [2, 4, 2]` means that the three parts should be respectively at least 2, 4 and 2).

```
[[4, 4, 2], [3, 5, 2], [3, 4, 3], [2, 5, 3], [2, 4, 4]]
```

```
>> compositions::list(5, MaxPart = 3, MinPart = 2, MinLength = 2, MaxLength = 3)
```

```
[[3, 2], [2, 3]]
```

```
>> partitions::list(5, MaxSlope = -1)
```

```
[[5], [4, 1], [3, 2]]
```

Those libraries actually use internally the same computational engine `combinat::integerListsLexTools`:

```
>> partitions::list(9, MinPart = 2, MaxPart = 5)
```

```
[[5, 4], [5, 2, 2], [4, 3, 2], [3, 3, 3], [3, 2, 2, 2]]
```

```
>>   integerListsLexTools::list(9, 0, infinity, 2, 5, -infinity, 0)
```

```
[[5, 4], [5, 2, 2], [4, 3, 2], [3, 3, 3], [3, 2, 2, 2]]
```

In fact, `combinat::integerListsLexTools` could also be used to generate Motzkin and Dyck words, etc.

In the same spirit, instead of implementing a specific generator for standard tableaux, we implemented a generator for the linear extensions of a poset. We already reused this generator internally for generating standard binary search trees, and it could be reused as well for generating standard skew tableaux, standard ribbons, and so on.

We also incorporated and extended the former `CS` library by S. Corteel, A. Denise, I. Dutour, and P. Zimmermann. This library allows for manipulating any combinatorial classes that can be defined by a deterministic grammar. Here we consider words of A's and B's without two consecutive B's:

```
>> fiWords := decomposableObjects(
       [FiWords = Union(Epsilon,
                        Atom(B),
                        Prod(FiWords, Atom(A)),
                        Prod(FiWords, Atom(A), Atom(B)))
       ]):
```

(Note: an `Epsilon` is an object of size 0 while an `Atom` is an object of size 1).

```
>> fiWords::list(4)
 [Prod(Prod(Prod(B, A), A), A), Prod(

    Prod(Prod(Prod(Epsilon, A), A), A), A),

    Prod(Prod(Prod(Epsilon, A, B), A), A),

    Prod(Prod(B, A, B), A), Prod(Prod(Prod(Epsilon, A), A, B), A

    ), Prod(Prod(B, A), A, B), Prod(Prod(Prod(Epsilon, A), A),

    A, B), Prod(Prod(Epsilon, A, B), A, B)]
```

The result is not very readable, but this can be fixed by a quick substitution:

```
>> map(fiWords::list(4), p -> [eval(subs(p, Prod = id, Epsilon = null()))])
 [[B, A, A, A], [A, A, A, A], [A, B, A, A], [B, A, B, A],

    [A, A, B, A], [B, A, A, B], [A, A, A, B], [A, B, A, B]]
```

Alternatively, we could have provided some rewriting rules in the grammar:

```
>> fiWords := decomposableObjects(
       [FiWords    = Alias(FiWordsRec, DOM_LIST),
        FiWordsRec = Union(Epsilon(),
                           Atom(B),
                           Alias(Prod(FiWordsRec, Atom(A)), op),
                           Alias(Prod(FiWordsRec, Atom(A), Atom(B)), op))
       ]):
   fiWords::list(4);
 [[B, A, A, A], [A, A, A, A], [A, B, A, A], [B, A, B, A],

    [A, A, B, A], [B, A, A, B], [A, A, A, B], [A, B, A, B]]
```

This seems to work nicely. Let us count those words:

```
>> fiWords::count(i) $ i = 0..10

            1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144
```

You will certainly recognize the Fibonnaci sequence. Not quite a surprise, the recurrence relation can be seen right away from the grammar. Actually, this recurrence relation is automatically determined by the library, and used for counting efficiently:

```
>> fiWords::recurrenceRelation() = 0

                u(n - 1) - u(n) + u(n - 2) = 0
```

This also applies for several libraries which are based on `combinat::decomposableObjects`. For example, here is the recurrence relation for binary trees:

```
>> collect(binaryTrees::grammar::recurrenceRelation(),
           [u(n), u(n-1)], factor) = 0

             u(n) (n + 1) - 2 u(n - 1) (2 n - 1) = 0
```

Defining new combinatorial classes

Let us define one of the most trivial combinatorial classes:

```
>> domain nonNegativeIntegers
       // This is a domain (not a library):
       inherits Dom::BaseDomain;
       // This is a combinatorial class:
       category Cat::CombinatorialClass;
       // This is a facade domain:
       axiom    Ax::systemRep;

       info := "Domain 'nonNegativeIntegers': the class of non negative integers";

       // The domain of the elements of this class:
       domtype := DOM_INT;
       // The type of the elements of this class:
       type := Type::NonNegInt;

       // The size of an integer is itself:
       size := n -> n;
       // There is exactly one integer of size n:
```

```
    count := n -> 1;
    list  := n -> [n];
    // No need to define generator; it is defined via list by default
end_domain:
```

```
>> testtype(x, nonNegativeIntegers), testtype(-3, nonNegativeIntegers),
   testtype(3, nonNegativeIntegers);

                      FALSE, FALSE, TRUE

>> nonNegativeIntegers::count(4);

                                1

>> nonNegativeIntegers::list(4)

                              [4]
```

In a first approximation, the three lines `inherits`, `category`, and `axiom` may be safely ignored and kept verbatim. For a deeper understanding, we strongly recommend to read the detailed explanations about the implementation of combinatorial classes in the design notes.

It is often practical to define a sub-class of an existing class. Here we show how to define the class of the permutations of `[1,2,3]`:

```
>> domain permutationsOf123
    // Inherits all the methods from combinat::permutations
    inherits combinat::permutations;
    // This is a combinatorial class
    category Cat::CombinatorialClass;
    // This is a facade domain
    axiom    Ax::systemRep;

    info := "Domain 'permutationsOf123': the class of the permutations of [1,2,3

    // Redefinition of isA
    isA := (p) -> permutations::isA(p, [1,2,3]);

    // Redefinition of count
    count     := () -> permutations::count(3);
    // Redefinition of generator
    generator := () -> permutations::generator(3);
    // No need to redefine list, since it is defined via generator by default
end_domain:
```

Let us use this new combinatorial class:

```
>> testtype(x,            permutationsOf123),
   testtype([1, 2, 3, 4], permutationsOf123),
   testtype([1, 2, 2],    permutationsOf123),
   testtype([1, 3, 2],    permutationsOf123);

                   FALSE, FALSE, FALSE, TRUE

>> permutationsOf123::count();

                                6

>> permutationsOf123::list()

 [[1, 2, 3], [1, 3, 2], [2, 1, 3], [2, 3, 1], [3, 1, 2],

    [3, 2, 1]]
```

Note: instead of implementing permutationsOf123 by hand, we could have alternatively used the generic utility `combinat::subClass`; it allows to automatically define a sub-class of an existing combinatorial class by providing extra parameters to be passed down to all the methods `count`, `list`, etc.:

```
>> permutationsOf123 := subClass(permutations, 3):
   permutationsOf123::list()

 [[1, 2, 3], [1, 3, 2], [2, 1, 3], [2, 3, 1], [3, 1, 2],

    [3, 2, 1]]
```

To conclude, we define the combinatorial class of Fibonacci words. Essentially, we reuse the definition of `fiWords` above, and wrap it into a domain to add type checking:

```
>> domain FibonacciWords
       inherits Dom::BaseDomain;
       // The objects of this class are defined by a grammar
       category Cat::DecomposableClass;
       // This is a facade domain
       axiom    Ax::systemRep;

       info := "Domain 'FibonacciWords': the class of Fibonacci words";

       // The domain of the elements of this class
```

```
        domtype := DOM_LIST;

        // The type of the elements of this class
        type := Type::Predicate(
            proc(w) // a procedure that tests if w is a Fibonacci word
                local i;
            begin
                if domtype(w) <>DOM_LIST then return(FALSE); end_if;
                for i from 1 to nops(w) do
                    if (w[i]<>A and w[i]<>B) or
                       (i<nops(w) and w[i]=B and w[i+1]=B) then
                        return(FALSE);
                    end_if;
                    TRUE;
                end_for;
            end_proc);

        // The size of a Fibonacci word is its length
        size := nops;

        // The grammar which defines the objects of this class
        grammar := decomposableObjects(
            [FiWords = Alias(FiWordsRec, DOM_LIST),
             FiWordsRec = Union(Epsilon(),
                                Atom(B),
                                Alias(Prod(FiWordsRec, Atom(A)), op),
                                Alias(Prod(FiWordsRec, Atom(A), Atom(B)), op))
            ]);
    end_domain:
```

Now, we can do type checking with this domain:

```
>> testtype(x, FibonacciWords),
   testtype([A, B, C], FibonacciWords),
   testtype([A, B, B], FibonacciWords),
   testtype([A, B, A], FibonacciWords)

                    FALSE, FALSE, FALSE, TRUE
```

And of course, we can still use all the previous functionalities of fiWords:

```
>> FibonacciWords::list(4);
```

```
 [[B, A, A, A], [A, A, A, A], [A, B, A, A], [B, A, B, A],

    [A, A, B, A], [B, A, A, B], [A, A, A, B], [A, B, A, B]]
```

```
>> FibonacciWords::count(4);
```

$$8$$

```
>> FibonacciWords::unrank(2, 4)
```

$$[A, A, A, A]$$

Using predefined combinatorial algebras

We now demonstrate how to do sample computations with predefined combinatorial algebras, starting with the algebra of symmetric functions. Note that we really consider those predefined algebras as mere examples of use of this package; important and useful examples of course, but just examples.

We define the ring of symmetric functions over the rational numbers:

```
>> S := examples::SymmetricFunctions(Dom::Rational);
```

$$\text{examples::SymmetricFunctions(Dom::Rational)}$$

This ring has several remarkable families like the symmetric *power-sums* p_k: recall that the symmetric power-sum p_k expands on any given specified alphabet (i.e. set of variables) as the sum of all the variables elevated to the power k; furthermore, given a partition $\lambda := (\lambda_1, \ldots, \lambda_k)$, the product of $p_{\lambda_1} \ldots p_{\lambda_k}$ is denoted by p_λ:

```
>> p1 := S::p([1]);
   p1([x, y, z]);
```

$$p[1]$$

$$x + y + z$$

```
>> p2 := S::p([2]);
   p2([x, y, z])
```

$$p[2]$$

$$x^2 + y^2 + z^2$$

```
>> p421 := S::p([4, 2, 1]);
   p421([x,y,z])
```

```
                          p[4, 2, 1]

   2    2    2    4    4    4
(x  + y  + z ) (x  + y  + z ) (x + y + z)
```

Note: the product being commutative, the order in which the terms appear in the expansion above depends on MuPAD internal order, and is mathematically irrelevant.

Actually, the ring of symmetric functions is the free commutative algebra on the symmetric power-sums:

```
>> p2 * p1 * p2 * p421

                       p[4, 2, 2, 2, 1, 1]
```

Note that any expression is immediately expanded by the system:

```
>> (p421 + 3*p2)*(1/4*p1 - p2)

   1/4 p[4, 2, 1, 1] - 3 p[2, 2] - p[4, 2, 2, 1] + 3/4 p[2, 1]
```

This happens because the call `S::p([1])` returns a typed object, for which the standard arithmetic operators are overloaded:

```
>> domtype(p1);

   examples::SymmetricFunctionsTools::powersum(Dom::Rational)

>> S::p

   examples::SymmetricFunctionsTools::powersum(Dom::Rational)
```

That is, `S::powersum` (or `S::p` for short) really represents the domain of symmetric functions expanded on the power-sums basis. If at some time you do not want the expansion to take place, the objects can always be converted to expressions:

```
>> f := (expr(p421) + 3*expr(p2))*(1/4*expr(p1) - expr(p2))

                                 / p[1]         \
              (3 p[2] + p[4, 2, 1]) | ---- - p[2] |
                                 \   4          /
```

Here is how to convert efficiently the expression back into an object of the domain `S::p`:

```
>> f := eval(subs(f, p = S::p::domainWrapper))

   1/4 p[4, 2, 1, 1] - 3 p[2, 2] - p[4, 2, 2, 1] + 3/4 p[2, 1]
```

This requires the use of a small trick because of the indexed notation for the basis elements. S::p::domainWrapper is a special MuPAD object which, when used as `S::p::domainWrapper[3,2]`, returns a call to S::p([3,2]).

Of course, `examples::SymmetricFunctions` provides the other classical bases of symmetric functions, like the elementary symmetric functions `S::e`, the monomial symmetric functions `S::m`, the homogeneous symmetric functions `S::h`, the Schur functions `S::s`, etc.:

```
>> expand(S::e([2])([x,y,z]))

                          x y + x z + y z

>> expand(S::m([2, 1])([x,y,z]))

                2    2        2    2        2    2
             x y  + x  y + x z  + x  z + y z  + y  z

>> expand(S::h([2])([x,y,z]))

                                    2    2    2
                 x y + x z + y z + x  + y  + z

>> expand(S::s([2])([x,y,z]))

                                    2    2    2
                 x y + x z + y z + x  + y  + z
```

Here is how to convert from one basis to the other:

```
>> f := S::p([4]);
   S::e(f);
   S::h(f);
   S::s(f);
   S::m(f)
```

$$p_{[4]}$$

$$e_{[1,1,1,1]} - 4\,e_{[2,1,1]} + 4\,e_{[3,1]} - 4\,e_{[4]} + 2\,e_{[2,2]}$$

$$-h_{[1,1,1,1]} + 4\,h_{[2,1,1]} - 4\,h_{[3,1]} + 4\,h_{[4]} - 2\,h_{[2,2]}$$

$$-s_{[1,1,1,1]} + s_{[2,1,1]} - s_{[3,1]} + s_{[4]}$$

$$m_{[4]}$$

When multiplying two symmetric functions which are not expressed in the same basis, the system will make an implicit conversion, and return the result in one or the other of the two bases:

```
>> S::m([2]) * S::s([2])
```

$$m_{2,1,1} + m_{3,1} + m_4 + 2\, m_{2,2}$$

If you want to force the product to be done on a given basis, you can call the proper conversion explicitly:

```
>> S::s(S::m([2])) * S::s([2]);
```

$$-s_{2,1,1} + s_4 + s_{2,2}$$

Now, we can combine everything, and do some complicated calculation:

```
>> S::p( S::m([1]) * ( S::e([3])*S::s([2]) + S::s([3]) ) )
```

$$\frac{1}{6} p_{3,2,1} + \frac{1}{6} p_{3,1,1,1} - \frac{1}{4} p_{2,2,1,1} + \frac{1}{12} p_{1,1,1,1,1,1} - \frac{1}{6} p_{2,1,1,1,1} + \frac{1}{6} p_{1,1,1,1} + \frac{1}{2} p_{2,1,1} + \frac{1}{3} p_{3,1}$$

Finally, there is some basic support for the Hall-Littlewood functions, in the P and Q' basis, which we demonstrate now. We need to take some ground field which contains the parameter t of those functions. The simplest (and actually most efficient with the current MuPAD version), is to take the full field of expressions as coefficient ring:

```
>> S := examples::SymmetricFunctions(Dom::ExpressionField()):
```

Here is the Hall-Littlewood function $Q'_{(3,2,1,1)}$:

```
>> el := S::QP([3, 2, 1, 1])
```

$$QP_{3,2,1,1}$$

The expansion of `el` in terms of Schur functions reads as:

```
>> S::s(el)
```

$$t\, s_{3,2,2} + (t + t^2)\, s_{3,3,1} + t\, s_{4,1,1,1} + (t^2 + t^3 + t^4)\, s_{4,3} + (t^2 + t^3 + t^4)\, s_{5,1,1} + (2\,t^3 + t^4 + t^5)\, s_{5,2} + (t^4 + t^5 + t^6)\, s_{6,1} + t^7\, s_7 + s_{3,2,1,1} + (t + 2\,t^2 + t^3)\, s_{4,2,1}$$

The expansion of `el` on the alphabet (q, qt) reads as:

```
>> expand(el([q, q*t]))
```

$$4\,q^{7}t^{5} + 7\,q^{7}t^{6} + 10\,q^{7}t^{7} + 9\,q^{7}t^{8} + 6\,q^{7}t^{9} + 5\,q^{7}t^{10} + 3\,q^{7}t^{11} + 2\,q^{7}t^{12} + q^{7}t^{13} + q^{7}t^{14}$$

Defining new combinatorial algebras

We now turn to the central feature of the `MuPAD-Combinat` package: the ability to easily implement new combinatorial algebras. We start by the free associative algebra over the rational numbers generated by non commutative letters $a, b, c, d, \ldots$. Its basis is indexed by words, and the product of two basis elements is obtained by concatenating the corresponding words:

```
>> domain FreeAlgebra                                                    // line 1
       inherits Dom::FreeModule(Dom::Rational, combinat::words);         // line 2
       category Cat::AlgebraWithBasis(Dom::Rational);                    // line 3

       one           := dom::term([]);                                   // line 5
       mult2Basis    := dom::term @ _concat;                             // line 6
   end_domain:                                                           // line 7
```

We will explain the bits of this definition in a minute after a few examples of use. Let us define two elements of the free algebra:

```
>> x := FreeAlgebra([a, b, c]);
   y := FreeAlgebra([d, e])
```

$$B([a, b, c])$$

$$B([d, e])$$

The `B` just stands for the name of the basis. We can compute linear combinations and products of `x` and `y`:

```
>> 3 * x;
   x + y;
   x * y
```

```
                        3 B([a, b, c])

                  B([d, e]) + B([a, b, c])

                     B([a, b, c, d, e])
```

Here is a more complicated expression:

```
>> x * (2*x + y) + (3 + y/2)^2

 1/4 B([d, e, d, e]) + 2 B([a, b, c, a, b, c]) +

    B([a, b, c, d, e]) + 3 B([d, e]) + 9 B([])
```

Note how the `3` in the expression is automatically converted into an element of the domain; declaring that `FreeAlgebra` was an algebra (with a unit) automatically defined the natural embedding of the coefficient ring into it.

We turn to the explanation of the implementation of `FreeAlgebra` above. Line 1 states that we are declaring a new *domain* called `FreeAlgebra` (a new class in the usual object oriented terminology). Line 2 lets `FreeAlgebra` inherit its implementation from the free module over the rationals (`Dom::Rational`) with basis indexed by words (`combinat::words`). Line 3 states that `FreeAlgebra` is actually an algebra with a distinguished basis; this allows, in particular, to define the multiplication by linearity on the basis. Line 5 defines that the unit of `FreeAlgebra` is the empty word (`dom` refers to the domain being defined, and `dom::term` is a constructor that takes an element of the basis, and returns it as an element of the domain). Finally, line 6 states that two elements of the basis are multiplied by concatenating them, and making an element of the domain with the result (`@` denotes the composition of functions). That's it.

Let us define the free commutative algebra on the letters $a, b, c, \ldots$:

```
>> domain FreeCommutativeAlgebra
       inherits  Dom::FreeModule(Dom::Rational, combinat::words);
       category Cat::AlgebraWithBasis(Dom::Rational);

       one     := dom::term([]);
       straightenBasis := dom::term @ sort;
       mult2Basis      := dom::straightenBasis @ _concat;
   end_domain:
```

Note that we cheated a little bit: we declared that the basis of `FreeCommutativeAlgebra` consisted of words, whereas it really consists of words up to permutation of its letters: `B([a,b])` and `B([b,a])` represent

the same element of the algebra. A careful implementation should define the combinatorial class of words up to permutation, and use it as the basis of `FreeCommutativeAlgebra`.

To enforce the uniqueness of the representation, we straighten the words in the basis by sorting them. This is the job of the `straightenBasis` constructor.

```
>> x := FreeCommutativeAlgebra([a, b]);
   y := FreeCommutativeAlgebra([c, b, a])
```

```
                          B([a, b])

                       B([a, b, c])
```

The product of two words is then defined by concatenating them and straightening the result:

```
>> x * y;
   y * x
```

```
                   B([a, a, b, b, c])

                   B([a, a, b, b, c])
```

If efficiency was at a premium, we could have used the MuPAD function `listlib::merge` which merges sorted lists instead.

Note that two elements of `FreeCommutativeAlgebra` and of `FreeAlgebra` may happen to be printed out the same way:

```
>> x := FreeAlgebra([a]);
   y := FreeCommutativeAlgebra([a])
```

```
                          B([a])

                          B([a])
```

and even share the exact same internal representation:

```
>> bool(extop(x) = extop(y))
```

```
                           TRUE
```

However, they are not equal, because they are not in the same domain:

```
>> bool(x = y);
   domtype(x), domtype(y)
```

```
                           FALSE

            FreeAlgebra, FreeCommutativeAlgebra
```

So, even if they share the same name of basis, there is no risk of confusion; for example we are not allowed to multiply them together:

```
>> x * y
```

```
 Error: Don't know how to multiply a FreeAlgebra by a FreeCommu\
 tativeAlgebra
```

Of course, this is still confusing for the user. He or she may always customize the basis names (as many other things) at any time should he or she wish to do so:

```
>> FreeAlgebra::basisName            := hold(T):
   FreeCommutativeAlgebra::basisName := hold(S):
   x, y
```

$$T([a]),\ S([a])$$

Here, `T` stands for "Tensor algebra", while `S` stands for "Symmetric algebra". The `hold` is there for safety, to avoid trouble if one of the identifiers `T` or `S` is assigned a value.

We can define the natural evaluation morphism from `FreeAlgebra` to `FreeCommutativeAlgebra` by linearity on the words; a word itself is simply sorted, and converted into an element of `FreeCommutativeAlgebra`:

```
>> evaluation := operators::makeLinear(FreeCommutativeAlgebra::term @ sort,
                                       Source   = FreeAlgebra,
                                       ImageSet = FreeCommutativeAlgebra):
```

Let us apply this morphism to the sum of two words which only differ by a permutation:

```
>> x := FreeAlgebra([c, b, a]) + FreeAlgebra([c, a, b]);
```

$$T([c,\ a,\ b]) + T([c,\ b,\ a])$$

```
>> evaluation(x);
```

$$2\ S([a,\ b,\ c])$$

The evaluation morphism is actually quite canonical, so it can make sense to declare it as a conversion to the system. This can be achieved with the `operators::overloaded::declareConversion` function:

```
>> operators::overloaded::declareConversion(FreeAlgebra,
    FreeCommutativeAlgebra,
    evaluation):
   FreeCommutativeAlgebra(x)
```

```
                              2 S([a, b, c])
```

Here, the conversion has been declared as implicit. If an expression mixes elements of `FreeAlgebra` and `FreeCommutativeAlgebra`, the former are automatically converted into `FreeCommutativeAlgebra`:

```
>> FreeCommutativeAlgebra([a, b]) + FreeAlgebra([c,b,a])

                        S([a, b]) + S([a, b, c])
```

Of course, such a feature is questionable. Depending on the context, it can prove very practical, or on the contrary dangerous. The user is the only judge, and she or he can restrict the scope of this conversion by using the `Explicit` option. In this case, the conversion will only be applied if requested explicitly by `convert` or by `new`:

```
>> operators::overloaded::declareConversion(FreeAlgebra, FreeCommutativeAlgebra,
    evaluation, Explicit):
   FreeCommutativeAlgebra(x);

                              2 S([a, b, c])

>> FreeCommutativeAlgebra([a, b]) + FreeAlgebra([c,b,a])

 Error: Don't know how to add a FreeCommutativeAlgebra and a Fr\
 eeAlgebra
```

Typically, for symmetric functions, we only provided explicit conversions to construct symmetric functions from partitions because those conversions are not canonical at all: the Schur function `s[3,2,1]` obtained by converting the partition `[3,2,1]` has nothing to do with the elementary function `e[3,2,1]`. We refer to the design notes and to the documentation of the `operators::overloaded` library for details on the mechanism we use for defining automatic conversions and overloaded operators and functions. Note that it is not (yet) completely possible to declare new conversions as above when the target domain of the conversion is one of the predefined domains of the MuPAD library.

To continue our exploration, we implement variations on the two previous domains, where we assume that the algebra generators are indexed by `1,2,...`. The basis elements of the free algebra and of the free commutative algebra are now respectively indexed by compositions and partitions.

```
>> domain FreeAlgebraInteger
       inherits Dom::FreeModule(Dom::Rational, combinat::compositions);
       category Cat::AlgebraWithBasis(Dom::Rational);

       basisName       := hold(E);
```

```
    exprTerm        := dom::exprTermIndex;
    one             := dom::term([]);
    mult2Basis      := dom::term @ _concat;
end_domain:
domain FreeCommutativeAlgebraInteger
    inherits Dom::FreeModule(Dom::Rational, combinat::partitions);
    category Cat::AlgebraWithBasis(Dom::Rational);

    basisName       := hold(e);
    exprTerm        := dom::exprTermIndex;
    one             := dom::term([]);
    straightenBasis := dom::term @ revert @ sort;
    mult2Basis      := dom::straightenBasis @ _concat;
end_domain:
```

The reader may have recognized here respectively the commutative and non commutative symmetric functions, expanded on the elementary symmetric functions; hence the basis names. To shorten the notations, we define two aliases, and declare the same evaluation conversion as before:

```
>> alias(NCSF = FreeAlgebraInteger,
         SF   = FreeCommutativeAlgebraInteger):
   operators::overloaded::declareConversion(NCSF, SF,
       operators::makeLinear(SF::straightenBasis,
                             Source   = NCSF,
                             ImageSet = SF)):
```

```
>> x := NCSF([1, 3, 2]);
```

```
                          E[1, 3, 2]
```

```
>> y := SF  ([1, 3, 2])
```

```
                          e[3, 2, 1]
```

```
>> SF(x)
```

```
                          e[3, 2, 1]
```

```
>> bool(SF(x)=y)
```

```
                             TRUE
```

Let us analyze the differences with our previous implementation of the free algebras. First, we chose an indexed notation for the basis elements, as this notation is more compact and quite conventional in other systems. This is the purpose of the line `exprTerm := dom::exprTermIndex`: `exprTerm` is the method of the domain which is called to convert a term into an expression, as well as to print a term if there is no `printTerm` method; `dom::exprTermIndex` is a possible implementation of `exprTerm`, inherited from the category, which gives indexed notations. The other difference is that, following the usual convention, the integers in the partitions are sorted decreasingly. Here, this is suboptimally achieved by reverting the list after sorting it in the `SF::straightenBasis` method.

A disadvantage of this implementation of `SF` is that elements with many repetitions are not represented compactly:

```
>> SF([1])^10
```

$$e[1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1,\ 1]$$

One might prefer to use another basis for SF, where the element above would be represented as the first generator to the power 10. This can be done *via* the usual exponent notation for partitions. The basis of the algebra now consists of integer vectors. The product of two elements is simply obtained by adding up the vectors part by part, which can conveniently be implemented using the `zip` MuPAD function.

```
>> domain SFExp
       inherits Dom::FreeModule(Dom::Rational, combinat::integerVectors);
       category Cat::AlgebraWithBasis(Dom::Rational);

       basisName       := hold(e);
       exprTerm        := dom::exprTermIndex;
       one             := dom::term([]);
       mult2Basis      := (v1,v2) -> dom::term(zip(v1,v2,_plus,0));
   end_domain:
```

Let us do some computations:

```
>> SFExp([1]);
   SFExp([2, 0, 1])*SFExp([1, 1]);
   SFExp([1])^10
```

$$e[1]$$

$$e[3,\ 1,\ 1]$$

$$e[10]$$

This notation could be confusing, so we override it:

```
>> SFExp::exprTerm := v -> _mult(dom::basisName.i^v[i] $ i=1..nops(v)):
   SFExp([1]);
   SFExp([2, 0, 1])*SFExp([1, 1]);
   SFExp([1])^10
```

$$e1$$

$$3$$
$$e1\ \ e2\ e3$$

$$10$$
$$e1$$

As is, the elements of this algebra are not uniquely represented. For example, the first generator of the algebra can be represented by any of `[1]`, `[1,0]`, `[1,0,0]`, `...`:

```
>> SFExp([1]), SFExp([1, 0]), SFExp([1, 0, 0]);
   bool(SFExp([1]) = SFExp([1, 0]))
```

$$e1,\ e1,\ e1$$

$$\mathtt{FALSE}$$

We leave it up as an exercise for the reader to fix this bug by implementing a `straightenBasis` method which strips out the trailing zeroes of the basis elements.

Of course, `SF` and `SFExp` really represent the same algebra; only the internal data representation changes. So, we provide as conversions the reciprocal isomorphisms obtained by extending by linearity the bijections `combinat::partitions::fromExp` and `combinat::partitions::toExp`:

```
>> operators::overloaded::declareConversion(SFExp, SF,
       operators::makeLinear(SF::term @ combinat::partitions::fromExp,
                             Source   = SFExp,
     ImageSet = SF)):
   operators::overloaded::declareConversion(SF, SFExp,
       operators::makeLinear(SFExp::term @ combinat::partitions::toExp,
                             Source   = SF,
     ImageSet = SFExp)):
```

Here is a simple conversion:

```
>> SF([4, 3, 3, 1]), SFExp(SF([4, 3, 3, 1]))
```

```
                                                    2
                    e[4, 3, 3, 1], e1 e3  e4
```

Let us check on an example that the conversions are indeed morphisms:

```
>> x := SF([3, 1]):
   y := SF([4, 3, 2]):
   x * y, SF( SFExp(x) * SFExp(y) )

                e[4, 3, 3, 2, 1], e[4, 3, 3, 2, 1]
```

We can write expressions that mix elements of both domains, and let the system find a way to convert them appropriately:

```
>> ( 1 + SF([3, 1])*x ) * SFExp([2, 0]) + SFExp([1])

                          4   2     2
                        e1  e3  + e1  + e1
```

A priori, the representation of the result cannot be predicted; it depends on how the overloading mechanisms choose to resolve the conversions. If the user prefers one of the representations, she or he can take over the control at any level of the expression by forcing proper conversions:

```
>>     (1 + SF([3, 1])*x) * SF( SFExp([2, 0]) )  +  SF( SFExp([1]) ) ;
   SF( (1 + SF([3, 1])*x) *     SFExp([2, 0]) )  +  SF( SFExp([1]) ) ;
   SF( (1 + SF([3, 1])*x) *     SFExp([2, 0])    +      SFExp([1]) ) ;

             e[3, 3, 1, 1, 1, 1] + e[1, 1] + e[1]

             e[3, 3, 1, 1, 1, 1] + e[1, 1] + e[1]

             e[3, 3, 1, 1, 1, 1] + e[1, 1] + e[1]
```

The implicit conversions are automatically applied transitively. As a consequence, we have without further work a conversion from `NCSF` to `SF`:

```
>> SFExp(NCSF([1, 4, 2, 2]))

                                    2
                                e1 e2  e4
```

Another consequence is that, when there are n different representations for an algebra (say the symmetric functions expressed on any of the `p`, `e`, `m`, `h`, or `s` basis), it is enough to implement $2n$ conversions to be able to get all the $n(n-1)$ possible conversions. Of course, it is still possible to implement some extra direct conversions for improved efficiency; when there are several ways to convert an element from one domain to another, the system always uses one of the shortest ones.

A typical computation

We conclude by a typical computation which involves basic linear algebra: we find the minimal polynomial of an element of the group algebra of the symmetric group of order 4:

```
>> SymGroup4 := subClass(permutations, 4):
   domain AlgSymGroup4
       inherits Dom::FreeModule(Dom::ExpressionField(), SymGroup4);
       category Cat::AlgebraWithBasis(Dom::ExpressionField());

       basisName       := hold(p);
       exprTerm        := dom::exprTermIndex;
       one             := dom::term([1,2,3,4]);
       mult2Basis      := dom::term @ permutations::mult2;
   end_domain:
   x := AlgSymGroup4([2,3,4,1]):
   y := x^0 + a1*x^1 + a2*x^2 + a3*x^3 + a4*x^4;

 a3 p[4, 1, 2, 3] + a2 p[3, 4, 1, 2] + a1 p[2, 3, 4, 1] +

    (a4 + 1) p[1, 2, 3, 4]

>> solve([coeff(y)], [a1,a2,a3,a4]);

               {[a1 = 0, a2 = 0, a3 = 0, a4 = -1]}

>> subs(z^0 + a1*z^1 + a2*z^2 + a3*z^3 + a4*z^4, op(last(1),1))

                                    4
                               1 - z
```

2.3 Current features

We conclude this guided tour by a summary of the current features. A first part of the package consists of predefined libraries to count, enumerate, and manipulate standard combinatorial objects (partitions, compositions, sets, words, permutations, tableaux, trees, ...), together with generic tools to help define new combinatorial classes:

- A computational engine for dealing with integer vectors with prescribed constraints (monomials, compositions, partitions, Dyck paths, ...)
- A computational engine for generating linear extensions of posets (standard young tableaux, standard ribbons, ...)

- The former `CS` library by S. Corteel, A. Denise, I. Dutour, and P. Zimmermann to deal with objects defined by a recursive grammar.

Most predefined libraries actually make use of these engines.

A second part consists of tools to build combinatorial algebras. The typical usage is to take a vector space with basis indexed by some combinatorial objects, to define a product for two basis elements and to extend the product by bilinearity. The system automatically takes care of the parsing of algebraic elements, of extensions of functions by linearity, bi-linearity or associativity, of conversions between different bases, etc. Similarly, one may define coproducts, antipods, and similar operators, to implement stronger structures such as Hopf algebras. Some preliminary work has been done to manipulate Lie algebras as well. In short, the system takes care of the algebraic work, so that one can concentrate on the underlying combinatorics rather than on the programming.

As examples of usage and applications, we provide a library for the algebra of symmetric functions, and we have (currently undocumented) libraries for the algebra of non commutative symmetric functions, the algebra of (free) quasi-symmetric functions, the Loday-Ronco algebra, the Weyl algebra, the rational Steenrod algebra, the type A Hecke and Hecke-Clifford algebras, as well as invariant rings of permutation groups, and group algebras.

In the mid-term we plan to provide predefined libraries for the free symmetric algebra, the algebra of matrix quasi symmetric functions, the descents and peaks algebras, general Ore-algebras, the symmetric Weyl algebra, the algebra of multi-symmetric functions, the divided power algebra, free Lie algebras, etc.

Finally, we provide a library for manipulating weighted automatons, and related semi-rings.

3 The design of the `MuPAD-Combinat` package

3.1 Naming conventions

Long names versus abbreviations

The convention for library, domain and function names is to use long names that are as meaningful and close to the English spelling as possible: e.g. partitions instead of PART, FreeQuasiSymmetricFunctions instead of FQSym, etc. In particular, abbreviations should be avoided, except in extreme cases where the short name is really well established (say Lex instead of Lexicographic). Here are the motivations for this convention:

- This is the convention used in MuPAD;
- Since MuPAD >= 2.0.0 has automatic name completion, long names are not too much of a pain to type in.

- This is helpful for users coming from other areas;
- The user can easily define shorthands (via aliases or assignments) for the functions he uses a lot. Actually this is quite reasonable: a working session starts by the definition of the notations and shorthands, exactly as any math document. Tip: in our daily usage, we have one file per topic we do research on, with a set of appropriate shorthands. Typically, when working on the Loday-Ronco Algebra, we use `BT` for `combinat::binaryTrees`, `Perm` for `combinat::permutations`, `LRA` for the Loday-Ronco Algebra, and so on.
- Given the variety of areas that intersect on combinatorial algebras, there are too many risks of conflicts with short names; the user needs to be able to choose his own notations given the context and the set of objects that are to be manipulated at the same time.

3.1.1 Case of names

We follow the capitalization rules of the MuPAD coding standard, which are quite similar to `Java` or `C++` rules:

- When a name is composed of several parts, the later parts are separated by capitalizing the first letter of the following parts. For example, "from reduced word" yields `fromReducedWord`. Using underscores to separate parts (as in `from_reduced_word`) is not recommended; some names in our code do not follow this recommendation yet.
- Names of options and local variables of domains are capitalized (`MinLength`, `R`).
- Names of normal variables, of functions, and of methods are not capitalized (`combinat::partitions::type`, `combinat::permutations::fromReducedWord`, `Dom::Matrix::transpose`).
- A few internal variables are fully capitalized to alert the user that they have a very specific behavior, and should be used with care (`DOM`, `TEXTWIDTH`).
- Badly enough neither the `MuPAD-Combinat` package, nor the MuPAD standard library do respect any clearly defined rule for domain names. As a rule of thumb, the name of a domain is not capitalized when the domain is a library (`combinat`, `combinat::generators`, and is capitalized when it is a true domain which contains elements (`Series`, `Dom::Rational`, `examples::SymmetricFunctions`). The later case includes for example all the domains in `Dom`, `examples`, `experimental`. On the other hand, the names of combinatorial classes in `combinat` are not capitalized (`combinat::partitions`). Other exceptions to this rule typically appear when the name of a library comes from initials (`IPC`) or from a person name.

This lack of coherency is a burden for both users and developers, and we hope to fix it at some point in the future, when the MuPAD library will undergo a similar naming convention cleanup.

Composite names

When the name of a library, domain or function is composed of several parts, and those parts are also used in other names, it may be worthwhile to order those parts from the most general to the most specific. For example, we used the name `combinat::integerVectorsWeighted` instead of the more natural name `combinat::weightedIntegerVectors`. The advantage is that all the domains dealing with integer vectors start with the same prefix, which is particularly practical with respect to automatic completion. This is also coherent with the hierarchy `library::sublibrary::subsublibrary`. Another typical case is when several functions return a similar result but under different forms; the function that is the most useful or natural gets the short name, and the names of the other functions, are suffixed with the "type" of the result (`words::inversions`/`words::inversionsList`, ...). We also used this rule of thumb for the names of the free module methods (`mult`/`multBasis`/`mult2`/`mult2Basis`, `straighten`/`straightenBasis`, `print`/`printTerm`/`printMonomial`/`printBasis`).

3.2 Representing combinatorial objects and classes

The notion of *combinatorial object* is best described by some examples: a partition, a binary tree, a permutation, a graph, a Feynman diagram, a Dyck word, and other similar discrete objects are all combinatorial objects.

A *combinatorial class* is a (countable) set of related combinatorial objects (e.g. the set of all partitions, the set of all binary trees, the set of all standard permutations), on which a *size* function is defined (e.g. the size of partition is the sum n of its parts; the size of an integer vector consist of a pair (n, k) of integers: its sum n and its length k; the size of a tree is the number of its nodes). Typically, the fibers of the size function define natural finite subsets of the class that one wants to count, enumerate, and so on (e.g. counting all the partitions of $n = 4$, listing all the integer vectors of sum 5 and length 3); we say "typically", because there are some cases where it is practical to use this framework even if the subsets are only countable. In many cases optional restrictions can be added to define smaller subsets of the class to be counted/enumerated/..., (e.g. the partitions of 4 of length at most 4). In some combinatorial classes (e.g. the class of the permutations of 5), the size function may be degenerated and have only one non trivial fiber.

Representing combinatorial objects

A combinatorial object may belong to several combinatorial classes simultaneously. For example, the list `[4,3,2,1]` may be interpreted as a partition, a permutation, an integer vector, a composition. This is reflected in MuPAD by our convention that a combinatorial object is not necessarily strongly typed by the combinatorial class(es) to which it belongs. An object has a unique domain: it corresponds to the data structure of the object and can be obtained by the command `domtype`. On the other hand, it may be of different types: they correspond to the different semantics that can be attached to the object, and they can be tested with `testtype`.

For example, `[3,4,2,1]` belongs to the MuPAD domain of lists, `DOM_LIST`; it is simultaneously a list of positive integers (`Type::ListOf(Type::PosInt)`), a word, a permutation, etc, while it is not a partition:

```
>> domtype ([3, 4, 2, 1]);
```

```
                              DOM_LIST
```

```
>> testtype([3, 4, 2, 1], Type::ListOf(Type::PosInt)),
   testtype([3, 4, 2, 1], combinat::words),
   testtype([3, 4, 2, 1], combinat::compositions),
   testtype([3, 4, 2, 1], combinat::integerVectors),
   testtype([3, 4, 2, 1], combinat::permutations),
   testtype([3, 4, 2, 1], combinat::partitions)
```

```
                TRUE, TRUE, TRUE, TRUE, TRUE, FALSE
```

In the MuPAD terminology, the domains like `combinat::compositions` are called *facade domains*; they do not really contain elements of their own.

On the other hand, some combinatorial objects, such as trees, require a specific data structure; these objects are strongly typed, that is their domain is the class itself. This has, among others, the advantage that they are pretty printed by the system:

```
>> t := combinat::binaryTrees([1, [1], [1]]);
   domtype(t);
   testtype(t, combinat::binaryTrees);
```

```
                                  o
                                 / \

                        combinat::binaryTrees

                                TRUE
```

This choice of not systematically using strong typing for combinatorial classes is not an obvious one, and there is no clear cut criteria for deciding whether a given combinatorial class should use strong typing or not. On the one hand, strong typing allows for object-oriented techniques and overloading. On the other hand, having to cope with all the conversions (a partition is also a composition, ...) can be quite a burden for both the user and the programmer; indeed, choosing which implicit conversions to provide is not an easy task, given the overwhelming number of natural bijections. Finally, with the current MuPAD language, there is a small memory and time overhead with strong typing; this can be considered as a misfeature of MuPAD though.

Aside from the data structure criteria, another reasonable criteria is whether the combinatorial class has natural "algebraic operations". This is why we currently have both a facade domain `combinat::permutations` for general permutations seen as words, and a real domain `Dom::SymmetricGroup` for standard permutations seen as elements of the symmetric group. Actually, it could be reasonable to have a real domain `Dom::Permutation`, and have `Dom::SymmetricGroup` and `Dom::PermutationGroup` be facade domains for `Dom::Permutation`. This is still under discussion, and comments are welcome.

Representing combinatorial classes

Combinatorial classes for which we want to do counting, generation, or other manipulations are represented by MuPAD domains, like `combinat::partitions` or `combinat::binaryTrees`. Note that, in many cases, those domains are just *facade domains* and do not really contain elements: as we said above, the domain of a partition, or of a permutation, is really `DOM_LIST`. Those domains also define a MuPAD type; by convention, it is named like `combinat::partitions::type`, and can be tested with:

```
>> testtype([3, 2, 2, 1], combinat::partitions)
```

```
TRUE
```

Simpler combinatorial classes, which we only want to use for type checking, are just represented by MuPAD types. This is typically used for subsets of other combinatorial classes. For example, the standard permutations form a subset of all permutations, and are represented by the type `combinat::permutations::typeStandard`. We are not quite happy with this naming convention; however, for better localization, we really would like to keep the types defining a subset of a domain inside this domain. Another option was to use subdomains even in this case. But domains are quite special (and expensive?) objects in MuPAD: they have a reference effect, they cannot be deleted, etc. So, we feel that this would be overkill, especially for parametrized types like `PermutationOf([a,b,c,d])`.

Another related situation: quite often, we have a function that returns a collection C of related objects, usually as a list. Think of `combinat::words::shuffle([1,2,3],[a,b,c])` which returns a list of words. Or think of the inverse of a function that is not at all injective like `combinat::permutations::fromCycleType` (it returns all the permutations having a given cycle type). In such cases, we often want to do some more involved things, like having a generator for the elements of C, or being able to count them without actually generating them. Then, it is natural to consider C as a combinatorial class, and to represent it by a MuPAD domain. This gives a unified interface to all the standard functions for counting, generating, ...:

- `combinat::words::shuffle::count(word1,word2)`
- `combinat::words::shuffle::list(word1,word2)`
- `combinat::words::shuffle::generator(word1,word2)`

As a nice side effect, the standard alias from `new` to `list` allows to use the natural syntax `combinat::words::shuffle(word1,word2)` to obtain the collection C. So, switching from a simple function which returns C to a domain for the elements of C is transparent for the user. Usually, such a domain will be a subdomain of an existing domain (here `combinat::words::shuffle` is a subdomain of `combinat::words`).

Combinatorial classes and categories

A domain which represents a combinatorial class belongs to the category `Cat::CombinatorialClass`. Such a domain should implement at least `generator` or `list`. This category also provides naming conventions for usual functions like `count`, `first`, `next`, `random`, `unrank`, ... The implementation of those functions is not explicitly required by the category `Cat::CombinatorialClass`: depending on the specific combinatorial class sometimes they are not yet implemented, sometimes there exists no efficient algorithm, or sometimes they simply do not really make sense.

In the future, we may think about refining `Cat::CombinatorialClass` into subcategories that describe which of those functions are available (for example, the category of combinatorial class which provide an `unrank` function). So far, the benefits coming from such refinements do not seem to justify the overhead in the complexity of the category hierarchy.

Also, all of this is not really specific to combinatorial classes. We could imagine generalizing this to any kinds of collections of objects, and mimic the category hierarchy of, e.g. `Aldor`.

By convention, all the subcategories of `Cat::CombinatorialClass` have a name of the form `Cat::XxxClass`. Right now, we have two sub categories of `Cat::CombinatorialClass`:

- `Cat::decomposableClass`
- `Cat::integerListsLexClass`

Those two categories are purely technical; they respectively provide wrappers around the generic domains `combinat::decomposableObjects` and `combinat::integerListsLexTo` and allow to factor out some routine code. For example, `combinat::partitions`, `combinat::integerVectors`, and `combinat::compositions` are in the category `Cat::integerListsLexClass`, which takes care of the parsing of common options.

Further naming comments

The names of the domains `combinat::integerListsLexTools` and `combinat::decomposableObjects` are quite different. This reflects the fact that those two domains do not play the same role. `combinat::decomposableObjects` is a parametrized domain whose instantiations represent combinatorial classes, whereas `combinat::integerListsLexTools` essentially is a collection of tools with a scarce interface, geared toward speed and internal use.

The name `Cat::integerListsLex` is too general, since this category contains only the combinatorial classes described using length, bound, and slope constraints. For example, the elements of `combinat::permutations` are integer lists and are naturally ordered lexicographically; however this combinatorial class is *not* in `Cat::integerListsLex`. Badly enough, we haven't found a better name that would not be too long. Unless someone comes up with a clever suggestion we will stick to this name.

We use `Next` for the name of the method that computes the next element in a combinatorial class. This is not coherent with `first`, `last` and with the general convention that a method name start by a lowercase letter. Badly enough, `next` is a reserved keyword, and we cannot use it as method name in MuPAD.

3.3 Representing combinatorial algebras

What is a combinatorial algebra after all?

Let us start by a precise definition for the term *combinatorial algebra* that we have used so far in a rather informal way.

Given a combinatorial class C, and a ring R, one can define the *free module F with basis indexed by C over the ring R*; an element of F is a formal finite linear combination of elements of C with coefficients in R. Alternatively, an element of F can be interpreted as a function from C to R with finite *support*; that is a function which is zero except on finitely many elements of the basis C.

For example, here is an element of the free module with basis indexed by partitions, over $\mathbb{Q}$:

$$x := 4[3,2,1] + 3[2,1,1] + 1/4[1,1,1,1]\,.$$

Polynomials are another typical example of free modules, and we extend the usual definitions used for polynomials. The *coefficient* of $[1,1,1,1]$ in x is $1/4$; we call the partition $[3,2,1]$, seen as an element of F, a *term*; $4[3,2,1]$ is a *monomial*; finally, the *support* of x is the set of the partitions with non-zero coefficients, that is $\{[3,2,1],[2,1,1],[1,1,1,1]\}$.

By *combinatorial algebra* we mean such a free module, together with some extra algebraic operations (a product, coproduct, antipod) which makes it an algebra, a bialgebra, or a Hopf algebra. Those operations are typically defined by linearity on the basis.

With this definition, we have distinguished a special basis of the combinatorial algebra. Most of the time, a combinatorial algebra (like the algebra of symmetric functions) will actually have several interesting basis (Schur functions, power-sum functions, ...), all of them indexed by C. The underlying free module remains the same, but the operations will vary accordingly. Changing from one basis to the other is one of the fundamental operations.

Why use strong typing?

Traditionally in computer algebra systems (say with `SF`, `ACE` [Vei98] or μ-`EC` [Pro99]), symmetric functions have been represented by symbolic expressions:

```
>> p[2]*p[1];
   muEC::SYMF::Top(p[2]*p[1]);
   muEC::SYMF::Tos(p[2]*p[1])
```

```
                          p[1] p[2]

                           p[2, 1]

                       s[3] - s[1, 1, 1]
```

This is also the approach used for polynomials, and more generally for Ore-algebras in `Maple` [CGG+88]. This has several advantages:

- This is simple, and requires (at first) very little programming and computer algebra knowledge from the user;
- The syntax for constructing elements is terse;
- All the standard tools for manipulating expressions (`factor`, `expand`, `simplify`, ...) are instantly available;

- One can easily manipulate factored expressions which mix different basis.

However, this approach has also serious drawbacks:

- The syntax for manipulating expanded expressions is lengthy; one cannot simply write (a*b);
- The tools for manipulating expressions do not know what they manipulate, and may do invalid operations; for example, symbolic expressions are usually considered as commutative, which may yield incorrect results when computing with non commutative symmetric functions. Staying on the safe side may require a fair amount of knowledge about the system from the user, which is not acceptable for beginners.
- Programming a function which deals with elements of the free module requires a fair amount of work just to parse the expressions on input (75% of the code in the symmetric functions package in ACE is related to this); one option to reduce the amount of code, is to first convert the input into an internal representation before manipulating it; however this means that the elements are converted back and forth all the time, which has a non-negligible computation cost.
- The data structure is not hidden, and there is no room left for optimization;
- There is a risk of conflict if two combinatorial algebras use the same name for their basis (e.g. all generalizations of the symmetric functions have some kind of elementary functions, which one would like to display as `e`). In particular, one cannot mix two algebras that use the same basis name in the same expression.
- One cannot easily choose the coefficient ring (think of symmetric functions with coefficients in a finite field, free symmetric functions with coefficients being themselves symmetric functions).
- One cannot easily hide and factor out the complexity, and let a user define his own algebra in a very short amount of code.

Altogether, this approach is fine when there are very few combinatorial algebras; however it does not scale to a dozen predefined algebras (that's our short-term goal) plus myriads of user-defined algebras. In practice, this is one of the main reasons why the `ACE` [Vei98] project stalled when defining many new algebras became a must.

It was time for a complete redesign and rewrite of the package. We will see that using strong typing allows for circumventing all those drawbacks, without loosing too much of the advantages. The choice of switching to MuPAD was largely influenced by the strong integration of their domains/axioms/category

mechanism in their system, that allows for strong typing, and object-oriented techniques.

Representing free modules

The first thing to do is to choose the internal data structure to store an element of a free module. There are different possible implementations without a clear cut advantage of one over the others (as a parallel, in C++ there exists two implementations of association tables: `map` using sorted lists and `hash_map` using hash tables). We provide several of them:

`Dom::FreeModuleTable(R, Basis)` An element `x` is stored as an association table (`DOM_TABLE`). For example, here is the internal representation of an element `x`:

```
>> F := Dom::FreeModuleTable(Dom::Rational, combinat::partitions):
   x := 4*F([3, 2, 1]) + 3*F([2, 1, 1]) + 1/4*F([1, 1, 1, 1]);
   extop(x)
```

```
   4 B([3, 2, 1]) + 3 B([2, 1, 1]) + 1/4 B([1, 1, 1, 1])
```

```
                  table(
                    [1, 1, 1, 1] = 1/4,
                    [2, 1, 1] = 3,
                    [3, 2, 1] = 4
                  )
```

Since any MuPAD object can be used as index of a table, there is no restriction on the basis elements. Accessing the coefficient of a term is constant time.

`Dom::FreeModulePoly(R, Basis)` The kernel polynomial objects of MuPAD (domain `DOM_POLY`) are stored in a sparse non-recursive way using sorted lists of monomials with a fixed number of variables. If one forgets about the product, this provides a sparse data structure which is both compact in memory and very fast for linear operations. Typically, the MuPAD sparse matrices (domain `Dom::SparseMatrix`) use univariate polynomials internally as internal representation for sparse column vectors.

Similarly, an element `x` of `Dom::FreeModulePoly(R, Basis)` is stored using a polynomial:

```
>> (F := Dom::FreeModulePoly(Dom::Rational, combinat::partitions);
   x := 4*F([3, 2, 1]) + 3*F([2, 1, 1]) + 1/4*F([1, 1, 1, 1]));
   extop(x)
```

```
1/4 B([1, 1, 1, 1]) + 3 B([2, 1, 1]) + 4 B([3, 2, 1])
```

```
                      3       2
poly(1/4 _X  + 3 _X  + 4 _X, [_X])
```

To achieve this, one needs to be able to represent an element of the basis using an exponent vector (an integer, or a fixed-length list of integers). This is trivial when the basis readily consists of fixed length lists of integers (integer vectors, standard permutations of a given n, ...). Otherwise, the user may provide a pair of functions `rank` and `unrank` that does the conversions. By default, the system creates a dummy pair of such functions: the `rank` function associate in turn the numbers `1,2,3,...` to each new object it encounters. For example, the rank of `[3,2,1]`, `[2,1,1]`, and `[1,1,1,1]` above are respectively `1`,`2`, and `3`, that corresponds to the order in which the corresponding elements of `F` have been created.

This representation is very fast for linear operations. Furthermore, if univariate polynomials are used with the variable `_X` (this is the default), the data structure coincides exactly with the one used by `Dom::SparseMatrix`. This allows for zero-cost conversions to and from sparse vectors, for doing linear algebra.

Accessing the coefficient of a term in an element `x` is logarithmic in the number of terms of `x` (in the multivariate case, with MuPAD $<$ 3.0.0 this is linear instead of logarithmic).

Ranking and unranking is only done for conversions, and computing products. In practice, the overhead with the dummy implementation seems to be negligible, and largely compensated by the fact that most operations deal with integers.

`Dom::FreeModuleList(R, Basis)` Thanks to Stefan Wehmeier, (Univ. Paderborn) and Werner M. Seiler (Univ. Karlsruhe), this was mostly already implemented in the MuPAD library under the name `Dom::FreeModule` since 1997. An element is represented by a sorted list of terms. For example, here is the representation of the element `x` above: `[[4, [3, 2, 1]], [3, [2, 1, 1]], [1/4, [1, 1, 1, 1]]]`.

Obviously, there needs to be an order on the basis elements (`Basis` should be a `Cat::OrderedSet`). Accessing a leading or trailing term is constant-time; accessing the coefficient of a given term in an element `x` is logarithmic in the number of terms of `x`.

All those implementations are in the category `Cat::ModuleWithBasis` which defines a unified interface. So, one can change the underlying implementation at any time. Unless you have a specific reason to choose one of the implementations, just use the default implementation `Dom::FreeModule(R, Basis)`.

Representing combinatorial algebras on a given basis

Once the underlying linear structure is implemented, it is very easy to construct functions on a free module by linearity / bilinearity / multilinearity on the basis (see the examples) using the utilities from `operators`. So, implementing operations like products, coproducts, antipods usually boils down to implement the underlying combinatorics. Note that we do not have yet a general construction for the tensor product of two free modules `F1` and `F2`, but you can emulate one by hand by building a free module whose basis elements are pairs of basis elements of `F1` and `F2`.

Altogether, this allows to implement a domain `F` for the elements of a combinatorial algebra expanded on a given basis (e.g. the domain of symmetric functions expanded on the Schur functions, or the domain of symmetric functions expanded on the power-sum functions). The product of two elements of `F` is automatically expanded on the basis, and belongs again to `F`. Such a domain belongs to the category `Cat::AlgebraWithBasis` (later on, there will be categories such as `Cat::BialgebraWithBasis`, `Cat::HopfAlgebraWithBasis`).

Representing combinatorial algebras with several bases

A combinatorial algebra with several natural bases will be represented by several domains. Converting from one basis to another is an essential operation, and it is strongly desirable to be able to mix in the same expression elements that are expressed in different basis. This can now be achieved through overloading and the definition of appropriate implicit conversions (see the demonstration).

Developing the underlying tools that allow to do this seamlessly required a fair amount of work. Indeed, one parameter overloading in MuPAD works fine by delegating the work to the corresponding method of the parameter; on the other hand, the plain system essentially does not help much for multi-parameter overloading, which has to be carefully done by hand in each and every library (think about computing a product where the operands are in turn a symmetric function on the p basis, an integer, a symmetric function on the e basis, and a rational number). So we had to specify and implement a new mechanism that takes care of implicit conversions, and multi-parameters overloading. We essentially mimicked ideas taken from the GAP system [GAP99], as well as from the static overloading mechanisms of standard languages like `C++`. The main difficulty was to choose the right level of generality, so as to make the system powerful enough, yet simple, safe, and sound. Our choices were largely influenced by our practical experience with the kind of computations we have in mind. This new overloading mechanism is being discussed for integration and systematic use in the MuPAD library. We are not at all specialists of this sensible subject, so comments and suggestions about this are very welcome. For details, see:

`http://mupad-combinat.sf.net/doc/html/operators/overloaded.html`

This mechanism is currently pretty rudimentary and limited. However, we have been playing with it intensively, and have done some really hairy stuff based on it. The semantic has proven so far to be safe, sound and robust, while really much more practical and powerful than the plain overloading mechanism. The time overhead is reasonable; if it became an issue, the specifications leave quite some room for optimisations, in particular by inclusion in the MuPAD kernel.

When defining combinatorial algebras with several bases, we organize the code in a fairly standardized way, which takes care of various technical issues such as initialization or parameterization of the algebra by the coefficient ring. We urge the interested reader to check out the code in the examples library, and in particular:

`http://mupad-combinat.sf.net/lib/EXAMPLES/SymmetricFunctions.mu`

Conversions to and from expressions

Having strong safeguards is essential so that a beginner can run computations with confidence. However, one of our motto is that the system should not try to be too clever, and in particular should always leave a way for the user to take over the control (and the responsibilities!). Indeed, there always are situations where the user knows that a given operation, invalid in general, happens to be perfectly legal in the current context. Most of the time, this can be taken care of by systematically providing conversions to and from symbolic expressions that the user may manipulate at his convenience. However, there is no clearly-defined way yet for how to represent elements of non-commutative algebras using symbolic expressions; indeed MuPAD (as most other systems) assumes that the latter are commutative. Just to give a flavor of the issue: which commutation rules should be applied automatically by the system in the expression `2 * e[1] * q * 3 * f[3]` ? Suggestions are very welcome here.

Compact notations

Throughout the tutorial, we have used fairly lengthy notations for constructing elements of combinatorial algebras. For example, to define the first symmetric power-sum, we wrote `S::p([1])`. This is fine in a tutorial when safety is at a premium, but in everyday's use, having terse notations is highly desirable. We are currently experimenting several tricks that allow for simultaneously using `p` to represent the domain of symmetric functions in the `p` basis, and `p[1]` for creating the first symmetric power-sum, while still being able to convert symmetric functions into symbolic expressions containing literals such as `p[1]`. As soon as we will have more experience with this, we will describe the recommended practice in the Tips and Tricks section of the reference manual.

Acknowledgments

We would like to thank all the authors who directly or indirectly contributed ideas and code to `MuPAD-Combinat`: Christophe Carré, Sébastien Cellier, Sylvie Corteel, Alain Denise, Isabelle Dutour, Teresa Gomez-Diaz, Daniel Krob, Axel Kohnert, Alain Lascoux, Éric Laugerotte, Jean-Christophe Novelli, Vincent Prosper, Frédéric Sarron, Jean-Yves Thibon, Chan Ung, Sébastien Veigneau, and Paul Zimmerman. We also would like to thank the members of the MuPAD team for their continuous support, and in particular Christopher Creuztig, Klaus Drescher, Ralf Hillebrand, Walter Oevel, and Stefan Wehmeier. Finally, we would like to thank the `sourceforge.net` open-source support center for hosting the project.

On Strongly Identifying Codes

TUCS Technical Report No. 417, August 2001
ISBN 952-12-0865-1
ISSN 1239-1891

Abstract

Identifying codes are designed for locating faulty processors in multiprocessor systems. In this paper we consider a natural extension of this problem and introduce strongly identifying codes. Several lower bounds and constructions are given and relations between different types of identifying codes are examined.

Keywords: Identifying code, binary code, Hamming space, covering code

ISSN 1239-1891

Abstract

We introduce the self-adding sequences, the binary case, and their associated languages. These languages are neither context-free nor *D0L* languages, but the inclusion (implicitly, the equivalence) problem is decidable, as well as other problems. Results concerning the periodicity of the self-adding sequences are also presented.

TILING SQUARES

ERWIN KALVELAGEN

Abstract. Tiling squares is a difficult geometric problem. In this document we illustrate how small instances of the problem can be solved using Mixed Integer Programming. Larger instances, however, are beyond the reach of this method.

1. Introduction

In this section we deal with the problem of tiling (integer) squares. We try to fill a given $n \times n$ square with smaller $k \times k$ squares. An example is given in figure 1 (see [1]).

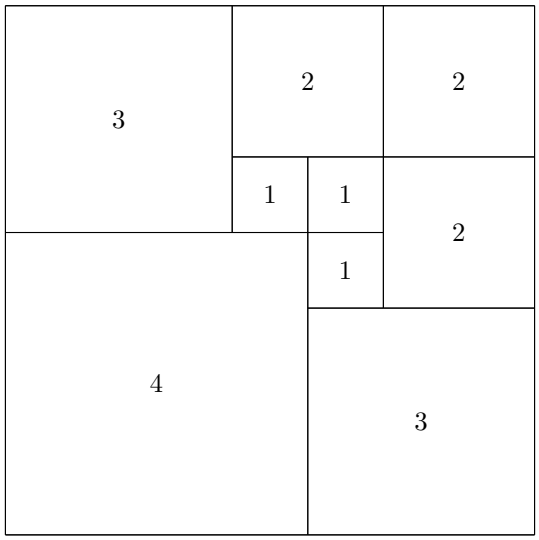

Figure 1. Tiling a 7×7 square

2. Modeling

Once we have a set of tiles that can fill the square, positioning them can be modeled as follows. For each tile i and j we need to make sure they don't overlap. Let's assume the following notation: x_i and y_i are the (x, y) coordinates of the

Date: September 22, 2002.

lower-left corner of each tile and s_i is the length of the side. At least one of the following constraints must hold:

$$x_i \geq x_j + s_j \tag{1}$$

$$x_i + s_i \leq x_j \tag{2}$$

$$y_i \geq y_j + s_j \tag{3}$$

$$y_i + s_i \leq y_j \tag{4}$$

The following big-M formulation can be used to implement this:

$$x_i \geq x_j + s_j - M\delta_{1,i,j} \tag{5}$$

$$x_i + s_i \leq x_j + M\delta_{2,i,j} \tag{6}$$

$$y_i \geq y_j + s_j - M\delta_{3,i,j} \tag{7}$$

$$y_i + s_i \leq y_j + M\delta_{4,i,j} \tag{8}$$

$$\sum_k \delta_{k,i,j} \leq 3 \tag{9}$$

with $\delta_{k,i,j}$ binary variables. Choosing M as two times the side of the total square is large enough. Using symmetry we only need to use the equations for $i > j$. The complete model is:

A more difficult problem arises if we want to let the model determine the tiles. As an example we consider the following sequence. Let

$$h(n) = \text{the smallest multiplicity of any tile needed} \tag{10}$$

The following numbers $h(n), n \geq 2$ are listed in [2]: 4, 5, 4, 4, 4, 3, 4, 3, 4, 3, 3, 3, 3, 3, 3, 3, 3, 2, 2, 3, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2. I.e. $h(9) = 3$, which indicates that we can form a square of 9×9 if tiles can appear up to three times. To prove that we can form such a square we create a pool of tiles $i = 1..3(n-1)$ with side $s_i = (1, 1, 1, 2, 2, 2, 3, 3, 3, ..., 8, 8, 8)$, and introduce binary variables u_i defined by:

$$u_i = \begin{cases} 1 & \text{if tile } i \text{ is used} \\ 0 & \text{otherwise.} \end{cases} \tag{11}$$

The counting constraint on $\delta_{k,i,j}$ (9) need to be changed into something like:

$$\sum_k \delta_{k,i,j} \le 3 + (1-u_i) + (1-u_j) \tag{12}$$

to make sure that the non-overlap constraints are not used on any (i,j) for which not both tile i and tile j are used. The additional constraint that is now needed is:

$$\sum_i s_i^2 u_i = n^2 \tag{13}$$

As a refinement we consider to specify priorities on the integer variables. Clearly the u_i variables should be dealt with before the other ones. Within the u_i larger tiles should be considered first. Prioritizing x and δ is more difficult, but it makes some sense to start with larger tiles.

A second improvement is to add constraints:

$$\delta_{k,i,j} \ge 1 - u_i \tag{14}$$

$$\delta_{k,i,j} \ge 1 - u_j \tag{15}$$

which forces $\delta_{k,i,j} = 1$ if $u_i = 0$ or $u_j = 0$.

The complete model is listed below:

```

MIP models are quite unpredictable in performance. This is illustrated by the following results.

Cplex Options	Nodes used
`mipemphasis 1`	24004
`mipemphasis 1`, priorities	42938
`mipemphasis 1`, extra equations	2479
`mipemphasis 1`, priorities, extra equations	1955

TABLE 1. GAMS CPLEX Results

The use of priorities initially seems to deteriorate the performance of the model. However if we add the extra constraints to the model, which in itself has a great effect on the node count, the use of priorities seems to modestly help the solver.

The Cplex option `mipemphasis 1` tells the solver that we aim for feasible solutions instead of optimal solutions. Indeed in our model there is no optimization at all: we only want the solver to find feasible solutions. In practice these models are very difficult to solve as MIP solvers are organized around the concept of an objective that can be used to ignore parts of the branch-and-bound tree. It is often argued that for these type of models, techniques such as constraint programming are more appropriate.

3. Open problem

I have not been able to proof yet that $h(110) = 1$ using the above techniques.

4. Thanks

This problem was suggested to me by Paul van der Eijk, who also came up with the idea to use a pool of tiles and corresponding usage variables u_i.

Abstract

Inspired by Denton Hewgill's identity:

$$\sum_{i=0}^{n} \binom{n}{i} \pmod 2 \; 2^i = \prod_{i=0}^{\infty} (2^{2^i}+1)^{bit_i(n)}$$

where

$$bit_i(n) \stackrel{\text{def}}{=} \lfloor \frac{n}{2^i} \rfloor \pmod 2$$

we prove an analogous identity involving the Fibonacci number system:

$$\sum_{i=0}^{2n} \binom{2n}{i} \pmod 2 \; F_{i+d} = E_{n+d} \prod_{i=0}^{\infty} L_{2^i}{}^{bit_i(n)}$$

which holds for all integers $n >= 0$, $d >= 0$, when E_{n+d} stands for F_{n+d} (the $n+d$:th Fibonacci number) if n is even, and L_{n+d} (the $n+d$:th Lucas number) if n is odd.

A Case for Efficient Solution Enumeration

Sarfraz Khurshid Darko Marinov Ilya Shlyakhter Daniel Jackson

Abstract. SAT solvers have been ranked primarily by the time they take to find a solution or show that none exists. And indeed, for many problems that are reduced to SAT, finding a single solution is what matters. As a result, much less attention has been paid to the problem of efficiently generating *all* solutions.
This paper explains why such functionality is useful. We outline an approach to automatic test case generation in which an invariant is expressed in a simple relational logic and translated to a propositional formula. Solutions found by a SAT solver are lifted back to the relational domain and reified as test cases. In unit testing of object-oriented programs, for example, the invariant constrains the representation of an object; the test cases are then objects on which to invoke a method under test. Experimental results demonstrate that, despite the lack of attention to this problem, current SAT solvers still provide a feasible solution.
In this context, symmetry breaking plays a significant, but different role from its conventional one. Rather than reducing the time to finding the first solution, it reduces the number of solutions generated, and improves the quality of the test suite.

1 Introduction

Advances in SAT technology have enabled applications of SAT solvers in a variety of domains, e.g., AI planning [11] or software verification [21]. These applications typically use a solver to find one solution, e.g., one plan that achieves a desired goal or one counterexample that violates a correctness property. Hence, most modern SAT solvers are optimized for finding one solution, or showing that no solution exists. That is also how the SAT competitions [1] rank solvers.

We present a novel application of SAT solvers in software testing. Our application requires a solver that can enumerate *all* solutions. We find it surprising that most modern SAT solvers, including zChaff [15], BerkMin [8], Limmat [3], and Jerusat [16], do not support solution enumeration at all, let alone that they do not optimize enumeration. We hope that our application can motivate research in solution enumeration.

Software testing is the most widely used method for establishing correctness of programs. It is conceptually simple: just create a test suite, i.e., a set of test inputs, run them against the program, and check if each output is correct. However, manually generating test suites is tedious, and automated testing can significantly reduce the cost of software development and maintenance [2].

We have developed the TestEra framework [14] for automated specification-based testing [2] of Java programs. To test a method, the user provides a specification that consists of a precondition (which describes allowed inputs to the method) and a postcondition (which describes the expected outputs). TestEra uses the precondition to automatically generate a test suite of *all* test inputs up to a given *scope*; a test input is within a scope of k if at most k objects of any given class appear in it. TestEra executes the method on each input, and uses the postcondition as a test oracle to check the correctness of each output.

TestEra allows users to give specifications as first-order logic formulas. As an enabling technology, TestEra uses the Alloy toolset. Alloy [9] is a first-order declarative language based on sets and relations. Alloy Analyzer (AA) [10] is a fully automatic tool that finds *instances* of Alloy specifications, i.e., finds assignments of values to the sets and relations in the specification such that the formulas in the specification evaluate to true. AA finds an instance by: 1) translating Alloy specification into boolean satisfiability formula, 2) using an off-the-shelf SAT solver to find a solution to the formula, and 3) translating the solution back into sets and relations. AA can enumerate all instances (within a given scope) using a SAT solver that supports enumeration, e.g., mChaff [15].

TestEra translates Alloy instances into test inputs. Some of these inputs are *isomorphic*, i.e., they only differ in the identity of their objects, e.g., two lists that have the same elements (more precisely isomorphic elements) in the same order are isomorphic regardless of the identity of the actual nodes in the lists. It is desirable to consider only non-isomorphic inputs; it reduces the time to test the program, without reducing the possibility to detect bugs, because isomorphic test inputs form a "revealing subdomain" [2], i.e., produce identical results. AA has automatic symmetry breaking [17] that eliminates many isomorphic inputs; we discuss this further in Section 2.1.

We initially used TestEra to check several Java programs. TestEra exposed bugs in a naming architecture for dynamic networks [12] and a part of the Alloy-alpha analyzer [14]; these bugs have now been corrected. We have also used TestEra to systematically check methods on Java data structures, such as from the Java Collection Framework [20]. More recently, we have applied TestEra to test a C++ implementation of a fault-tree solver [7] and a system for data management in distributed environments (industrial study covered by a NDA).

We already presented TestEra [14] as an application of SAT solvers in software testing. This paper makes the following new contributions:

- We describe a compelling application of SAT solvers that suggests that solution enumeration is an important feature that merits research in its own right. To the best of our knowledge, this is the first such application.
- We provide a set of formulas that can be used to compare different solvers in their enumeration. According to the categorization for SAT competitions [1], our formulas fall into the (satisfiable) "industrial" benchmarks.
- We show how TestEra users can completely break symmetries, such that each solution of a boolean formula that encodes test inputs corresponds to a non-isomorphic input.

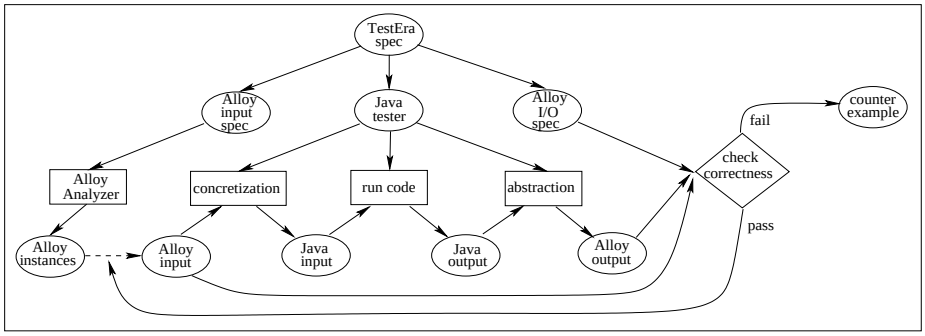

Fig. 1. Basic TestEra framework

2 TestEra

Figure 1 illustrates the main components of the TestEra framework. Given a method precondition in Alloy, TestEra uses AA to generate all instances that satisfy the precondition. TestEra automatically *concretizes* these instances to create Java objects that form the test inputs for the method under test. TestEra executes the method on each input and automatically *abstracts* each output to an Alloy instance. TestEra then uses AA to check if this instance satisfies the postcondition. If it does not, TestEra reports a concrete counterexample, i.e., an input/output pair that violates the correctness specification. TestEra can graphically display the counterexample, e.g., as a heap snapshot, using the visualization facility of AA.

2.1 Symmetry Breaking

AA adapts symmetry-breaking predicates [6] to reduce the total number of instances generated—the original boolean formula that corresponds to the Alloy specification is conjoined with additional clauses in order to generate only a few instances from each isomorphism class [17]. There is a trade-off, however: the more clauses that AA generates, the more symmetries AA breaks, but the boolean formula also becomes larger, and it can become too large so that solving takes more time, although there are fewer instances. The goal of symmetry breaking in AA was to make the analysis faster and not to generate exactly non-isomorphic instances. Therefore, with default symmetry breaking, AA can significantly reduce the number of instances, but it is not always optimal, i.e., it sometimes generates more than one instance from some isomorphism classes.

AA has a special support for total orders: for each set $\{a_1, \ldots, a_n\}$ of n elements that is declared to have a total order, AA generates only one order $\{\langle a_1, a_2\rangle, \langle a_2, a_3\rangle, \ldots, \langle a_{n-1}, a_n\rangle\}$, out of $n!$ (isomorphic) orders. This support has been used for faster analysis. We show in Section 3.1 how TestEra and Alloy users can also use total orders to constrain specifications such that AA generates exactly one instance from each isomorphism class. Conceptually, the idea is to conjoin Alloy specification with additional constraints such that AA generates, from each isomorphism class, only the instance that is the *smallest* with respect to the total orders on the sets whose elements appear in the instance.

3 Example

We next show a simple example that illustrates the use of TestEra. Consider the following Java code that declares a binary tree and its `removeRoot` method:

```
package testera.example;
class BinaryTree {
    Node root; // root node
    int size;  // number of nodes in the tree
    static class Node {
        Node left;  // left child
        Node right; // right child
    }

    void removeRoot() { ... }
}
```

Each object of the class `BinaryTree` represents a binary tree; objects of the inner class `Node` represent nodes of the trees. For these classes, TestEra produces the following Alloy specification:

```
module testera/example/BinaryTree
sig BinaryTree {
  root: option Node,
  size: Integer }
sig Node {
  left: option Node,
  right: option Node }
```

The declaration `module` names the specification. The keyword `sig` introduces a *signature*, i.e., a set of indivisible atoms. We use Alloy atoms to model objects of the corresponding classes. Each signature can have *field* declarations that introduce relations between atoms. By default, fields are total functions; `size` is a total function from `BinaryTree` to `Integer`, where `Integer` is a predefined signature. The modifier `option` is used for partial functions (and the modifier `set` for general relations); e.g., `root` is a partial function from `BinaryTree` to `Node`. Partiality is used to model `null`: when the Java field `root` of some object `b` has the value `null`, i.e., points to no object, then the function `root` does not map the atom corresponding to `b` to any other atom.

The method `removeRoot` has only the implicit `this` argument, which is a `BinaryTree`. We consider a simple specification for this method: both precondition and postcondition require only that `this` satisfy the *representation invariant* (also known as class invariant) [13] for `BinaryTree`. A predicate that checks the invariant is typically called `repOk` (or `checkRep`) [13]. For `BinaryTree`, this predicate requires that the graph of nodes reachable from `root` indeed be a tree (i.e., have no cycles) and that the `size` be correct; in Alloy, it can be written as follows:

```
fun BinaryTree::repOk() {
  all n: this.root.*(left + right) {
    n !in n.^(left + right) // no directed cycle
    sole n.~(left + right)  // at most one parent
    no n.left & n.right }   // distinct children
  this.size = #(this.root.*(left + right)) } // size is consistent
```

The Alloy *function* `repOk` records constraints that can be invoked elsewhere in the specification. This function has only the implicit `this` argument, introduced with '`::`'. The function body has two formulas. They are within (outer) curly braces, and thus implicitly conjoined. The first formula, which has three subformulas,

constrains `this` to be a valid binary tree. The expression `left + right` denotes the union of relations `left` and `right`; the prefix operator '`*`' is reflexive transitive closure, and the dot operator '`.`' is relational composition. The entire `root.*(left + right)` denotes the set of all nodes reachable from `root`. The quantifier `all` denotes for universal quantification: the formula `all n: S { F }` holds iff the formula `F` holds for each element in the set `S`. The operators '`^`', '`~`', and '`&`' denote transitive closure, transpose, and intersection, respectively. The formulas `sole S` and `no S` hold iff the set `S` has "at most one" and "no" elements, respectively. If all nodes `n` are not reachable from itself, have at most one parent, and have distinct children, then the underlying graph is indeed a tree. The second formula constrains `this` to have the correct `size`; '`#`' denotes set cardinality.

We add the function `repOk` to the above Alloy specification to obtain the entire specification for `removeRoot`'s inputs. The Alloy command `run repOk for` N `but 1 BinaryTree` instructs the Analyzer to find an instance for this specification, i.e., the valuation of signatures (sets) and relations that make the function `repOk` evaluate to true. The parameter N needs to be replaced with a specific constant that determines the scope, i.e., the maximum number of atoms in each signature, except those mentioned in the `but` clause. In our example, N determines the maximum number of `Node`s, and the instance has only one `BinaryTree`. Note that *one* instance has one tree (with several nodes) corresponding to `this` argument, but we further instruct AA to generate all instances, effectively generating all trees with up to the given number of nodes.

In the first phase, TestEra uses AA to generate all (non-isomorphic) instances. In the second phase, TestEra operates on each instance in turn: 1) translates it to appropriate Java test input by creating objects (of classes `BinaryTree` and `Node`) that correspond to the atoms in the instance and setting the object fields to correspond to the relations in the instance; 2) executes `removeRoot` on the obtained test input; 3) translates the resulting Java objects back into an Alloy instance by translating the values of object fields into relations; and 4) evaluates the postcondition on this translated output and the original input instance. (In general, a postcondition can refer to both input and output, but our simplified example considers only output.) If the code contains a bug that can be observed for one of these trees, e.g., the code does not decrement the number of nodes after deleting the root, TestEra readily exposes the bug.

In the sequel, we focus on test input generation. To compare different ways for generation, we consider test inputs of size exactly N. To this end, we add to the specification the following:

```
fact Connected { BinaryTree.root.*(left+right) = Node }
```

A *fact* is a formula that puts more constraints on the instances: `run`ning a function finds instances that satisfy the function body conjoined with all the facts in the specification. `Connected` states that the set of nodes reachable from `BinaryTree` is the same as the universe of `Node`s, whose cardinality is exactly N.

For illustration, consider $N = 5$. There are 14 non-isomorphic trees with five nodes [18]. If we use AA without any symmetry breaking, AA generates 1680 instances/trees, i.e., for each of the 14 isomorphism classes, AA generates all 120

distinct trees corresponding to the 5! permutations/labelings of the five nodes. If we use AA with symmetry breaking [17], we can tune how many symmetries to break. With the default value of symmetry breaking, AA generates 17 trees with five nodes. If we increase symmetry breaking, AA generates exactly 14 trees.

3.1 Complete Symmetry-Breaking using Total Order

We next show how to use the special support that AA has for total orders to completely break all symmetries in our example. AA's standard library of models provides a polymorphic signature `Ord[t]`. Each instantiation of `Ord` with some set (Alloy signature) `t` imposes a total order on the elements in `t`. In consequence, these elements are not indistinguishable any more, and AA does not break any symmetries on that set. However, AA considers only one total order, instead of $(\#t)!$ possible total orders.

In addition to the definition of total order, AA's standard library also provides several Alloy functions for totally-ordered sets. We use two of those functions in the following fact:

```
fact BreakSymmetries {
  all b: BinaryTree {
    all n: b.root.*(left + right) {
      n.left.*(left + right) in OrdPrevs(n) // library function that instantiates Ord[Node]
      n.right.*(left + right) in OrdNexts(n) } }
```

The function `OrdPrevs`, respectively `OrdNexts`, returns the set of all elements that are smaller, respectively larger, than the given element. The fact requires that all trees in the instance (the example instances have only one tree) have nodes in an *in-order* [5]: the nodes in the left, respectively right, subtree of the node `n` are smaller, respectively larger, than `n` with respect to the `Ord[Node]` order. Note that the comparisons are for *node identities*, not for the values in the nodes. (For simplicity of illustration, our example does not even have values.)

We add the above fact to the specification for binary trees so that each instance can have nodes in only one order, effectively eliminating isomorphic instances. Indeed, AA now generates exactly 14 non-isomorphic trees, as expected. In general, the user can break all symmetries by: 1) declaring that each set has a total order and 2) defining a traversal that linearizes the whole instance. The combination of the linearization and the total orders gives a lexicographic order that is used to compare instances.

4 Results

We next present some performance results for solution enumeration obtained with mChaff [15]. Table 1 presents the results for a set of benchmark formulas that represent structural invariants. Each benchmark is named after the class for which data structures are generated; the structures also contain objects from other classes.

`BinaryTree` is our running example. `LinkedList` is the implementation of linked lists in the Java Collections Framework, a part of the standard Java libraries. This implementation uses doubly-linked, circular lists that have a `size`

			manual symmetry breaking				automatic symmetry breaking

Table 1. Performance. All times are in seconds (of total elapsed wall-clock time); the experiments were performed on a 1.8 GHz Pentium 4 processor. For sizes larger than presented, enumeration of solutions for automatically constructed symmetry-breaking predicates takes longer than 1 hour.

field and a `header` node as a sentinel node [5]. (Linked lists also provide methods that allow them to be used as stacks and queues.) `TreeMap` implements the `Map` interface using red-black trees [5]. Each node has a `key` and a `value`. (Setting all `value` fields to `null` corresponds to the set implementation in `java.util.TreeSet`.) `HashSet` implements the `Set` interface, backed by a hash table [5]. This implementation builds collision lists for buckets with the same hash code. `HeapArray` is an array-based implementation of heap (priority queue) data structure [5]. (`HeapArray`s are similar to array-based stacks and queues, as well as `java.util.Vector`s, so the results presented here are similar to those results.)

We show results for several size values for each benchmark. All scope parameters are set exactly to the given size; e.g., all lists have exactly the given number of nodes and the elements come from a set with the given size. For each size, we use mChaff to enumerate solutions for two CNF formulas: 1) one with symmetry-breaking predicates generated automatically (using the default values of the Alloy Analyzer) and 2) one with symmetry-breaking predicates added manually to Alloy specifications (as described in Section 3.1). We tabulate the number of primary variables, the total number of variables, the number of clauses, the number of solutions, and the time it takes to generate all solutions.

For `BinaryTree`, `LinkedList`, `TreeMap`, and `HashSet`, the numbers of non-isomorphic structures appear in the Sloane's On-Line Encyclopedia of Integer Sequences [18]. For all sizes, formulas with manually added symmetry-breaking predicates have as many solutions as the actual number of structures, which shows that these predicates eliminate all symmetries. (For this comparison, we generated inputs with exactly the given size; for software testing in practice, we generate all inputs *up to* the given size.) For `HeapArray`, no symmetry-breaking is required: two array-based heaps are isomorphic iff they are identical.

In all cases with symmetry breaking, formulas with automatic symmetry breaking have more solutions than formulas with manual symmetry breaking. Also, in most cases it takes longer to generate the solutions for formulas with automatic symmetry breaking; a simple reason for this is that enumerating a

larger number of solutions usually takes a larger amount of time. However, note that it is not always the case: for `HashSet` and `TreeMap` of size seven, it takes less time to enumerate more solutions. This illustrates the general trade-off in (automatic) symmetry breaking: adding more symmetry-breaking predicates can reduce the number of (isomorphic) solutions, but it makes the boolean formula larger, which can increase the enumeration time. The Alloy Analyzer allows users to tune symmetry breaking; we have experimented with different parameter values and the default values seem to achieve a sweet spot for our benchmarks.

Note that we do not present numbers for `LinkedList` of size nine with automatic symmetry breaking; for this formula mChaff runs out of 2 GB of memory. This suggests that the scheme for clause learning in mChaff [15] may need to be modified when enumerating all solutions. If there is no effective pruning or simplification of clauses added in order to exclude the already found solutions, complete solution enumeration can become infeasible. For all other benchmark formulas, mChaff is able to enumerate all solutions, even when there are more than a million of them. Test inputs that correspond to these solutions, for the sizes from the table, are sufficient to achieve complete code and branch coverage [2] for methods in the respective Java classes.

We next discuss the use of Binary Decision Diagrams (BDDs), instead of SAT solvers, for solution enumeration. We considered BDDs because they make it easier to read off all solutions, once there's a BDD for a formula. However, constructing a BDD can take long time (and exponential space). We have briefly experimented with the CUDD [19] BDD package. We constructed BDDs bottom-up, using automatic variable reordering via sifting [4], from the boolean DAGs from which the CNFs were produced. For all benchmarks, the BDD approach scaled poorly; BDD construction timed out for nontrivial sizes (over five).

5 Conclusions

We have presented a novel application of SAT solvers in software testing. Our application requires a solver that can enumerate all satisfying assignments; each assignment provides a (non-isomorphic) input for the program. The experimental results indicate that it is feasible to use a SAT solver to systematically generate structurally complex inputs that would be hard to generate manually. We hope that our work provides motivation for exploring efficient solution enumeration in modern SAT solvers.

STRUCTURED GRAMMAR-BASED CODES FOR UNIVERSAL LOSSLESS DATA COMPRESSION*

JOHN KIEFFER† AND EN-HUI YANG‡

Abstract. A grammar-based code losslessly compresses each finite-alphabet data string x by compressing a context-free grammar G_x which represents x in the sense that the language of G_x is $\{x\}$. In an earlier paper, we showed that if the grammar G_x is a type of grammar called irreducible grammar for every data string x, then the resulting grammar-based code has maximal redundancy/sample $O(\log\log n/\log n)$ for n data samples. To further reduce the maximal redundancy/sample, in the present paper, we first decompose a context-free grammar into its structure and its data content, then encode the data content conditional on the structure, and finally replace the irreducible grammar condition with a mild condition on the structures of all grammars used to represent distinct data strings of a fixed length. The resulting grammar-based codes are called *structured grammar-based codes*. We prove a coding theorem which shows that a structured grammar-based code has maximal redundancy/sample $O(1/\log n)$ provided that a weak regular structure condition is satisfied.

Keywords. lossless data compression, universal codes, redundancy, context-free grammars, grammar-based codes

1. Introduction.

Universal lossless source coding first arose in the late 1960's, becoming systematized with Davisson's seminal 1973 paper [2]. A universal lossless code is a lossless source code which is asymptotically optimal for all finite-state information sources on a given finite alphabet. The most famous class of universal lossless codes consists of the Lempel-Ziv codes (LZ77 [13], LZ78 [14], and their many variants). In the 20+ years since the Lempel-Ziv codes were introduced, other classes of universal lossless codes have been proposed and analyzed. One of these classes is the class of grammar-based codes [3].

A grammar-based code can be thought of as a type of transform code. It losslessly encodes/decodes a finite-alphabet data string x according to the following four stages:

- *Analysis Stage:* A context-free grammar G consisting of a set of production rules is found which represents x in the sense that the language $L(G)$ of the grammar G is $\{x\}$, where the language $L(G)$ is simply the set of all sequences derived from G.
- *Encoding Stage:* A binary codeword $B(G)$ from which the grammar G can

be reconstructed is formed and transmitted to the decoder.

- *Decoding Stage:* The grammar G is reconstructed from the codeword $B(G)$.
- *Synthesis Stage:* The data string x is "grown" from the production rules of G.

The most important of these four stages is the Analysis Stage, because the other three stages are determined from it. In the paper [3], the grammar representing the data string in the Analysis Stage was taken to be an *irreducible grammar*, a type of grammar that had been used by previous workers in the applications of context-free grammars. (Irreducible grammars are discussed thoroughly in [3]; the reader does not need to understand what an irreducible grammar is for the purposes of this paper.) Grammar-based codes based upon the use of irreducible grammars in the Analysis Stage were shown in [3] to exhibit maximal redundancy/sample $O(\log\log n/\log n)$, where the parameter n is the number of data samples.

Since the paper [3] appeared, the natural question has been whether a different type of grammar could be used in the Analysis Stage, which would bring about grammar-based codes with maximal redundancy/sample $O(1/\log n)$. This question is of interest because

(i) the Lempel-Ziv codes (possibly the most popular class of universal lossless source codes) have not yet been shown to exhibit maximal redundancy/sample $O(1/\log n)$, although LZ78 is known to have maximal redundancy/sample $O(\log\log n/\log n)$ [6], and

(ii) the maximal redundancy/sample of the context-tree weighting algorithm (CTW)[10], [11] and the prediction by partial match algorithm (PPM) [1] is bounded below by a positive constant for all large n, let alone any convergence rate.

(The notion of the maximal redundancy/sample is much stronger than the usual definition of redundancy against the so-called tree sources[9], [10], [11]. In terms of the latter weak definition of redundancy, CTW is known to have $O(\log n/n)$ redundancy/sample.) The present paper settles this question in the affirmative.

Our approach is to use *structured grammars* in the Analysis Stage. The precise details concerning the notion of a structured grammar shall be presented later in this paper. In this introduction, we can give an intuitive feeling for this concept. Roughly speaking, a context-free grammar G representing x can be decomposed into two parts: the structure of G and the data content of G. The structure of G is related to the *derivation tree* of G—a tree via which the data string x can be grown from the production rules of G. If x has n entries, then the derivation tree of G will have n leaf vertices labeled with the entries of x from left to right (the internal vertices of the derivation tree are labeled with variables of G). The data content of G is uniquely determined by the structure of G and the data string x itself. In [3], [12], the grammar G is encoded without decomposing G into its structure and data content. The grammar encoding methods presented in [3], [12] can be applied to any context-free

grammar. In particular, the binary codewords $B(G)$ for all context-free grammars G form a prefix set. However, this generality does indicate that there is room to improve as far as the compression of x is concerned. Since different grammars can represent the same string and different grammars representing different strings can have the same structure, the improvement of compression efficiency of x can be made if we first decompose G into its structure and data content, then encode its structure, and finally encode its data content conditional on its structure. By imposing certain mild conditions on the structure of each grammar used in the Analysis Stage to represent a data string of a given length, the encoding of the structure is either free or has a negligible overhead, and the dominating term is the encoding of the data content conditional on the structure, thereby improving the compression performance and reducing the redundancy from $O(\log\log n/\log n)$ to $O(1/\log n)$. The resulting grammar-based codes with the new encoding method are called the *structured grammar-based codes*. In a special case, one may require that all grammars used in the Analysis Stage to represent all distinct data strings of a given length have the same structure.

1.1. Terminology. We present terminology and notation to be used throughout the rest of the paper. Since we have to start somewhere, we assume that the reader has had some previous exposure to the concept of a context-free grammar. (Those readers who work in pattern recognition, machine intelligence, image processing, or many other areas will already have some familiarity with this concept. Readers having less familiarity are encouraged to consult the paper [3].)

- $\mathcal{S}^+$ denotes the set of all strings $s_1 s_2 \cdots s_k$ in which $s_1, \cdots, s_k$ are $1 \le k < \infty$ entries from set $\mathcal{S}$.
- $*$ denotes the concatenation operation in $\mathcal{S}^+$.
- $|\mathcal{S}|$, $card(\mathcal{S})$ denote cardinality of set $\mathcal{S}$.
- $|x|$ denotes the length of string x.
- $V(G)$ denotes the set of variables of a grammar G.
- $L(G)$ denotes the language of a grammar G.
- $|G|$ denotes the total number of elements appearing in the right members of the production rules of a grammar G.
- $L(v|T)$ denotes the number of leaf vertices of a tree T which are equal or subordinate to vertex v of T.
- All logarithms are to base 2.

2. Bracketed Expressions and Their Trees. A context-free grammar G is said to represent a string x if $L(G) = \{x\}$. In the next section, we shall derive the grammars that we shall use to represent the data strings that we wish to compress. The most convenient way for us to derive these grammars will be through the use of fully bracketized expressions. This section is devoted to the presentation of useful material on fully bracketized expressions and the trees associated with them. As

shown below, fully bracketized expressions are related to multilevel refined parsing.

Let $\mathcal{S}$ be a finite set. The set $Br(\mathcal{S})$ of fully bracketized expressions over $\mathcal{S}$ is defined by

$$Br(\mathcal{S}) \stackrel{\Delta}{=} Br_{at}(\mathcal{S}) \cup Br_{nat}(\mathcal{S}), \tag{2.1}$$

where

- $Br_{at}(\mathcal{S}) = \{[s] : s \in \mathcal{S}\}$; and
- $Br_{nat}(\mathcal{S})$ is the smallest subset U of $(\mathcal{S} \cup \{[,]\})^+$ satisfying the property that $[s_1 s_2 \cdots s_k] \in U$ whenever $k \geq 2$ and $s_1, s_2, \cdots, s_k$ are members of $U \cup \mathcal{S}$.

The members of $Br(\mathcal{S})$ shall be called $\mathcal{S}$-expressions, the members of $Br_{at}(\mathcal{S})$ shall be called atomic $\mathcal{S}$-expressions, and the members of $Br_{nat}(\mathcal{S})$ shall be called nonatomic $\mathcal{S}$-expressions. For each left bracket in an $\mathcal{S}$-expression, there is a right bracket that is paired with it. If an $\mathcal{S}$-expression σ consists of $n + k$ entries, with n of the entries belonging to $\mathcal{S}$ and k of the entries being brackets, then there corresponds to σ a rooted tree $T(\sigma)$ having exactly n leaf vertices and $k/2$ internal vertices; the tree $T(\sigma)$ is uniquely characterized by the following properties:

(i): There is a one-to-one correspondence between the n $\mathcal{S}$-filled positions in σ and the n leaf vertices of $T(\sigma)$. Letting $x_1, x_2, \cdots, x_n$ denote the left-to-right entries of σ which belong to $\mathcal{S}$, the correspondence is made clear by labeling the i-th left-to-right leaf vertex of $T(\sigma)$ with x_i $(i = 1, 2, \cdots, n)$.

(ii): There is a one-to-one correspondence between the $k/2$ left-right bracket pairs in σ and the $k/2$ internal vertices of $T(\sigma)$. The vertex in $T(\sigma)$ corresponding to a given left-right bracket pair in σ is the vertex whose leaf vertex successors correspond, according to *(i)*, to the $\mathcal{S}$-filled positions in σ that lie between the left bracket and paired right bracket.

For each atomic $\mathcal{S}$-expression, the corresponding tree is trivial, consisting of root vertex and one leaf vertex. For each nonatomic $\mathcal{S}$-expression σ, the tree $T(\sigma)$ has at least two children for each internal vertex (see Fig. 1); conversely, every finite rooted tree which carries a label from $\mathcal{S}$ on each leaf vertex and which has two or more children for each internal vertex corresponds to a unique nonatomic $\mathcal{S}$-expression.

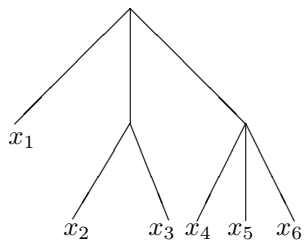

FIG. 1. *Tree $T(\sigma)$ for the expression $\sigma = [x_1[x_2x_3][x_4x_5x_6]]$.*

For each positive integer n, let $Br^n(\mathcal{S})$ be the set of all $\mathcal{S}$-expressions which have exactly n $\mathcal{S}$-filled positions. Let $\{s(n) : n = 1, 2, \cdots\}$ be the sequence

$$s(n) = \begin{cases} 1, & n = 1 \\ n^{-1} \sum_{k=0}^{n-2} \binom{2n-k-2}{n-1} \binom{n-2}{k}, & n \geq 2 \end{cases}$$

The numbers $s(n)$ are called little Schröder numbers [7] [8]. The little Schröder numbers are important to us here because

$$|Br^n(\{0\})| = s(n), \quad n \geq 1 \tag{2.2}$$

$$|Br^n(\mathcal{S})| = |\mathcal{S}|^n s(n), \quad n \geq 1 \tag{2.3}$$

The relation (2.2) is well known [8, Ch. 6]; the relation (2.3) becomes clear by noticing that each entry of a $\{0\}$-expression where 0 occurs can be regarded as a placeholder for an element of $\mathcal{S}$. The first few little Schröder numbers are given in Table 1.

TABLE 1
Little Schröder Numbers

n	$s(n)$	n	$s(n)$
1	1	6	197
2	1	7	903
3	3	8	4279
4	11	9	20793
5	45	10	103049

Example 1: The $s(4) = 11$ expressions in $Br^4(\{0\})$ are seen to be [[00][00]], [0000], [0[00]0], [[00]00], [00[00]], [[000]0], [0[000]], [[0[00]]0], [[[00]0]0], 0[[00]0]], [0[0[00]]].

A *subexpression* of an $\mathcal{S}$-expression σ is defined to be any $\mathcal{S}$-expression which occurs as a substring of σ. Let σ be a fixed $\mathcal{S}$-expression. The occurrences of subexpressions in σ are in one-to-one correspondence with the internal vertices of $T(\sigma)$, since each subexpression begins with a left bracket and ends with the matching right bracket. For example, the occurrence of $[x_4x_5x_6]$ as a subexpression of $\sigma = [x_1[x_2x_3][x_4x_5x_6]]$ corresponds to the vertex of $T(\sigma)$ in Fig. 1 whose children are labeled x_4, x_5, x_6.

3. Representational Grammars. Let $\mathcal{A}$ be a fixed finite alphabet. We shall call the members of $\mathcal{A}^+$ $\mathcal{A}$-strings. Our goal in this paper is to efficiently compress each $\mathcal{A}$-string via the grammar-based approach. In order that we may do this, we put forth in this section a set $\mathcal{G}(rep)$ of context-free grammars called *representational grammars* which satisfy

(i): The language $L(G)$ of each grammar $G \in \mathcal{G}(rep)$ consists of a unique string, and that string is an $\mathcal{A}$-string.

(ii): For each $\mathcal{A}$-string x, there is at least one grammar $G \in \mathcal{G}(rep)$ which represents x (in the sense that $L(G) = \{x\}$).

In the paper [3], we used context-free grammars which we called admissible grammars to represent data strings in the sense of (i)-(ii) above. Simply put, an admissible grammar is any context-free grammar G for which the language generated by G is a singleton. The class of representational grammars introduced in this section is a proper subclass of the class of admissible grammars. Since writing [3], we have come to realize that the class of representational grammars is more suitable for data compression purposes than the class of admissible grammars.

A context-free grammar G is uniquely specified by defining the following four entities:

(i): The set $V(G)$ of variables of G.
(ii): The start variable of G.
(iii): The set of terminal symbols of G.
(iv): The set of production rules of G.

Let σ be a fixed (but arbitrary) $\mathcal{A}$-expression. In the rest of this paragraph, we describe how to build from σ a unique context-free grammar $G_{rep}(\sigma)$. Recall from the end of Sec. 2 how a subexpression of σ corresponds to each internal vertex of the tree $T(\sigma)$. Traverse each internal vertex of $T(\sigma)$ in the top-down left-to-right order (i.e., the breadth-first order), appending the subexpression corresponding to that vertex to a list if that subexpression has not appeared previously in the list (start with the empty list). Let

$$\sigma_0, \sigma_1, \cdots, \sigma_t$$

be the final list of distinct subexpressions of σ after all of the internal vertices of $T(\sigma)$ have been traversed. The set of variables of $G_{rep}(\sigma)$ is

$$V(G_{rep}(\sigma)) = \{A_0, A_1, A_2, \cdots, A_t\},$$

where each A_i is an abstract symbol not belonging to the data alphabet $\mathcal{A}$. The start variable of $G_{rep}(\sigma)$ is A_0. The set of terminal symbols of $G_{rep}(\sigma)$ is the set consisting of those symbols in $\mathcal{A}$ that appear in σ. For each $i = 0, 1, \cdots, t$, there is exactly one production rule

$$A_i \to \alpha_1 \alpha_2 \cdots \alpha_k \tag{3.1}$$

of $G_{rep}(\sigma)$ whose left member is A_i, obtained as follows. First, form the unique factorization

$$\sigma_i = [s_1 s_2 \cdots s_k],$$

in which $s_1, s_2, \cdots, s_k$ are members of $\mathcal{A} \cup Br_{nat}(\mathcal{A})$. If $s_i \in \mathcal{A}$, then α_i in (3.1) is taken to be s_i. If $s_i \in Br_{nat}(\mathcal{A})$, then α_i is taken to be A_j, where j is the unique integer such that $\sigma_j = s_i$.

We now formally define the set of representational grammars by

$$\mathcal{G}(rep) \stackrel{\Delta}{=} \{G_{rep}(\sigma) : \sigma \in Br(\mathcal{A})\}$$

We list properties of representational grammars easily deduced from the construction given in the preceding paragraph.

Properties of Representational Grammars.

Prop 1: For each representational grammar G, there is exactly one $\mathcal{A}$-expression σ such that $G = G_{rep}(\sigma)$.

Prop 2: The language of a representational grammar $G_{rep}(\sigma)$ is $\{x\}$, where x is the $\mathcal{A}$-string consisting of those entries of σ belonging to $\mathcal{A}$ (taken left-to-right).

Prop 3: The unique derivation tree of a representational grammar $G_{rep}(\sigma)$ yields $T(\sigma)$ when the labels on the internal vertices are removed.

Prop 4: For each positive integer n and each $\mathcal{A}$-string x of length n, there are exactly $s(n)$ representational grammars which represent x.

Example 2: Let $\mathcal{A} = \{0, 1\}$, and we pick

$$\sigma = [[[01][01]][[11][01]][[11][01]]] \tag{3.2}$$

as an $\mathcal{A}$-expression for which we construct the grammar $G_{rep}(\sigma)$. There are five subexpressions of σ, to which we assign variables as follows:

$$\begin{aligned} A_0 &\leftrightarrow [[[01][01]][[11][01]][[11][01]]] \\ A_1 &\leftrightarrow [[01][01]] \\ A_2 &\leftrightarrow [[11][01]] \\ A_3 &\leftrightarrow [01] \\ A_4 &\leftrightarrow [11] \end{aligned} \tag{3.3}$$

The production rules of our grammar $G_{rep}(\sigma)$ are then seen to be:

$$\begin{aligned} A_0 &\rightarrow A_1 A_2 A_2 \\ A_1 &\rightarrow A_3 A_3 \\ A_2 &\rightarrow A_4 A_3 \\ A_3 &\rightarrow 01 \\ A_4 &\rightarrow 11 \end{aligned} \tag{3.4}$$

The derivation tree of $G_{rep}(\sigma)$ is given in Fig. 2. From the labels on the leaf vertices of the derivation tree, we see that

$$L(G_{rep}(\sigma)) = \{010111011101\}.$$

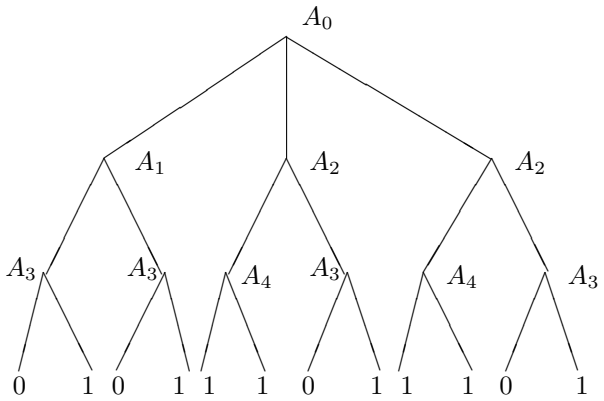

FIG. 2. *Derivation tree of $G_{rep}(\sigma)$ in Example 2.*

Removing the labels on the internal vertices of the derivation tree, the tree $T(\sigma)$ can be seen to result.

Example 3: For an atomic $\mathcal{A}$-expression $[a]$, the grammar $G_{rep}([a])$ has only one production rule $A_0 \to a$.

4. Structure Grammars. We put forth in this section a set of context-free grammars $\mathcal{G}(str)$ called *structure grammars*. We shall see that there is a useful interplay between the grammars in $\mathcal{G}(rep)$ and the grammars in $\mathcal{G}(str)$.

In the previous section, we explained how to form the grammar $G_{rep}(\sigma)$ for any $\mathcal{A}$-expression σ. By the same technique, we form a unique grammar corresponding to each $\{0\}$-expression, the only difference being that we denote the set of variables of the resulting grammar by

$$\{U_0, U_1, \cdots, U_t\}$$

instead of

$$\{A_0, A_1, \cdots, A_t\},$$

where the U_i's are special symbols reserved for denoting variables of structure grammars. The grammar corresponding to $\sigma \in Br(\{0\})$ formed in this way shall be denoted $G_{str}(\sigma)$. The set of structure grammars can now be formally defined as

$$\mathcal{G}(str) = \{G_{str}(\sigma) : \sigma \in Br(\{0\})\}.$$

If σ is an $\mathcal{A}$-expression, and σ' is the $\{0\}$-expression that arises by changing to 0 each entry of σ which belongs to $\mathcal{A}$, then we henceforth write $\sigma \to \sigma'$ to denote this fact. If $G = G_{rep}(\sigma)$ is a representational grammar, then we define G^* to be the grammar $G_{str}(\sigma')$ for which $\sigma \to \sigma'$. We call G^* the *structure grammar of* G. Given any representational grammar G, there is a natural mapping $\phi_G : V(G) \cup \mathcal{A} \to V(G^*) \cup \{0\}$ defined as follows. Let σ, σ' be the bracketed expressions such that $G = G_{rep}(\sigma)$

and $G^* = G_{str}(\sigma')$. Let $A_i \leftrightarrow \sigma_i$ be the correspondence between variables A_i of G and subexpressions σ_i of σ that was used in defining the grammar G, and let $U_j \leftrightarrow \sigma'_j$ be the correspondence between variables U_j of G^* and subexpressions σ'_j of σ' that was used in defining the grammar G^*. If $A_i \in V(G)$, we define $\phi_G(A_i) = U_j$, where $U_j \in V(G^*)$ is the variable of G^* such that $\sigma_i \to \sigma'_j$. If $a \in \mathcal{A}$, we define $\phi_G(a) = 0$.

The proof of the following simple lemma is omitted.

LEMMA 1. *Let G be any representational grammar. If*

$$A_i \to \alpha_1\alpha_2\cdots\alpha_k$$

is any production rule of G, then

$$\phi_G(A_i) \to \phi_G(\alpha_1)\phi_G(\alpha_2)\cdots\phi_G(\alpha_k)$$

is a production rule of G^*. Conversely, every production rule of G^* is mapped onto by at least one production rule of G in this way.

Example 4: Let G be the representational grammar of Example 2. From the correspondences (3.3), we see that G^* must have three variables U_0, U_1, U_2 with correspondences

$$\begin{aligned} U_0 &\leftrightarrow [[[00][00]][[00][00]][[00][00]]] \\ U_1 &\leftrightarrow [[00][00]] \\ U_2 &\leftrightarrow [00]. \end{aligned} \tag{4.1}$$

(Simply change every 1 to 0 on the right sides of (3.3) and eliminate duplications.) The mapping ϕ_G must map the set $\{A_0, A_1, A_2, A_3, A_4, 0, 1\}$ onto the set $\{U_0, U_1, U_2, 0\}$. We see that ϕ_G is specified by

$$\begin{aligned} \phi_G(A_0) &= U_0 \\ \phi_G(A_1) &= U_1 \\ \phi_G(A_2) &= U_1 \\ \phi_G(A_3) &= U_2 \\ \phi_G(A_4) &= U_2 \\ \phi_G(0) &= 0 \\ \phi_G(1) &= 0 \end{aligned}$$

by seeing how the correspondences (4.1) arose from the correspondences (3.3). Applying the mapping ϕ_G to the production rules of G in (3.4), we automatically obtain the following production rules of G^* via Lemma 1:

$$\begin{aligned} U_0 &\to U_1U_1U_1 \\ U_1 &\to U_2U_2 \\ U_2 &\to 00 \end{aligned}$$

The structure grammar G^* of G represents the structural information of G. From the above, it follows that one can easily get G^* from G through the mapping ϕ_G. On the other hand, if x is the data string represented by G, then one can uniquely determine G from G^* and x. In the next section, we will exploit this relationship to define the unnormalized conditional entropy $H(G|G^*)$ of the representational grammar G given its structure grammar G^* and conditionally encode G given G^*. If encoder and decoder know the grammar G^*, it will be possible for the encoder to encode the grammar G for perfect recovery by the decoder using approximately $H(G|G^*)$ code bits.

To conclude this section, we present a structure grammar concept that will be useful to us later on. Let G be any structure grammar. We define the *spreading factor* $\beta(G)$ of G as follows. Letting T be the derivation tree of G, $\beta(G)$ is the largest ratio $L(v|T)/L(v'|T)$ as (v, v') ranges through all parent-child vertex pairs of T. The spreading factor $\beta(G)$ measures, to some degree, how children from an internal vertex are spread.

Example 5: Let G be the structure grammar presented in Example 4. Its derivation tree T, stripped of all labels, coincides with the tree in Fig. 2 when it is stripped of all labels. When v is the root of T and v' is any of the children of v, we see that $L(v|T) = 12$ and $L(v'|T) = 4$. The parent-child pair (v, v') yields the largest ratio $L(v|T)/L(v'|T)$; hence $\beta(G) = 12/4 = 3$.

The following result is proved in Appendix A.

THEOREM 1. *Let n be any integer ≥ 2 and let G be any representational grammar which represents an $\mathcal{A}$-string of length n. Then*

$$|G| \leq 72\beta(G^*)^2(|\mathcal{A}| + 2)^2 \log(|\mathcal{A}| + 2) \left(\frac{n}{\log n}\right).$$

5. Conditional Grammar Encoding. Our first task in this section is to define the unnormalized conditional entropy $H(G|G^*)$ of any representational grammar G given its structure grammar G^*.

DEFINITION: Let $S = s_1 s_2 \cdots s_k$ be any nonempty string of finite length over any alphabet. We define the (unnormalized) entropy of the string S by

$$H(S) \stackrel{\Delta}{=} \sum_{i=1}^{k} -\log p(s_i),$$

where for any $s \in \{s_1, \cdots, s_k\}$,

$$p(s) = k^{-1} card(\{1 \leq i \leq k : s_i = s\}).$$

If S is the empty string, define $H(S) = 0$. Let $U = u_1 u_2 \cdots u_k$ be any string of the same length as S. Let $\mathcal{U} = \{u_1, \cdots, u_k\}$, and for each $u \in \mathcal{U}$, let $S(u)$ be the

substring obtained from S by removing each entry s_i of S for which $u_i \neq u$. We define the unnormalized conditional entropy of S given U as

$$H(S|U) \triangleq \sum_{u \in \mathcal{U}} H(S(u)).$$

From information theory, it is easy to see that $H(S|U) \leq H(S)$.

Let G be a fixed (but arbitrary) representational grammar. We are now ready to define $H(G|G^*)$. First, letting $V(G) = \{A_0, A_1, \cdots, A_t\}$, form the string

$$\alpha(A_0) * \alpha(A_1) * \cdots * \alpha(A_t), \tag{5.1}$$

where $\alpha(A_i)$ denotes the string in $(V(G) \cup \mathcal{A})^+$ which is the right member of the production rule of G whose left member is A_i. Let $\omega_G = \omega_1\omega_2 \cdots \omega_k$ be the string in $(V(G) \cup \mathcal{A})^+$ formed from the string (5.1) by striking from this string the first left-to-right appearance of each variable in $V(G)$. Then the unnormalized conditional entropy $H(G|G^*)$ of G given its structure grammar G^* is defined as

$$H(G|G^*) \triangleq H(\omega_1\omega_2 \cdots \omega_k | \phi_G(\omega_1)\phi_G(\omega_2) \cdots \phi_G(\omega_k)).$$

Example 6: Let G be the representational grammar introduced in Example 2. We compute $H(G|G^*)$. From the production rules (3.4), we see that

$$\omega_G = A_2A_3A_30111. \tag{5.2}$$

We can apply the mapping ϕ_G derived in Example 4 to each term on the right side of (5.2), from which we conclude that

$$H(G|G^*) = H(A_2A_3A_30111|U_1U_2U_20000) \approx 3.25.$$

REMARK. The quantity $H(G) \triangleq H(\omega_G)$ was defined in [3] as the definition of the unnormalized entropy of a representational grammar G. It was shown in [3] that without being decomposed into its structure G^* and its data content, G can be encoded by a prefix code into a codeword of roughly $H(G)$ bits. However, this encoding method is not efficient because

(a) given a data sequence of length n, it follows from (2.2) and Section 4 that there are $s(n)$ distinct representational grammars representing x and yet in the Analysis Stage one needs just one grammar for each distinct string x; and

(b) grammars representing distinct strings may have the same structure grammar.

As a result, a better way is to conditionally encode G given G^*. The following theorem says that given G^*, G can be losslessly encoded into a codeword of roughly $H(G|G^*)$ bits. By imposing some mild condition on G^*, the encoding of G^* is either free or has a negligible overhead. Since $H(G|G^*) \leq H(G)$, the compression performance is improved, as shown in the next section. This is the essence of structured grammar-based coding.

THEOREM 2. *Let G' be any structure grammar. There are binary strings $\{B(G|G') : G \in \mathcal{G}(rep),\ G^* = G'\}$ such that*

- *For each representational grammar G whose structure grammar is G',*

$$|B(G|G')| \leq H(G|G') + 4|G| + |\mathcal{A}|.$$

- *For each pair of distinct representational grammars G_1, G_2 whose structure grammar is G', the string $B(G_1|G')$ is not a prefix of the string $B(G_2|G')$.*

Proof of Theorem 2. Let G' be a fixed structure grammar. Let G be any representational grammar such that $G^* = G'$. Let

$$V(G) = \{A_0, A_1, \cdots, A_K\}$$

$$V(G') = \{U_0, U_1, \cdots, U_J\}$$

We show how to construct a binary codeword $B(G|G')$ such that G will be recoverable from $B(G|G')$ and G'. By superimposing the derivation tree of G over the derivation tree of G', a tree T is obtained such that each of its vertices carries a label from $V(G) \cup \mathcal{A}$ (which we call the G-label of the vertex) and also carries a label from $V(G') \cup \{0\}$ (which we call the G'-label of the vertex). The tree T has the following properties

(1): The root vertex of T carries G-label A_0 and G'-label U_0.

(2): If the G-label of a vertex of T is A_i and the G-labels of its children are $a_1, a_2, ..., a_r$ from left to right, then $A_i \to a_1 a_2 \cdots a_r$ is a production rule of G.

(3): If the G'-label of a vertex of T is U_j and the G'-labels of its children are $b_1, b_2, \cdots, b_s$, then $U_j \to b_1 b_2 \cdots b_s$ is a production rule of G'.

We now prune the tree T according to the following procedure:

Step 1 Traverse the internal vertices of T in the breadth-first order.

Step 2 If the G-label of the currently traversed internal vertex appears before, cut the subtree rooted at this internal vertex except this internal vertex itself.

Step 3 Continue to traverse the remaining internal vertices of the pruned tree in the breadth-first order.

Step 4 Repeat Steps 2 and 3 until all the remaining internal vertices are traversed.

(The above procedure is illustrated in Example 7 after this proof.) After pruning T, one eventually obtains a tree $T(G|G')$ such that (i) $T(G|G')$ possesses exactly $|G|$ edges and $|V(G)|$ internal vertices; (ii) the G-labels on the internal vertices of $T(G|G')$ are the variables in $V(G)$. Let B_1 be a binary codeword of length $2|G|$ from which the tree $T(G'|G)$, without labels, can be recovered (an internal vertex of $T(G'|G)$ with k children will generate $2k$ consecutive bits in B_1—k bits to tell how many children the vertex has followed by k bits to tell which of these children are internal vertices and which are leaf vertices). The codeword B_1 will appear at the beginning of the codeword $B(G|G')$. After the decoder has recovered the tree $T(G|G')$ without labels from B_1, it can then insert the G-labels on the internal vertices of $T(G|G')$ (because

of the numbering convention with which the variables in $V(G)$ were generated), and it can also insert the G'-labels on all of the vertices of $T(G|G')$ (since the decoder knows G'). At this point, the decoder will not know the G-labels on the leaf vertices of $T(G|G')$ (once these are known, G is determined). However, the decoder can determine the mapping ϕ_G from $V(G) \cup \mathcal{A}$ into $V(G') \cup \{0\}$ (by seeing what label from $V(G')$ is on each internal vertex of $T(G|G')$). Let B_2 be a binary codeword of length $|\mathcal{A}| + |G|$ which gives the frequency of each member of $V(G) \cup \mathcal{A}$ in the right members of the production rules of G (the first $|\mathcal{A}|$ bits of B_2 identify those members of $\mathcal{A}$ which are terminal symbols of G; in the remaining $|G|$ bits, each frequency f of a symbol lying in the right members of the production rules of G is represented by f bits). The codeword B_2 appears right after the codeword B_1 at the beginning of $B(G|G')$. For each $U \in V(G') \cup \{0\}$, let $S(U)$ be the (possibly empty) sequence of G-labels that appear on the leaf vertices of $T(G|G')$ whose G'-label is U. From the mapping ϕ_G that the decoder learns from B_1 and the frequencies that the decoder learns from B_2, the decoder will then know how long each sequence $S(U)$ is, what the alphabet of each $S(U)$ is, and what is the frequency with which each member of the alphabet of $S(U)$ appears in $S(U)$. Consequently, for each $U \in V(G') \cup \{0\}$ there is a binary codeword $B(U)$ of length $\lceil H(S(U)) \rceil$ which will allow the decoder to recover $S(U)$. Once the decoder knows each $S(U)$, the decoder will know the complete G-labeling of $T(G|G')$, and therefore will know G. Our argument has shown that we can take

$$B(G|G') = B_1 B_2 B(U_1) B(U_2) \cdots B(U_J) B(0).$$

The length of $B(G|G')$ is

$$3|G| + |\mathcal{A}| + \sum_{U \in V(G') \cup \{0\}} \lceil H(S(U)) \rceil. \tag{5.3}$$

The sum comprising the last term of (5.3) has no more than $|V(G')|$ nonzero terms; hence this last term is $\leq |V(G')| + H(G|G') \leq |G| + H(G|G')$. The conclusion of Theorem 2 is now established.

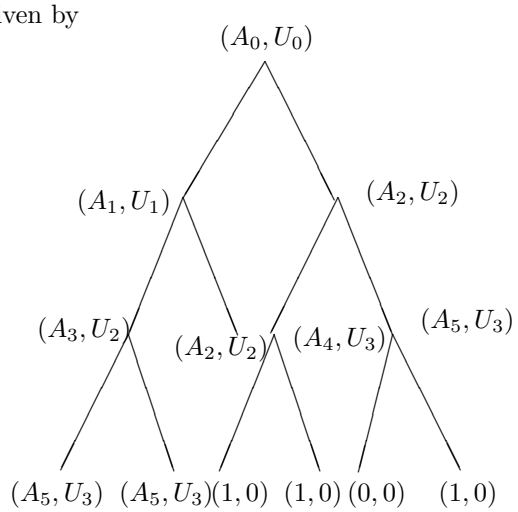
Example 7: Let G' be the structure grammar with production rules

$$\begin{aligned} U_0 &\to U_1 U_2 \\ U_1 &\to U_2 U_2 \\ U_2 &\to U_3 U_3 \\ U_3 &\to 00 \end{aligned}$$

and let G be the representational grammar with production rules

$$\begin{aligned} A_0 &\to A_1A_2 \\ A_1 &\to A_3A_2 \\ A_2 &\to A_4A_5 \\ A_3 &\to A_5A_5 \\ A_4 &\to 11 \\ A_5 &\to 01 \end{aligned} \tag{5.4}$$

The tree $T(G|G')$ is given by



where in the pair $(\bullet, \bullet)$ at each vertex, the first coordinate is the G-label and the second coordinate is the G'-label. (Note that the subtrees rooted at (A_2, U_2) of depth 2 and at (A_5, U_3) of depth 3 are deleted according to the pruning procedure mentioned in the proof of Theorem 2.) The codeword B_1 is

$$B_1 = 01 * 11 * 01 * 10 * 01 * 11 * 01 * 00 * 01 * 00 * 01 * 00$$

of length $24 = 2|G|$. The frequencies of A_1, A_2, A_3, A_4, A_5, 0, 1 in the right members of (5.4) are $1, 2, 1, 1, 3, 1, 3$, respectively. Thus,

$$B_2 = 11 * 1 * 01 * 1 * 1 * 001 * 1 * 001,$$

where the first two bits tell the decoder that both $0, 1$ in the alphabet $\mathcal{A} = \{0, 1\}$ are terminal symbols of G. The length of B_2 is $14 = |G| + |\mathcal{A}|$. The distinct G'-labels used on the leaf vertices of $T(G|G')$ are $U_2, U_3, 0$, and so the decoder can obtain the G-labels on these vertices from the sequences $S(U_2), S(U_3), S(0)$. These sequences are

$$\begin{aligned} S(U_2) &= A_2 \\ S(U_3) &= A_5A_5 \\ S(0) &= 1101 \end{aligned}$$

From the G'-labels on the 7 leaf vertices of $T(G|G')$, the decoder determines that the sequences $S(U_2)$, $S(U_3)$, $S(0)$ are of lengths $1, 2, 4$, respectively. From the G'-labels on the internal vertices of $T(G|G')$, the decoder determines that the alphabets of $S(U_2), S(U_3)$ are subsets of $\{A_2, A_3\}, \{A_4, A_5\}$, respectively; the decoder knows that the alphabet of $S(0)$ is a subset of $\mathcal{A} = \{0, 1\}$. From the codeword B_2, the decoder determines that $S(U_2)$ consists of 1 A_2 and 0 A_3's and therefore $S(U_2) = A_2$; that $S(U_3)$ consists of 0 A_4's and 2 A_5's and therefore $S(U_3) = A_5A_5$; and that $S(0)$ consists of 3 zeroes and 1 one. Only $S(0)$ remains to be determined; since the alphabet of $S(0)$ is binary, and since the length of $S(0)$ coincides with $\lceil H(S(0)) \rceil$, $S(0)$ can be transmitted to the decoder as is. Thus, in this example, we can take

$$B(G|G') = B_1B_2 1101,$$

of length 42.

6. Universal Coding Theorem. We embark upon the main section of the paper. A formal definition of the concept of structured grammar-based code is given. Redundancy bounds for a structured grammar-based code with respect to families of information sources are obtained.

Information Sources. An *alphabet $\mathcal{A}$ information source* is defined to be any mapping $\mu : \mathcal{A}^+ \to [0, 1]$ such that

$$\begin{aligned} 1 &= \textstyle\sum_{a \in \mathcal{A}} \mu(a) \\ \mu(\boldsymbol{x}) &= \textstyle\sum_{a \in \mathcal{A}} \mu(\boldsymbol{x}a), \quad \boldsymbol{x} \in \mathcal{A}^+ \end{aligned}$$

That is, μ is a probability distribution induced by a random process with alphabet $\mathcal{A}$.

Finite-State Sources. Let k be a positive integer. An alphabet $\mathcal{A}$ information source μ is called a *k-th order finite-state source* if there is a set $\mathcal{S}$ of cardinality k, a symbol $s_0 \in \mathcal{S}$, and nonnegative real numbers $\{p(s, x|s') : s, s' \in \mathcal{S},\ x \in \mathcal{A}\}$ such that both of the following hold:

$$\sum_{s,x} p(s, x|s') = 1, \quad s' \in \mathcal{S} \tag{6.1}$$

$$\mu(x_1x_2 \cdots x_n) = \sum_{s_1, s_2, \cdots, s_n \in \mathcal{S}} \prod_{i=1}^{n} p(s_i, x_i|s_{i-1}), \quad x_1x_2 \cdots x_n \in \mathcal{A}^+. \tag{6.2}$$

We let Λ_k denote the family of all alphabet $\mathcal{A}$ k-th order finite-state sources. We call members of the set $\cup_k \Lambda_k$ *finite-state sources*. Note that finite-state sources defined here are much broader than tree sources considered in [10], [11], [9].

Lossless Source Codes. We define an *alphabet $\mathcal{A}$ lossless source code* to be a sequence of pairs $\mathcal{C} = \{(\epsilon_n, \delta_n) : n = 1, 2, \cdots\}$ in which

i) For each $n = 1, 2, \cdots$, ϵ_n is a mapping (called the n-th encoder mapping of the code $\mathcal{C}$) which maps each string $\boldsymbol{x}$ in $\mathcal{A}^n$ into a codeword $\epsilon_n(\boldsymbol{x}) \in \{0, 1\}^+$,

and δ_n is the mapping (called the n-th decoder mapping of $\mathcal{C}$) which maps $\epsilon_n(\boldsymbol{x})$ back into $\boldsymbol{x}$; and

ii) for each $n = 1, 2, \cdots$, and each distinct pair of strings $\boldsymbol{x}_1, \boldsymbol{x}_2$ in $\mathcal{A}^n$, the codeword $\epsilon_n(\boldsymbol{x}_1)$ is not a prefix of the codeword $\epsilon_n(\boldsymbol{x}_2)$.

Structured Grammar-Based Codes. We define a *structure transform* to be a mapping $x \to G'_x$ from $\mathcal{A}^+$ into the set $\mathcal{G}(str)$ of structure grammars such that the structure grammar G'_x has $|x|$ leaf vertices in its derivation tree for every $\mathcal{A}$-string x. Fix an arbitrary structure transform $x \to G'_x$. For each positive integer n, let

$$\mathcal{G}^n \stackrel{\Delta}{=} \{G'_x : x \in \mathcal{A}^n\}.$$

Let $\mathcal{C} = \{(\epsilon_n, \delta_n) : n = 1, 2, \cdots\}$ be an alphabet $\mathcal{A}$ lossless source code. We call $\mathcal{C}$ a *structured grammar-based code induced by the structure transform* $x \to G'_x$ if ϵ_n and δ_n losslessly encode and decode respectively each $\mathcal{A}$-string x of length n according to the following four stages:

- *Analysis Stage:* Determine the structure grammar G'_x corresponding to x and then form the unique representational grammar G_x that represents x and has G'_x as its structure grammar.
- *Encoding Stage:* Encode the structure grammar G'_x, if needed, into a binary string $B(G'_x)$, and then conditionally encode G_x given G'_x into the binary string $B(G_x|G'_x)$, resulting in the total codeword $\epsilon_n(x) = B(G'_x)B(G_x|G'_x)$.
- *Decoding Stage:* Reconstruct G'_x using $B(G'_x)$ and G_x using $B(G_x|G'_x)$ and G'_x.
- *Synthesis Stage:* Recover x via propagation of the derivation tree of G_x.

The manner in which G'_x is encoded will depend in general on the underlying structure transform. As shown in Theorems 3 and 4, under certain mild conditions on the structure grammars in $\mathcal{G}^n$, the encoding of G'_x can be done quite naturally.

Redundancy Results. The type of redundancy we employ in this paper is *maximal redundancy/sample*. Let Λ be a family of alphabet $\mathcal{A}$ information sources. Let $\mathcal{C} = \{(\epsilon_n, \delta_n) : n = 1, 2, \dots\}$ be an alphabet $\mathcal{A}$ lossless source code. The n-th order maximal redundancy/sample of $\mathcal{C}$ with respect to the family of sources Λ is the number

$$\mathrm{R}ed_n(\mathcal{C}, \Lambda) \stackrel{\Delta}{=} n^{-1} \max_{x \in \mathcal{A}^n} \left[|\epsilon_n(x)| - H(x|\Lambda)\right],$$

where $H(x|\Lambda)$ is defined by

$$H(x|\Lambda) \stackrel{\Delta}{=} \inf\{-\log \mu(x) : \mu \in \Lambda\}.$$

It should be pointed out that when the source class Λ is broad enough, the redundancy notion defined here is very strong. For instance, it can be shown that if $\mathcal{C}$ is CTW or PPM, then $\mathrm{R}ed_n(\mathcal{C}, \Lambda_k)$ is bounded below by a positive constant for large n.

Let us now impose some mild conditions on the underlying structure transform and analyze the redundancy of the resulting structured grammar-based code. Suppose

that

$$\beta \stackrel{\Delta}{=} \sup_{x \in \mathcal{A}^+} \beta(G'_x) < \infty \tag{6.3}$$

That is, we require that the structure grammars $\{G'_x\}$ have uniformly bounded spreading factors. We now consider two cases. In Case 1, we assume that

$$|\mathcal{G}^n| = 1, \quad n = 1, 2, \cdots \tag{6.4}$$

In this case, the encoding of G'_x is free because all strings $x \in \mathcal{A}^n$ share a common structure grammar and hence there is no need to encode the common structure grammar. Theorem 3, stated below and proved in Appendix B, upper bounds the redundancy of this type of structured grammar-based code.

THEOREM 3. *Let $\mathcal{C}$ be a structured grammar-based code induced by a structure transform satisfying (6.3) and (6.4). Let*

$$D \stackrel{\Delta}{=} 72\beta^2(|\mathcal{A}| + 2)^2 \log(|\mathcal{A}| + 2).$$

Then, for every positive integer k,

$$\mathrm{R}ed_n(\mathcal{C}, \Lambda_k) \leq \frac{|\mathcal{A}|}{n} + \frac{(4 + \log k)D}{\log n}, \quad n = 2, 3, \cdots \tag{6.5}$$

REMARK. Theorem 3 tells us that any structured grammar-based code satisfying the regularity conditions (6.3) and (6.4) has maximal redundancy/sample $O(1/\log n)$. Compared to the conditions considered in [5] and [4], these are mild regularity conditions because they allow the use of grammars having highly unbalanced derivation trees. Previously considered $O(1/\log n)$ redundancy/sample grammar-based codes (such as the MPM code [5] and the codes in [4]) were more restrictive in that they employed grammars with approximately balanced derivation trees.

In Case 2, we allow strings $x \in \mathcal{A}^n$ to have different structure grammars, but require that structure grammars in $\mathcal{G}^n$, $n = 1, 2, \cdots$, satisfy the following condition:

Condition A: For any structure grammar $G'_x \in \mathcal{G}^n$, $n = 1, 2, \cdots$, different variables U_j of G'_x represent distinct $\{0\}$-strings.

(If $G'_x = G_{str}(\sigma')$, then the $\{0\}$-string represented by $U_j \in V(G'_x)$ is obtained by striking out all brackets from the subexpression σ'_j of σ' corresponding to U_j.) It is easy to see that the structure grammar G' in Example 7 satisfies Condition A with U_3, U_2, U_1, and U_0 representing $\{0\}$-strings 00, 0000, 00000000, and 000000000000, respectively. Under Condition A and (6.3), the encoding of each G'_x contributes only a negligible overhead, as shown in Theorem 4.

THEOREM 4. *Let $\mathcal{C}$ be a structured grammar-based code induced by a structure transform satisfying (6.3) and Condition A. Assume that each structure grammar $G'_x \in \mathcal{G}^n$ is encoded into a codeword of length $\lceil \log |\mathcal{G}^n| \rceil$. Then, for every positive integer k,*

$$\mathrm{R}ed_n(\mathcal{C}, \Lambda_k) \leq \frac{|\mathcal{A}|}{n} + \frac{(4 + \log k)D}{\log n} + 12\beta^{3/2}\left(\frac{\log n}{\sqrt{n}}\right), \quad n = 2, 3, \cdots \tag{6.6}$$

In Theorem 4, the third term on the right hand side of (6.6) represents the overhead per sample contributed by the encoding of the structure grammar G'_x. Theorem 4 is proved in Appendix C.

Appendix A. This appendix is devoted to the proof of Theorem 1. The following lemma is our first step towards proving Theorem 1.

LEMMA 2. *Let n be an integer at least 2 and let $\mathcal{D}$ be a finite set with at least two elements. Let $J(n,\mathcal{D})$ be the largest number of distinct strings in $\mathcal{D}^+$ which are of total length at most n. Then,*

$$J(n,\mathcal{D}) \le 4|\mathcal{D}|^2 \log|\mathcal{D}| \left(\frac{n}{\log n}\right).$$

Proof. Let $d = |\mathcal{D}|$. Let us assume until the end of the proof that $n > d^8$. If we list all strings in $\mathcal{D}^+$ in order of length, then the first $J(n,\mathcal{D})$ strings in this list will have total length $\le n$ and the first $J(n,\mathcal{D})+1$ strings in this list will have total length $> n$. It follows that there is an integer $j \ge 2$ such that

$$d + d^2 + \cdots + d^j \le J(n,\mathcal{D}) < d + d^2 + \cdots + d^{j+1} \tag{A1}$$

and

$$d + 2d^2 + \cdots + jd^j \le n < d + 2d^2 + \cdots + (j+1)d^{j+1}. \tag{A2}$$

Summing the right side of (A1), we obtain

$$J(n,\mathcal{D}) < d\left(\frac{d^{j+1}-1}{d-1}\right) \le d^2\left(\frac{d^j}{d-1}\right). \tag{A3}$$

Summing the left and right sides of (A2), we obtain

$$d\left[\frac{jd^j}{d-1} + \frac{1-d^j}{(d-1)^2}\right] \le n < d\left[\frac{(j+1)d^{j+1}}{d-1} + \frac{1-d^{j+1}}{(d-1)^2}\right]$$

and then

$$\frac{(j-1)d^j}{d-1} \le n < (d^2)^{j+1} \tag{A4}$$

follows because

$$d\left[\frac{jd^j}{d-1} + \frac{1-d^j}{(d-1)^2}\right] \ge \frac{(j-1)d^j}{d-1}$$

and

$$d\left[\frac{(j+1)d^{j+1}}{d-1} + \frac{1-d^{j+1}}{(d-1)^2}\right] \le \frac{(j+1)d^{j+2}}{d-1} \le (d^2)^{j+1}.$$

The right half of inequality (A4) gives us

$$j > (1/2)\left(\frac{\log n}{\log d}\right) - 1$$

which, applied to the left half of (A4), yields

$$\begin{aligned}\frac{d^j}{d-1} &\leq \frac{n}{j-1} \\ &\leq \frac{n}{(1/2)(\log n/\log d) - 2} \\ &= \frac{2n\log d}{\log(n/d^4)}\end{aligned}$$

Applying the preceding to (A3), we obtain

$$J(n,\mathcal{D}) < d^2\left(\frac{d^j}{d-1}\right) \leq 2d^2\log d\left(\frac{n}{\log(n/d^4)}\right).$$

Since we are assuming that $n > d^8$, it follows that

$$\frac{n}{\log(n/d^4)} \leq 2\left(\frac{n}{\log n}\right)$$

and the conclusion of Lemma 2 is true. For $2 \leq n \leq d^8$, the conclusion of Lemma 2 is also true, because

$$J(n,\mathcal{D}) \leq n \leq 8\log d\left(\frac{n}{\log n}\right) < 4d^2\log d\left(\frac{n}{\log n}\right).$$

Proof of Theorem 1. Fix $n \geq 2$ and an arbitrary representational grammar G which represents an $\mathcal{A}$-string of length n. Let σ be the $\mathcal{A}$-expression such that $G = G_{rep}(\sigma)$. Let $T(G|G^*)$ be a tree with $|G|$ edges and $|V(G)|$ internal vertices, obtained by pruning $T(\sigma)$ from the bottom up, such that

Prop(1): Each vertex v of $T(G|G^*)$ carries a label $\sigma(v)$ which is either a subexpression of σ or an element of $\mathcal{A}$.

Prop(2): Each label $\sigma(v)$ on an internal vertex v of $T(G|G^*)$ is a subexpression of σ, and each distinct subexpression of σ is a label $\sigma(v)$ for exactly one internal vertex v of $T(G|G^*)$.

Prop(3): The expression σ can be obtained via the concatenation of the labels $\sigma(v)$ on the leaf vertices v of $T(G|G^*)$ and some left and right brackets.

Let r be the number of leaf vertices of $T(G|G^*)$. Since $|G| \leq 2r$, we may upper bound $|G|$ by doubling any upper bound we obtain on r. Since each internal vertex of $T(G|G^*)$ has at most $K \stackrel{\Delta}{=} \lfloor\beta(G^*)\rfloor$ children, it follows that there must exist $s \geq r/K$ distinct internal vertices $v_1, v_2, \cdots, v_s$ of $T(G|G^*)$, such that each leaf vertex of $T(G|G^*)$ has one of these vertices v_i as its parent and each v_i has a leaf vertex of $T(G|G^*)$ as one of its children. Pick a leaf vertex u_i which is the child of v_i for each i.

Since $L(v_i|T(\sigma)) \le KL(u_i|T(\sigma))$, and since the length of $\sigma(v_i)$ is at most three times $L(v_i|T(\sigma))$, we have

$$|\sigma(v_i)| \le 3L(v_i|T(\sigma)) \le 3KL(u_i|T(\sigma)) \le 3K|\sigma(u_i)|.$$

By *Prop(3)*, the summation of the $|\sigma(u_i)|$ is less than $|\sigma|$; also, σ is of length at most $3n-2$. Therefore, the distinct strings $\sigma(v_i)$ have total length $< 9Kn$. Applying Lemma 2 with $\mathcal{D} = \mathcal{A} \cup \{[,]\}$ and $|\mathcal{D}| = |\mathcal{A}| + 2$, we obtain

$$\begin{aligned} s &\le 4(|\mathcal{A}|+2)^2 \log(|\mathcal{A}|+2)(9Kn/\log(9Kn)) \\ &\le 36K(|\mathcal{A}|+2)^2 \log(|\mathcal{A}|+2)(n/\log n) \end{aligned}$$

The bound on r is then K times this, and the bound on $|G|$ is obtained by doubling the bound on r. This gives us the conclusion of Theorem 1.

Appendix B. This appendix is devoted to the proof of Theorem 3. We present the key lemma needed to prove Theorem 3.

LEMMA 3. *Let k be any positive integer. Then*

$$H(G|G^*) - H(x|\Lambda_k) \le |G| \log k \tag{B1}$$

for any $\mathcal{A}$-string x and any representational grammar G which represents x.

Proof of Lemma 3. Let x be a fixed $\mathcal{A}$-string and let G be a fixed representational grammar which represents x. Let k be a fixed positive integer. Our task is to show that (B1) is true. Given a set $\mathcal{S}$ with k elements, a symbol $s_0 \in \mathcal{S}$, and a set of nonnegative real numbers $p = \{p(s,u|s') : s, s' \in \mathcal{S}, u \in \mathcal{A}\}$ satisfying (6.1), let μ_{p,s_0} denote the source in Λ_k defined by equation (6.2). As we let s_0 and p vary through all possibilities, μ_{p,s_0} varies over all sources in Λ_k. Fix p and define λ_p to be the function

$$\lambda_p(u) = \max_{s_0 \in \mathcal{S}} \mu_{p,s_0}(u), \quad u \in \mathcal{A}^+.$$

The function λ_p has the following two properties which are exploited in this proof:

(p.1): If $u_1, u_2, \cdots, u_j$ are $\mathcal{A}$-strings which yield the $\mathcal{A}$-string u when concatenated together, then

$$\lambda_p(u) \le \lambda_p(u_1)\lambda_p(u_2)\cdots\lambda_p(u_j).$$

(p.2): For every positive integer m,

$$1 \le \sum_{u \in \mathcal{A}^m} \lambda_p(u) \le k.$$

Let σ be the $\mathcal{A}$-expression such that $G_{rep}(\sigma) = G$, and let σ' be the $\{0\}$-expression such that $G_{str}(\sigma') = G^*$. Let $T(G|G^*)$ be the tree used in our earlier proofs. For our purposes here, $T(G|G^*)$ has the following properties:

(p.3): The tree $T(G|G^*)$ has $|G| - |V(G)| + 1$ leaf vertices.

(p.4): Each leaf vertex v of $T(G|G^*)$ has a label $\sigma(v)$ which is either a subexpression of σ or an element of $\mathcal{A}$, a label $\sigma'(v)$ which is either 0 or a subexpression of σ', and a label $x(v)$ which is a substring of x. The label $\sigma'(v)$ is obtained from the label $\sigma(v)$ by replacing each $\mathcal{A}$-entry of $\sigma(v)$ with 0, and the label $x(v)$ is obtained from the label $\sigma(v)$ by removing all brackets from $\sigma(v)$.

(p.5): For each α' which is either 0 or a proper subexpression of σ', if we let $S(\alpha')$ be the sequence formed by the labels $\sigma(v)$ for those leaf vertices v of $T(G|G^*)$ for which $\sigma'(v) = \alpha'$, then

$$H(G|G^*) = \sum_{\alpha'} H(S(\alpha')). \tag{B2}$$

(p.6): The labels $x(v)$ on the leaf vertices v of $T(G|G^*)$ yield x when concatenated together (according to the left-to-right ordering of the leaf vertices).

For each α' which is either 0 or a proper subexpression of σ', let the positive integer $m(\alpha')$ be the number of entries of α' which are equal to 0, and let $\mathcal{V}(\alpha')$ be the set of leaf vertices v of $T(G|G^*)$ for which $\sigma'(v) = \alpha'$. Then, for each $v \in \mathcal{V}(\alpha')$, the string $x(v)$ has length $m(\alpha')$. For each positive integer m, let τ_m be the probability distribution on $\mathcal{A}^m$ such that

$$\tau_m(u) = \lambda_p(u)/\Sigma_m, \quad u \in \mathcal{A}^m,$$

where, using property *(p.2)*,

$$\Sigma_m \triangleq \sum_{u \in \mathcal{A}^m} \lambda_p(u) \le k. \tag{B3}$$

It follows that

$$\begin{aligned} H(S(\alpha')) &\le \sum_{v \in \mathcal{V}(\alpha')} -\log \tau_{m(\alpha')}(x(v)) \\ &\le |S(\alpha')| \log k + \sum_{v \in \mathcal{V}(\alpha')} -\log \lambda_p(x(v)). \end{aligned}$$

Summing each side of the preceding inequality over α', we obtain

$$H(G|G^*) + \log \lambda_p(x) \le |G| \log k. \tag{B4}$$

Here, we used (B2) and the fact that

$$\sum_{\alpha'} \sum_{v \in \mathcal{V}(\alpha')} -\log \lambda_p(x(v)) \le -\log \lambda_p(x),$$

which follows from properties *(p.1)* and *(p.6)*. We also used the fact that

$$\sum_{\alpha'} |S(\alpha')| \le |G|,$$

which is true because $T(G|G^*)$ has no more than $|G|$ leaf vertices (property *(p.3)*). Inequality (B1) now results by taking the supremum of both sides of (B4) over p.

Proof of Theorem 3. Let $\mathcal{C} = \{(\epsilon_n, \delta_n)\}$ be a structured grammar-based code induced by a structure transform satisfying (6.3) and (6.4). Let n be a fixed positive integer. Since all $\mathcal{A}$-strings of length n share a common structure grammar, denote this common structure grammar by G^n. Fix an arbitrary string $x \in \mathcal{A}^n$ and let G_x be the representational grammar representing x whose structure grammar is G^n. Applying Theorem 2,

$$|\epsilon_n(x)| = |B(G_x|G^n)| \le H(G_x|G^n) + 4|G_x| + |\mathcal{A}|.$$

Subtracting $H(x|\Lambda_k)$ from both sides and applying Lemma 3, we see that

$$\mathrm{R}ed_n(\mathcal{C}, \Lambda_k) \le n^{-1}|\mathcal{A}| + n^{-1}(4 + \log k) \max_{x \in \mathcal{A}^n} |G_x|.$$

Applying Theorem 1 to the last term on the right in the preceding equation, we see that the conclusion of Theorem 3 is true.

Appendix C. In this appendix, we prove Theorem 4. In view of the proof of Theorem 3, it suffices to upper bound the overhead contributed by the encoding of each G'_x.

LEMMA 4. *Under Condition A and (6.3),*

$$\lceil \log |\mathcal{G}^n| \rceil \le 12\beta^{3/2}\sqrt{n}\log n$$

for any integer $n \ge 2$.

Proof of Lemma 4: Let G' be an arbitrary structure grammar from $\mathcal{G}^n$. Let σ be the $\{0\}$-expression such that $G' = G_{str}(\sigma)$. We first use a technique similar to the proof of Theorem 1 to upper bound the size of G'. Let G be the representational grammar $G_{rep}(\sigma)$; then $G^* = G'$ and the grammars G, G' are identical except for the fact that variables of G are denoted A_j and variables of G' are denoted U_j. Let r be the number of leaf vertices of the tree $T(G|G^*)$ defined in the proof of Theorem 1. (Throughout the rest of this proof, notation will be the same as in the proof of Theorem 1, unless otherwise specified.) Then

$$|G'| \le 2r \le 2\beta(G')s \tag{C1}$$

For each vertex v of $T(G|G^*)$, let $x(v)$ be the $\{0\}$-string obtained by striking out all possible brackets from $\sigma(v)$. From the proof of Theorem 1, it follows that

$$|x(v_i)| \le \beta(G')|x(u_i)|$$

and hence

$$\sum_{i=1}^{s} |x(v_i)| \le \beta(G') \sum_{i=1}^{s} |x(u_i)| \le \beta(G')n \tag{C2}$$

Note that under Condition A, all $x(v_i)$, $i = 1, 2, \cdots, s$, are distinct. Let N be the positive integer equal to the left side of (C2). Let $J(N)$ be the maximum number of distinct $\{0\}$-strings which are of total length at most N. Then

$$\frac{1}{2}J(N)[J(N)+1] \le N < \frac{1}{2}[J(N)+1][J(N)+2] < [J(N)+1]^2.$$

From this, we have

$$J(N) \le 2\sqrt{N}$$

which, together with (C2) and (C1), implies

$$s \le 2\sqrt{\beta(G')n} \text{ and } |G'| \le 4[\beta(G')]^{3/2}\sqrt{n} \tag{C3}$$

Let us now describe how to encode G'. The first part B_1 of the codeword of G' tells the decoder the length of the right member of each production rule of G'. This can be accomplished by the unary representation of each length. Thus, the length of B_1 is $|G'|$. The second part B_2 tells the decoder the actual symbols in the right member of each production rule. This can be accomplished by using $\lceil \log n \rceil$ bits to represent each symbol U_j or 0. The length of B_2 is $|G'|\lceil \log n \rceil$. The complete codeword is the concatenation of B_1 with B_2. The total codeword length is

$$\begin{aligned} |B_1B_2| &= |G'|(1 + \lceil \log n \rceil) \\ &\le 4\lfloor [\beta(G')]^{3/2}\sqrt{n} \rfloor (1 + \lceil \log n \rceil) \\ &\le 4\lfloor \beta^{3/2}\sqrt{n} \rfloor (1 + \lceil \log n \rceil) \end{aligned}$$

In the above, the first inequality is due to (C3), and the second inequality is attributed to (6.3). Since such a coding scheme is a prefix code for $\mathcal{G}^n$, Lemma 4 follows.

Proof of Theorem 4: It now follows immediately from Lemma 4 and the proof of Theorem 3.

INTERSPERSIONS AND DISPERSIONS

The numbers you see to the right form a northwest corner of the *Wythoff array*:

Interestingly, the Wythoff array (1) contains every positive integer exactly once, (2) has increasing rows and columns, and (3) has interspersed rows - i.e., once the first term of any row lies between two consecutive terms of any other row, the alternating between the two rows continues forever. The three properties define an *interspersion*. (The Wythoff array is only one of uncountably many interspersions.)

19	31	50	81	131	212	343	555	898	1453	2351
22	36	58	94	152	246	398	644	1042	1686	2728

Now, suppose X = (x(1), x(2), x(3), . . .) is an increasing sequence of positive integers, with x(1) > 1. Write 1,2,3,...,30 across the top of a piece of paper, and then beneath each of these n, write the number x (n). Then write out successive rows of an array as follows:

Row 1 consists of

1, x(1), x(x(1)), x(x(x(1))), . . .

Let x(i) be the least positive integer not in row 1, and write row 2 as

x(i), x(x(i)), x(x(x(i))), . . .

Let x(j) be the least positive integer not in row 1 or row 2, and write row 3 as

x(j), x(x(j)), x(x(x(j))), . . .

Continue indefinitely, obtaining a *dispersion*, namely that of the sequence x. In the article

C. Kimberling, "Interspersions and dispersions," *Proceedings of the American Mathematical Society* 117 (1993) 313-321,

it is proved that every interspersion is a dispersion, and conversely. Special cases are discussed in

Generating Indecomposable Permutations

Andrew King
Department of Computer Science
University of Toronto
Toronto, Ontario, Canada

Abstract

An indecomposable permutation π on $[n]$ is one such that $\pi([m]) = [m]$ for no $m < n$. We consider indecomposable permutations and give a new, inclusive enumerative recurrence for them. This recurrence allows us to generate all indecomposable permutations of length n in transposition Gray code order, in constant amortized time (CAT). We also present a CAT generation algorithm which is based on the Steinhaus-Johnson-Trotter algorithm for generating all permutations of length n. The question of whether or not there exists an adjacent transposition Gray code for indecomposable permutations remains open.

1 Introduction

A permutation π on the interval $[n]$ is indecomposable if and only if $\pi([m]) = [m]$ for no $m < n$. In other words, if and only if it has no proper prefix which is itself a permutation. It is easy to see that there is one indecomposable permutation of length 1, one such permutation of length 2, and three such permutations of length 3.

Indecomposable permutations (sometimes called irreducible permutations) were introduced by Comtet [1, 2], who enumerated them and discussed them in the more general context of permutations with a given number of components (see [2], Exercise 6.14). They have since been investigated in several

contexts, mostly combinatorial and algebraic. We seek to generate them quickly and in a meaningful order.

2 Combinatorial Issues

Let the set of indecomposable permutations of length n be denoted I_n. Comtet [1, 2] noted that $|I_n|$, the number of indecomposable permutations of length n, has the generating function

$$f(t) = 1 - \frac{1}{\sum_{n=1}^{\infty} n! t^n}. \tag{1}$$

The well-known recurrence for $|I_n|$ considers cases of permutations which are not indecomposable. Consider the number of decomposable permutations π on $[n]$ having i as the smallest integer such that $\pi([i]) = [i]$. It is easy to see that there are $|I_i|$ such prefixes, and the other $n-i$ elements can be permuted arbitrarily, therefore there are $|I_i|(n-i)!$ such sequences. The prefix length i lies between 1 and $n-1$, and there are $n!$ permutations in total. This yields the recurrence

$$|I_n| = n! - \sum_{i=1}^{n-1} |I_i|(n-i)! \tag{2}$$

This recurrence is simple, but not particularly useful, as it uses exclusion and is therefore unlikely to help us in finding a Gray code. The more useful recurrence follows:

Theorem 1.

$$|I_n| = \sum_{r=2}^{n} \sum_{j=0}^{r-2} |I_{n-j-1}| j! \tag{3}$$

$$= \sum_{j=0}^{n-2} (n-j-1) |I_{n-j-1}| j! \tag{4}$$

Proof. Consider the number of indecomposable permutations on $[n]$ with first element r. Remove the first element and subtract 1 from any element greater than r. The result is a permutation π on $[n-1]$. Consider the

Table 1: Indecomposable permutations with parameters r and j for $n = 5$

largest $m < n$ such that $\pi([j]) = [j]$ (let $j = 0$ if none exists). Remove this prefix and subtract j from each element. The result is a permutation on $[n - j - 1]$, and this must be indecomposable since decomposability would imply that j was chosen incorrectly. So there are $|I_{n-j-1}|$ such suffixes, and for it there are $j!$ possible prefixes of length j. Since the original permutation is indecomposable, $0 \leq j \leq r - 2$. This yields the first identity. The second follows by simple arithmetic. See Table 1 as an example of the parameters r and j. □

This parameterization is essential to generating the permutations in Gray

code order in Section 4.

3 Generation in SJT Order

The Steinhaus-Johnson-Trotter (SJT) algorithm (see [5], p. 136) is a CAT generation algorithm for all permutations on $[n]$ in adjacent transposition Gray code order. Algorithm 1 generates all permutations in the same order as the SJT algorithm, put outputs only those which are indeomposable.

Algorithm 1 can be turned into the SJT algorithm by removing lines 9 to 16 and changing the condition on line 4 to be merely $m > n$. Initially, $spp[i] = 1$ and $p[i] = i$ for all i. As with the SJT algorithm, the initial call is Perm(1).

Algorithm 1 Generate indecomposable permutations in SJT order

```
 1: procedure Perm ( int m )
 2: local int i, j, t
 3: begin
 4:    if m > n and spp[n] = n then
 5:       Printit;
 6:    else
 7:       Perm(m + 1);
 8:       for i := 1 to m − 1 do
 9:          p[m] := p[m] + dir[m];
10:          for j := m to n do
11:             if p[j] ≤ s[j − 1] then
12:                spp[j] := j;
13:             else
14:                spp[j] := spp[j − 1];
15:             end if
16:          end for
17:          t := π^{-1}[m];   π[t] := π[t + dir[m]];   π[t + dir[m]] := n;
18:          π^{-1}[m] := t + dir[m];   π^{-1}[π[t]] := t;
19:          Perm(n + 1);
20:       end for
21:    end if
22:    dir[m] := −dir[m];
23: end
```

$p[i]$ represents the position that i would hold in the permutation if all numbers greater than i were to be removed. For example, in the permutation 635142, p would be [1, 2, 1, 3, 2, 1]. This explains line 9, because as a property of the SJT algorithm, m is always transposed with a smaller number, so $p[m]$ will always change by 1, and no other entry of p will change.

$spp[i]$ is the length of the smallest prefix which is itself a permutation, once all numbers greater than i have been removed. For example, in the permutation 635142, spp would be [1, 1, 3, 4, 5, 6]. Note that $spp[1] = 1$ always, and for $i > 1$, $spp[i] = i$ if and only if removing all numbers greater than i leaves an indecomposable permutation. In this example, 1, 312, 3142, 35142, and 635142 are all indecomposable.

Lemma 2. *Let π be a permutation on $[n]$. For $1 < i \leq n$,*

$$spp[i] = \begin{cases} i & \text{if } p[i] \leq spp[i-1] \\ spp[i-1] & \text{otherwise} \end{cases} \tag{5}$$

This follows from the fact that, when inserting i into a permutation on $[i-1]$, if i comes before the end of the smallest prefix which is itself a permutation, the result will be an indecomposable permutation. If i comes after the end of this prefix, then the existing prefix will remain the shortest such prefix.

Theorem 3. *Algorithm 1 generates all indecomposable permutations, and no others.*

Proof. It is clear that a permutation on $[n]$ is indecomposable if and only if $spp[n] = n$, so it remains only to show that lines 9 through 16 maintain p and spp correctly. We have already illustrated that line 9 increments or decrements $p[m]$ appropriately.

Lemma 2 establishes the appropriate value for $spp[n]$ when n is inserted into a permutation on $[n-1]$. Moving m in π in the algorithm will never change $spp[i]$ for $i < m$; that much is clear. However, it can change $spp[i]$ for $i > m$. By the claim, we can correctly maintain spp by recomputing $spp[m], spp[m+1], \ldots, spp[n]$ in that order. Hence lines 9 through 16 correctly maintain p and spp.

Therefore, adding to the SJT algorithm the specification that a permutation is printed if and only if $spp[n] = n$ ensures that the algorithm generates exactly all indecomposable permutations. □

Theorem 4. *Algorithm 1 runs in constant amortized time.*

Proof. We know from Comtet ([1]) that $\lim_{n\to\infty} |I_n|/(n!) = 1$, and we know further that $n!/|I_n| \leq 2$. Therefore it suffices to show that the algorithm's running time is bounded by a constant factor with respect to the running time of the SJT algorithm, since the SJT algorithm is itself CAT.

Modifying line 4 and adding line 9 clearly adhere to this constraint (because they do no more than add a constant amount of work to each node in the computation tree), so we need only be concerned about the **for** loop beginning at line 10. This loop does a constant amount of work $n - m$ times at each node at distance m from the root of the computation tree, for $m = 0, 1, 2, \ldots, n$. There are $m!$ nodes at distance m from the root, so let us bound the total amount of work done in the tree.

We take as granted that for $n > 0$, $\sum_{i=0}^{n} i! \leq 2 \cdot n!$. This can be proven trivially by induction. Let $W(n)$ be the number of times the inner **for** loop (line 10) is run through in total. Now consider the computation tree for $W(n+1)$. It is the same as the tree for $W(n)$ but with $n+1$ children added to each leaf, and with the inner **for** loop run through one extra time in every node at distance $\leq n$ from the root. There are $\sum_{i=0}^{n} i!$ such nodes, so $W(n+1) = W(n) + \sum_{i=0}^{n} i! \leq W(n) + 2 \cdot n!$. The sequence $\{W(n)\}_{n=1}^{\infty}$ begins $1, 3, 7, 17, 51, \ldots$, so we will show that for $n \geq 4$, $W(n) < n!$, using the basis $W(4) = 17$. Take $n \geq 4$ and suppose that $W(n) < n!$.

$$\begin{aligned} W(n+1) &\leq W(n) + 2 \cdot n! \\ &< 3 \cdot n! \\ &< (n+1)! \end{aligned} \tag{6}$$

So $W(n)$ is bounded by a constant times the number of nodes in the computation tree for $\mathsf{Perm}(n)$. Therefore Algorithm 1 runs in constant time amortized over the number of permutations output by the SJT algorithm, and therefore over the number of its own output permutations. □

4 Generation in Gray Code Order

In this section we first present the theory behind the Gray code, then present the Gray code generation algorithm.

4.1 Existence of a Gray Code

There is a transposition Gray code for indecomposable permutations which uses the partitioning of the set of indecomposable permutations induced jointly by the parameters r and j, discussed in Section 2. We must introduce several terms.

Terminology 1. *We shall denote the transposition Gray graph of indecomposable permutations G_n. Let the subgraph of G_n induced by those permutations which begin with r be denoted $G_{n,r}$. Let the subgraph of $G_{n,r}$ induced by those permutations with parameter j (as in Section 2) be denoted $G_{n,r,j}$. Let the vertex sets of these graphs be denoted I_n, $I_{n,r}$, and $I_{n,r,j}$ respectively.*

Terminology 2. *Consider two finite sets S_1, $S_2 \subseteq \mathbb{Z}^+$ such that $|S_1| = |S_2| = n > 0$. Now consider two bijections (permutations), $\pi_1 : S_1 \to [n]$ and $\pi_2 : S_2 \to [n]$. We say that π_1 and π_2 are* equivalent *permutations if and only if for any i and j such that $0 < i, j \leq n$, we have that $\pi_1^{-1}(i) < \pi_1^{-1}(j) \iff \pi_2^{-1}(i) < \pi_2^{-1}(j)$. When an underlying set S is implied or known, and π is a permutation on a set of size $|S|$, let $E(\pi)$ denote the permutation on S which is equivalent to π.*

Lemma 5. *Let j satisfy $0 \leq j \leq n-2$. Then for any two r_1 and r_2 satisfying $j+2 \leq r \leq n$, $G_{n,r_1,j} \cong G_{n,r_2,j}$.*

Proof. Consider the bijection $f : I_{n,r_1,j} \to I_{n,r_2,j}$ which maps $\pi_1 \in I_{n,r_1,j}$ to $\pi_2 \in I_{n,r_2,j}$ if and only if when the first elements of each permutation (i.e. the prefixes of length 1) are removed, the remaining permutations are equivalent. The image of π_1 is unique, as there can only be one permutation on $[n] \setminus r_2$ equivalent to a given permutation on $[n] \setminus r_1$.

Since r_1 and r_2 are both greater than $j+1$, it is easy to see that $f(\pi_1) \in I_{n,r_2,j}$. Now consider a permutation $\pi_1' \in I_{n,r_1,j}$ which is reached from π_1 by a single transposition. $f(\pi_1')$ is reached from π_2 by transposing the same two positions. By generality, the same rule applies in the other direction, so f is a graph isomorphism. □

At this point, we must define special vertices in the Gray graph.

Terminology 3. *Let the* top *vertices of $G_{n,r,j}$ and G_n be denoted* $\text{top}_{n,r,j}$ *and* top_n *respectively. Let the* bottom *vertices of $G_{n,r,j}$ and G_n be denoted*

$\mathrm{bot}_{n,r,j}$ *and* bot_n *respectively. Let them be defined as follows:*

$$
\begin{aligned}
\mathrm{top}_n &= 2, 3, 4, \ldots, n, 1 \\
\mathrm{bot}_n &= n, 1, 2, 3, \ldots, n-1 \\
\mathrm{top}_{n,n,j} &= \begin{cases} n, 2, 3, \ldots, n-1, 1 & \text{if } j = 0 \\ n, 1, 3, 4, \ldots, n-1, 2 & \text{if } j = 1 \\ n, 1, 2, \ldots, j-2, j, j-1, n-1, j+1, j+2, \ldots, n-2 & \text{otherwise} \end{cases} \\
\mathrm{bot}_{n,n,j} &= n, 1, 2, \ldots, j-2, j-1, j, n-1, j+1, j+2, \ldots, n-2
\end{aligned}
$$

For $r \neq n$, $\mathrm{top}_{n,r,j}$ *and* $\mathrm{bot}_{n,r,j}$ *are those vertices in* $G_{n,r,j}$ *which are isomorphic to* $\mathrm{top}_{n,n,j}$ *and* $\mathrm{bot}_{n,n,j}$ *respectively, under the isomorphism described in the proof of Lemma 5.*

The following facts are to be noted:

- $\mathrm{top}_n = \mathrm{top}_{n,2,0} = 2, E(\mathrm{top}_{n-1})$.
- $\mathrm{bot}_n = \mathrm{bot}_{n,n,n-2}$.
- For $j \geq 2$, $\mathrm{top}_{n,n,j} = n, 1, 2, \ldots, j-2, j, j-1, E(\mathrm{bot}_{n-j-1})$.
- $\mathrm{bot}_{n,n,j} = n, 1, 2, \ldots, j-2, j-1, j, E(\mathrm{bot}_{n-j-1})$.
- Transposing positions $j+2$ and $j+4$ in $\mathrm{bot}_{n,n,j}$ results in $\mathrm{top}_{n,n,j+2}$.
- Transposing positions 2 and n in $\mathrm{top}_{n,n,0}$ results in $\mathrm{top}_{n,n,1}$.
- Because of isomorphism, the above apply to all values of r, not just n.
- For $2 \leq r < n$, transposing elements (not positions) r and $r+1$ in $\mathrm{bot}_{n,r,j}$ results in $\mathrm{bot}_{n,r+1,j}$.

Let P_n be the transposition Gray graph of all permutations on $[n]$. Note, then, that $G_{n,r,j} \cong G_{n-j-1} \times P_j$. To see this, consider the explanation of Theorem 1.

Lemma 6. *To show that there is a Gray code for* I_n*, it suffices to show that for* $0 \leq j \leq n-2$*, there is a Gray code for* $I_{n,n,j}$ *that begins at* $\mathrm{top}_{n,n,j}$ *and ends at* $\mathrm{bot}_{n,n,j}$.

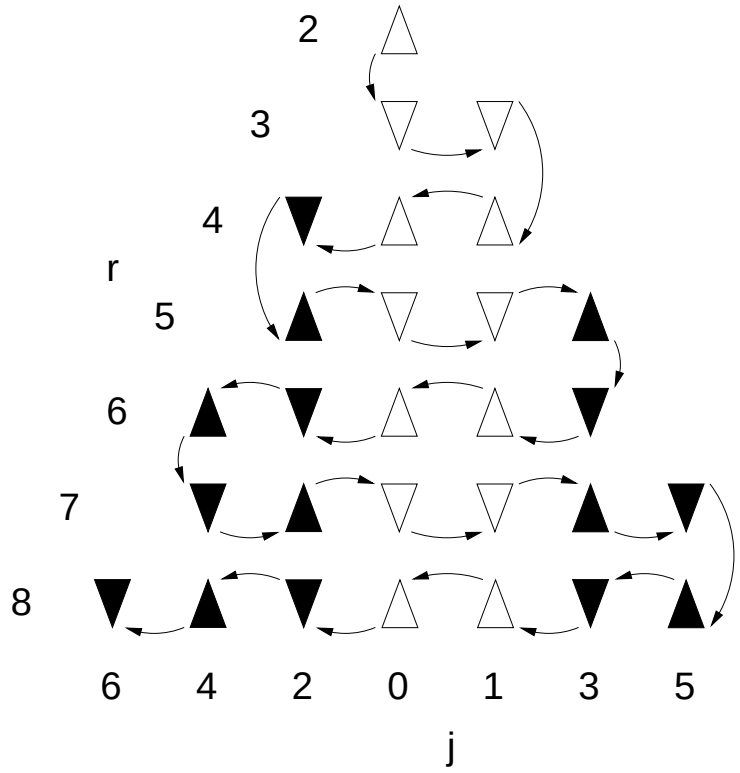

Figure 1: The traversals of $G_{n,r,j}$ graphs, combined to traverse G_n. Empty triangles indicate traversal from top to bottom, or bottom to top. Filled triangles indicate traversal from middle to bottom, or bottom to middle.

Proof. Suppose there are such Gray codes. Then by isomorphism, there is a top-to-bottom Gray code for $I_{n,2,0}$. We can traverse it, then make a transposition to reach $\text{bot}_{n,3,0}$. We can then traverse the previous Gray code in reverse to reach $\text{top}_{n,3,0}$ and make a transposition to reach $\text{top}_{n,3,1}$. Since there is a Gray code for $I_{n,n,1}$, we can traverse $G_{n,3,1}$ in Gray code order, then make a transposition to jump from $\text{bot}_{n,3,1}$ to $\text{bot}_{n,4,1}$.

Again, we can traverse from $\text{bot}_{n,4,1}$ to $\text{bot}_{n,4,2}$ by making the transpositions we used to traverse $r = 3$, only in reverse order. We can then jump from $\text{bot}_{n,4,0}$ to $\text{top}_{n,4,2}$. At this point, we can traverse $G_{n,4,2}$ from top to bottom, since there is a Gray code isomorphic to that for $I_{n,n,2}$.

In this fashion, we can continue jumping between values of r and j in the order shown in Figure 1 until we have traversed I_n completely. □

Theorem 7. *There is a transposition Gray code for I_n.*

Proof. We will use strong induction to prove the theorem.

BASIS: $n = 1$. $|I_1| = 1$, so there is a trivial Gray code from top to bottom.

INDUCTION: Assume that for all $0 < i < n$, there is a Gray code for I_i which runs from top_i to bot_i.

$\text{top}_{n,n,0} = n, E(\text{top}_{n-1})$. $\text{bot}_{n,n,0} = n, E(\text{bot}_{n-1})$. So by traversing the Gray code for I_{n-1} in the last $n-1$ positions of the permutation, we can traverse $G_{n,n,0}$ from top to bottom in Gray code order. Similarly, $\text{top}_{n,n,1} = n, 1, E(\text{top}_{n-2})$ and $\text{bot}_{n,n,1} = n, 1, E(\text{bot}_{n-2})$, so we can traverse $G_{n,n,1}$ from top to bottom in Gray code order using the Gray code for I_{n-2}.

We must now address the case where $j \leq 2$, i.e. the top to bottom traversals, using the fact that $G_{n,r,j} \cong G_{n-j-1} \times P_j$. First note that we have a transposition Gray code for P_j whose final permutation is the same as its initial permutation, but with the final two positions transposed: left-to-right SJT. This is the same as the Steinhaus-Johnson-Trotter algorithm, but the element in the leftmost position is moved first, not the element in the rightmost position. In order to traverse $G_{n,n,j}$, we must traverse G_{n-j-1} in the final $n-j-1$ positions once for every permutation of length j.

Recall that $\text{top}_{n,n,j} = n, 1, 2, \ldots, j-2, j, j-1, E(\text{bot}_{n-j-1})$, and $\text{bot}_{n,n,j} = n, 1, 2, \ldots, j-2, j-1, j, E(\text{bot}_{n-j-1})$, and note that we have an even number ($j!$) of permutations of length j. Therefore we can simply traverse G_{n-j-1} from bottom to top, advance the permutation of length j, traverse G_{n-j-1} from top to bottom, advance the permutation, etc., until every permutation

in $I_{n,n,j}$ has been exhausted. Because $j!$ is even and we are using left-to-right SJT, by beginning at $\text{mid}_{n,n,j}$ we ensure that we will end the traversal of $G_{n,n,j}$ at $\text{bot}_{n,n,j}$.

We have now established the necessary conditions given Lemma 6, so there is a Gray code for I_n. □

4.2 Generating the Gray Code

In this section we present a recursive algorithm for generating I_n in Gray code order. The initial call is PrintIt; Indec$(n, 0)$. RevIndec$(n, 0)$ generates I_n in reverse order (from bottom to top). To generate I_n with Indec, we must initialize the permutation p to top_n. Swap simply transposes the two positions, given as parameters, in p.

Indec and RevIndec call Permute, which in turn calls Indec and RevIndec. Every time Permute$(n, j, depth, m,$ true$)$ is called, we must allocate three vectors of length j, as in Algorithm 1: π, π^{-1}, and $dirArr$. To perform the left-to-right SJT traversal of permutations, we initialize π and π^{-1} to $j, j-1, j-2, \ldots, 1$, and we initialize $dirArr[i]$ to 1 for all i.

Indec jumps between the $I_{n,r,j}$ graphs in the order shown in Figure 1, traversing each subgraph by calling Permute. The algorithm uses the subgraph isomorphism described earlier in this section. NextJ and its inverse RevNextJ select the next value of j by simple case analysis. The values of j are changed in Indec, lines 18–24, and in RevIndec, lines 14–20, choosing the positions to transpose by the difference in j. The values of r are changed in Indec, lines 27–31, and in RevIndec, lines 23–27, this time choosing between two transpositions, depending on the structure of the current permutation. We will now prove that this algorithm is CAT, but first we will prove two technical lemmas.

Lemma 8. *Let $W_I(n)$ be the number of times a single call to* Indec$(n, 0)$ *results in a call to* Indec$(i, 0)$ *for $i \leq 2$. $W_I(n) = |I_n|$.*

Proof. $W_I(1) = 1$. For $n > 1$,

$$W_I(n) = \sum_{r=2}^{n} \sum_{j=0}^{r-2} W_I(n-j-1)j!. \tag{7}$$

This is because for a given value of j, Indec calls Indec$(n-j-1, depth)$ $j!$ times, and each of these calls contains $W_i(n-j-1)$ calls to Indec$(i, 0)$ for

Algorithm 2 Traverse G_n in Gray code order

```
 1: procedure Indec ( int n, depth )
 2: local int r, j, j'; boolean dir
 3: begin
 4:   if n > 2 then
 5:     for r := 2 to n do
 6:       if r > 2 then
 7:         j := r − 3;
 8:       else
 9:         j := 0;
10:       end if
11:       while true do
12:         dir := (r % 2 = j);
13:         Permute(n, j, depth, 1, dir, true);
14:         j' := NextJ(r, j);
15:         if j' > r − 2 then
16:           break;
17:         end if
18:         if j' = j + 2 then
19:           Swap(depth + j + 2, depth + j + 4); PrintIt;
20:         else if j' = j − 2 then
21:           Swap(depth + j, depth + j + 2); PrintIt;
22:         else
23:           Swap(depth + 2, depth + n); PrintIt;
24:         end if
25:         j := j';
26:       end while
27:       if r < n − 1 then
28:         Swap(depth + 1, depth + r + 2); PrintIt;
29:       else if r = n − 1 then
30:         Swap(depth + 1, depth + r); PrintIt;
31:       end if
32:     end for
33:   end if
34: end
```

Algorithm 3 Traverse G_n in reverse Gray code order

```
 1: procedure RevIndec ( int n, depth )
 2: local int r, j, j'; boolean dir
 3: begin
 4:   if n > 2 then
 5:     for r := n down to 2 do
 6:       j := r − 2;
 7:       while true do
 8:         dir := (r % 2 ≠ j);
 9:         Permute(n, j, depth, 1, dir, true);
10:         j' := RevNextJ(r, j);
11:         if j' > r − 2 then
12:           break;
13:         end if
14:         if j' = j + 2 then
15:           Swap(depth + j + 2, depth + j + 4); PrintIt;
16:         else if j' = j − 2 then
17:           Swap(depth + j, depth + j + 2); PrintIt;
18:         else
19:           Swap(depth + 2, depth + n); PrintIt;
20:         end if
21:         j := j';
22:       end while
23:       if r = n then
24:         Swap(depth + 1, depth + r − 1); PrintIt;
25:       else if r > 2 then
26:         Swap(depth + 1, depth + r + 1); PrintIt;
27:       end if
28:     end for
29:   end if
30: end
```

Algorithm 4 Traverse $G_{n,r,j}$

```
 1: procedure Permute ( int n, j, depth, m; boolean first )
 2: local int i, t
 3: begin
 4:   if m > j then
 5:     if ¬first then
 6:       Printit;
 7:     end if
 8:     if dir then
 9:       Indec(n − j − 1, depth + j + 1)
10:     else
11:       RevIndec(n − j − 1, depth + j + 1)
12:     end if
13:     dir := ¬dir;
14:   else
15:     Permute(n, j, depth, m + 1, first);
16:     first := false;
17:     for i := 1 to m − 1 do
18:       t := π^{-1}[m];   π[t] := π[t + dirArr[m]];   π[t + dirArr[m]] := n;
19:       π^{-1}[m] := t + dirArr[m];   π^{-1}[π[t]] := t;
20:       Permute(n, j, depth, m + 1, false);
21:     end for
22:   end if
23:   dirArr[m] := −dirArr[m];
24: end
```

Algorithm 5 Determine the next value of j to traverse

```
1:  procedure NextJ ( int r, j )
2:  begin
3:    if j = 0 and r is even then
4:      return j + 1;
5:    else if j = 1 and r is odd then
6:      return j − 1;
7:    else if j % 2 = r % 2 then
8:      return j + 2;
9:    else
10:     return j − 2;
11:   end if
12: end
13:
14: procedure RevNextJ ( int r, j )
15: begin
16:   if j = 0 and r is odd then
17:     return j + 1;
18:   else if j = 1 and r is even then
19:     return j − 1;
20:   else if j % 2 = r % 2 then
21:     return j − 2;
22:   else
23:     return j + 2;
24:   end if
25: end
```

$i \leq 2$. Recall that this is the same recurrence as in Equation 3, and since $W_I(1) = 1$, $W_I(n) = |I_n|$. □

Lemma 9. *Let $W_P(n)$ be the number of times a single call to* Indec$(n, 0)$ *results in a call to* Permute(n, j) *for $j \leq 1$. $W_P(n) \leq n!$.*

Proof. $W_I(1) = 0$ and $W_I(2) = 0$. For $n > 2$, Indec$(n, 0)$ calls Permute$(n, 0)$ $n - 1$ times, Permute$(n, 1)$ $n - 2$ times. These are the only such calls that happen in the calls at the top level. Beyond that, we have the familiar recurrence for calls to Permute(n, j) for $j \leq 1$ by recursive calls. This gives us

$$W_P(n) = 2n - 3 + \sum_{j=0}^{n-2} (n - j - 1) \cdot W_P(n - j - 1) \cdot j! \tag{8}$$

$$= 2n - 3 + \sum_{j=0}^{n-4} (n - j - 1) \cdot W_P(n - j - 1) \cdot j!, \tag{9}$$

the second formulation coming from the knowledge that $W_I(i) = 0$ for $i < 2$. The sequence $\{W_P(n)\}_{n=1}^{\infty}$ begins $0, 0, 3, 14, 72, 443, \ldots$. We claim that $W_P(n) \leq |I_n|$ for $n \geq 6$, and will prove it by induction.

Basis: $|I_6| = 461$, $W_P(6) = 443$.

INDUCTION: Let $n \geq 7$. Assume that all $6 \leq i \leq n-1$, $W_P(i) < |I_i|$.

$$\begin{aligned}
W_P(n) &= 2n-3+\sum_{j=0}^{n-7}((n-j-1)\cdot W_P(n-j-1)\cdot j!) \\
&\quad + \sum_{j=n-6}^{n-2}((n-j-1)\cdot W_P(n-j-1)\cdot j!) && (10)\\
&\leq 2n-3+\sum_{j=0}^{n-7}((n-j-1)\cdot |I_{n-j-1}|\cdot j!) \\
&\quad + \sum_{j=n-6}^{n-2}((n-j-1)\cdot W_P(n-j-1)\cdot j!) && (11)\\
&= 2n-3+|I_n|-\sum_{j=n-6}^{n-2}((n-j-1)\cdot |I_{n-j-1}|\cdot j!) \\
&\quad + \sum_{j=n-6}^{n-2}((n-j-1)\cdot W_P(n-j-1)\cdot j!) && (12)\\
&= |I_n| + (2n+5(n-6)!+4(n-5)!) \\
&\quad - (3+2(n-3)!+(n-2)!) && (13)\\
&\leq |I_n| + 2n - 43(n-6)! - 60(n-5)! && (14)\\
&\leq |I_n| && (15)
\end{aligned}$$

These steps are reasonably straightforward. (13) recalls Equation 4, and the steps that follow are arithmetical facts which rely on n being greater than 6. Since $|I_n| \leq n!$, the lemma is proved. □

These bounds on the call counts help us prove that the algorithm is efficient (CAT).

Theorem 10. *Indec*$(n, 0)$ *generates* I_n *in constant amortized time.*

Proof. Each call counted by $W_I(n)$ and $W_P(n)$ runs in constant time and outputs no permutations (though Permute will still call Indec once), so we can omit them from our analysis, since both $W_I(n)$ and $W_P(n)$ are bounded by $2|I_n|$; the total time is constant per indecomposable permutation generated by the main call, so it suffices to show that the rest of the algorithm is CAT.

Not counting the time taken during the recursive calls to Permute, each call to Indec$(n, depth)$ outputs $(n^2 - n - 2)/2$ permutations (one for each jump between a $G_{n,r,j}$ subgraph) and makes $(n^2 - n)/2$ calls to Permute (one for each $G_{n,r,j}$) in $O(n^2)$ time. Since we can assume $n \geq 3$, $(n^2 - n - 2)/2$ and $(n^2 - n)/2$ are each greater than $n^2/5$. Therefore Indec$(n, depth)$ itself does a constant amount of work per output and a constant amount of work per call to Permute.

Not counting the time taken during the recursive calls, each call to Permute(n, j) outputs $j! - 1$ permutations and makes $j!$ calls to Indec in $O(j!)$ time, which we can see because the SJT algorithm is CAT, and we have added only a constant amount of work per node. Because we can assume that $j \geq 2$, we know that $j! - 1 \geq j!/2$. Therefore we know that Permute(n, j) itself does a constant amount of work per output and a constant amount of work per recursive call made.

We have now shown that each of Indec and Permute does a constant amount of work per permutation output (recall that NextJ runs in constant time), so the entire algorithm is CAT. □

5 Conclusions

We have given two CAT algorithms for generating indecomposable permutations: one generates them by selecting them efficiently in the Steinhaus-Johnson-Trotter algorithm, and one generates them in transposition Gray code order. The Gray code was developed by using a new parameterization of indecomposable permutations. The question of whether or not there is an adjacent transposition Gray code for these permutations remains open.

6 Acknowledgements

I would like to thank Frank Ruskey for presenting the problem to me and helping me along the way, and Joe Sawada for his helpful comments on CAT algorithms.

Generalized Pattern Avoidance with Additional Restrictions

Abstract. Babson and Steingrímsson introduced generalized permutation patterns that allow the requirement that two adjacent letters in a pattern must be adjacent in the permutation. We consider n-permutations that avoid the generalized pattern 1-32 and whose k rightmost letters form an increasing subword. The number of such permutations is a linear combination of Bell numbers. We find a bijection between these permutations and all partitions of an (n-1)-element set with one subset marked that satisfy certain additional conditions. Also we find the e.g.f. for the number of permutations that avoid a generalized 3-pattern with no dashes and whose k leftmost or k rightmost letters form either an increasing or decreasing subword. Moreover, we find a bijection between n-permutations that avoid the pattern 132 and begin with the pattern 12 and increasing rooted trimmed trees with n+1 nodes.

Abstract

These are partitions of $[l] = \{1, 2, \ldots, l\}$ into n blocks such that no four term subsequence of $[l]$ induces the mentioned pattern and each k consecutive numbers of $[l]$ fall into different blocks. These structures are motivated by Davenport-Schinzel sequences. We summarize and extend known enumerative results for the pattern $p = abab$ and give an explicit formula for the number $p(abab, n, l, k)$ of such partitions. Our main tool are generating functions. We determine the corresponding generating function for $p = abba$ and $k = 1, 2, 3$. For $k = 2$ there is a connection with the number of directed animals. We solve exactly two related extremal problems.

1 Introduction and notation

A *partition* P of $[l] = \{1, 2, \ldots, l\}$ is a collection $(B_1, B_2, \ldots, B_n)$ of nonempty disjoint subsets of $[l]$, called *blocks*, whose union is $[l]$ and which are listed in the increasing order of their least elements. We define $|P| = l$ and $\|P\| = n$. Empty partition is denoted by $\emptyset$. Any partition P can be written in the *canonical sequential form* $P = a_1 a_2 \ldots a_l$ where $i \in B_{a_i}$. One can use any set of n symbols to express P this way. We call it *sequential form* and we call the set of symbols *alphabet* of P. For instance, 123242151 is the canonical sequential form of $P_0 = (\{1, 7, 9\}, \{2, 4, 6\}, \{3\}, \{5\}, \{8\})$. One of possible sequential forms is *ctrtdtcwc*, the alphabet is $\{c, t, r, d, w\}$. We are interested in enumeration of pattern-free partitions and therefore we will use often the sequential form.

A partition P is *k-regular*, $k \geq 1$, if $x, y \in B_i, x > y$, implies $x - y \geq k$. In other words, each k or less consecutive elements in the sequence are mutually different. The partition P_0 is not 3-regular but is 2-regular. 1-regularity poses no restriction. We say that P is *abab-free* if $x, y \in B_i$ and $z, t \in B_j$ for no four numbers $x < z < y < t$ and two different blocks B_i, B_j. Similarly, P is *abba-free* if $x, y \in B_i$ and $z, t \in B_j$ for no four numbers $x < z < t < y$ and two different blocks. In other words, no four term subsequence of the type *abab*, resp. *abba*, is present. It is easy to check that P_0 above is *abab*-free but not *abba*-free.

Suppose $p = abab$ or $p = abba$. By $p(p, n, l, k)$ we denote the cardinality of the set $\mathcal{P}(p, n, l, k)$ of k-regular and p-free partitions of $[l]$ with n blocks. $P(p, k)$ stands for the bivariate generating function

$$P(p, k) = P(p, k)(x, y) = \sum_{n,l \geq 0} p(p, n, l, k) x^n y^l.$$

By $p(p, n, \cdot, k)$, resp. $\mathcal{P}(p, n, \cdot, k)$, we mean $\sum_{l \geq 0} p(p, n, l, k)$, resp. $\bigcup_{l \geq 0} \mathcal{P}(p, n, l, k)$. Similarly for n replaced by the dot. Obviously $p(p, n, \cdot, 1) = \infty$ but it is not difficult to see that $p(p, n, \cdot, k) < \infty$ for $k \geq 2$. We define, for $k \geq 2$ and $n \geq 0$, $Ex(p, n, k)$ to be the maximum l such that $\mathcal{P}(p, n, l, k)$ is nonempty.

The sets $\mathcal{P}(abab, n, l, 1)$ appeared first in Kreweras [11] under the name of *noncrossing partitions*. The sets $\mathcal{P}(abab, n, \cdot, 2)$ were introduced by Davenport and Schinzel [3] when they studied $Ex(abab, n, 2)$ as a special case of a more general extremal function. The function $Ex(abab, n, 2)$ is often denoted as $\lambda_2(n)$ and is a special case of maximum lengths of *Davenport-Schinzel sequences* (we determine $Ex(abab, n, k)$ in Theorem 2.2). What is $\lambda_3(n)$ then? $Ex(ababa, n, 2)$, this function is far more difficult to handle. See [7], [15], [1], and [8] for more information and referrences.

The next section contains strenghtenings and generalizations of several known enumerative results concerning $\mathcal{P}(abab, \cdot, \cdot, \cdot)$. We determine the generating function $P(abab, k)$ and use it to generalize in Theorem 2.5 an identity of Simion and Ullman and to derive a general explicit formula for $p(abab, n, l, k)$. Nice formulas for these numbers are summarized in Theorem 2.7. Various specializations lead to Catalan, Motzkin, Narayana, and Schröder numbers. In the third section we determine in Theorem 3.1 the function $Ex(abba, n, k)$ and in Theorem 3.5 we derive an identity for $P(abba, k)$. Then we proceed to determine $P(abba, k)$ for $k = 1, 2, 3$. A specialization leads to numbers of directed animals with one root. In the last section we pose several problems.

2 *abab*-free partitions

The set of k-regular partitions of length $< k - 1$ is simply $\mathcal{C}(k) = \{\emptyset, x_1, x_1 x_2, \ldots, x_1 x_2 \ldots x_{k-2}\}$. The symbol X^j means the cartesian product $X \times X \times \ldots \times X$ j times. Here $A \times \emptyset = A$. Consider the mapping

$$F : \bigcup_{j \geq 1} (\mathcal{P}(abab, \cdot, \cdot, k) \backslash \mathcal{C}(k))^{j-1} \times \mathcal{P}(abab, \cdot, \cdot, k) \to \mathcal{P}(abab, \cdot, \cdot, k) \backslash \{\emptyset\}$$

defined by $F(u_1, u_2, \ldots, u_j) = xu_1xu_2x \ldots xu_j$ where the partitions u_i are interpreted as sequences with disjoint alphabets and x is a completely new symbol. The following easy lemma is crucial for handling *abab*-free partitions.

Lemma 2.1 *F is a bijection and if $F(u_1, u_2, \ldots, u_j) = u$ then $\sum \|u_i\| = \|u\| - 1$ and $\sum |u_i| = |u| - j$.*

Proof. It is easy to see that F is defined correctly and preserves lengths and numbers of blocks in the stated manner. Take a $u \in \mathcal{P}(abab, \cdot, \cdot, k)$, $u \neq \emptyset$, and consider the unique decomposition $u = xu_1xu_2x \ldots xu_j$ given by the occurrences of the first symbol. Note that the alphabets of u_is are disjoint. Obviously $F(u_1, u_2, \ldots, u_j) = u$ and we see that F is bijective. □

The following theorem generalizes the result $Ex(abab, n, 2) = 2n - 1$ of Davenport and Schinzel [3].

Theorem 2.2 *Suppose $k \geq 2$. For $0 \leq n \leq k - 1$ we have $Ex(abab, n, k) = n$. For $n \geq k - 1$ we have $Ex(abab, n, k) = 2n - k + 1$ and, for $k \geq 3$, only one partition realizing this length:*

$$u(n, k) = a_1a_2 \ldots a_{n-k+1}b_1b_2 \ldots b_{k-1}a_{n-k+1}a_{n-k} \ldots a_2a_1.$$

Proof. The first equality is trivial. We prove the rest by induction on n. For $n = k - 1$ it is true. We show first $Ex(abab, n, k) \leq 2n - k + 1$. Suppose $n > k - 1$ and take a $u \in \mathcal{P}(abab, n, \cdot, k)$. If no symbol in u repeats we are done. Otherwise consider the shortest interval I in u starting and ending with the same symbol. Clearly $|I| \geq k + 1$ and, except for the end elements, no symbol in I repeats. The inner symbols of I cannot apppear elsewhere. Deleting the first two elements of I we get a partition v in $\mathcal{P}(abab, n - 1, \cdot, k)$. So $|u| = |v| + 2 \leq 2n - 2 - k + 1 + 2 = 2n - k + 1$ and we conclude that $Ex(abab, n, k) = 2n - k + 1$.

Now suppose, in addition, that u attains the maximum length. Consider the decomposition $u = xu_1xu_2x \ldots xu_j$ of Lemma 2.1. $j = 1$ is impossible for then x could be added to the end of u. So $j \geq 2$. If u_j is nonempty and has no repetition then it can be added before u in the opposite order. If u_j is nonempty and has a repetition then x again can be added to the end of u. So u_j is empty. If $j > 2$ we get a contradiction $|u| = \sum_{i=1}^{j-1} |xu_i| + 1 \leq \sum_{i=1}^{j-1} (2\|xu_i\| - k) + 1 = 2n + 2(j - 2) - (j - 1)k + 1 = 2n - (j - 1)(k - 2) - 1 < 2n - k + 1$. So $j = 2$ and $u_2 = \emptyset$. Applying the induction assumption on u_1 we conclude that $u = u(n, k)$. □

For $k = 2$ the longest partition is not unique, actually $p(abab, n, 2n - 1, 2) = \binom{2n-2}{n-1}/n$. This was proved first by Mullin and Stanton [12]. The following is both generalization and simplification of the argument of Gardy and Gouyou-Beauchamps [5] ($k = 2$).

Theorem 2.3 *For any $k \geq 1$,*

$$P(abab, k)(x, y) = \frac{1}{2y}\left(1 + y + yC(k) - xy - \sqrt{(1 + y + yC(k) - xy)^2 - 4y(1 + yC(k))}\right)$$

where $C(k) = C(k)(x, y) = 1 + xy + (xy)^2 + \ldots + (xy)^{k-2}$ ($C(2) = 1, C(1) = 0$) is the generating function for $\mathcal{C}(k)$.

Proof. Lemma 2.1 translates directly to generating functions:

$$P(abab, k) = 1 + x \sum_{j \geq 1} y^j (P(abab, k) - C(k))^{j-1} P(abab, k) = 1 + \frac{xyP(abab, k)}{1 + yC(k) - yP(abab, k)}.$$

Thus we have the quadratic equation $yP(abab, k)^2 - (1 + y + yC(k) - xy)P(abab, k) + 1 + yC(k) = 0$. Taking $P(abab, k)(0, 0) = 1$ into account we get the above solution. □

Some specializations of $P(abab,k)(x,y)$ generate standard sequences of numbers. Several special cases of $P(abab,k)(x,y)$ were also investigated before. Setting $k=1$ and $x=1$ we get the generating function $\frac{1}{2y}\left(1-\sqrt{1-4y}\right)$ of the sequence $\{p(abab,\cdot,l,1)\}_{l\geq 1}=\{1,2,5,14,42,132,429,\ldots\}$ of notorious *Catalan numbers*, A0108 in [E]. For $k=2$ and $y=1$ we get the generating function $\frac{1}{2}\left(3-x-\sqrt{1-6x+x^2}\right)$ of $\{p(abab,n,\cdot,2)\}_{n\geq 1}=\{1,2,6,22,90,394,1806,\ldots\}$. These are twice the *Schröder numbers*, A1003 in [E], which appeared first in [14]. The generating function $(P(abab,2)(x,1)-1+x)/2$ was derived in [12]. The specialization $k=2$ and $x=1$ yields $\frac{1}{2y}\left(1+y-\sqrt{1-2y-3y^2}\right)$ generating $\{p(abab,\cdot,l,2)\}_{l\geq 1}=\{1,1,2,4,9,21,51,\ldots\}$ which are *Motzkin numbers*, A1006 in [E], see [4]. For $k\geq 4$ the sequences $\{p(abab,n,\cdot,k)\}_{n\geq 1}$ seem new, for instance $\{p(abab,n,\cdot,4)\}_{n\geq 3}=\{1,2,5,13,35,97,275,\ldots\}$. For $k=3$ we get Catalan number once again. $\{p(abab,\cdot,l,k)\}_{l\geq 1}$ for $k\geq 3$ are not new, $\{p(abab,\cdot,l,3)\}_{l\geq 3}=\{1,2,4,8,17,37,82,\ldots\}$ is the sequence A4148 in [E]. These sequences were investigated in [17] by Stein and Waterman who, motivated by the secondary structure of the molecules of nucleic acids, introduced there the sets $\mathcal{P}(abab,\cdot,l,k)$. They mentioned without proof the result of C. J. Everett which we restate as the second half of the following theorem. We omit the proof as well.

Theorem 2.4

$$\lim_{k\to\infty}\lim_{n\to\infty}p(abab,n,\cdot,k)^{1/n}=\frac{3+\sqrt{5}}{2}\ \textit{and}\ \lim_{k\to\infty}\lim_{l\to\infty}p(abab,\cdot,l,k)^{1/l}=2.$$

The following theorem refines the identity of [16] where the version with two parameters k and l can be found (the proof there is combinatorial).

Theorem 2.5 *For any $n,l\geq 1$, $k\geq 2$, it is true that $p(abab,n,l,k)=p_{\leq 2}(abab,n-1,l-1,k-1)$. The subscript ≤ 2 means that we consider only the partitions with all blocks of size at most 2. Briefly, $xyP_{\leq 2}(abab,k-1)=P(abab,k)-1$.*

Proof. The generating function $P_{\leq 2}(abab,k)(x,y)$ is defined in the obvious manner. The relation for it differs from the one for $P(abab,k)$ only in that j may now attain only the values 1 and 2. So $P_{\leq 2}(abab,k)=1+x(yP_{\leq 2}(abab,k)+y^2(P_{\leq 2}(abab,k)-C(k))P_{\leq 2}(abab,k))$ and we get the equation $y(xyP_{\leq 2}(abab,k))^2-(1+xy^2C(k)-xy)(xyP_{\leq 2}(abab,k))+xy=0$. Thus

$$xyP_{\leq 2}(abab,k-1)(x,y)=\frac{1}{2y}\left(1+xy^2C(k-1)-xy-\sqrt{(1+xy^2C(k-1)-xy)^2-4xy^2}\right).$$

Taking $xy^2C(k-1)=yC(k)-y$ into account and comparing with the expression in Theorem 2.3 we get $xyP_{\leq 2}(abab,k-1)=P(abab,k)-1$. The identity is verified. □

Example

$$\mathcal{P}(abab,\cdot,5,2)=\{12345,12343,12342,12341,12324,12321,12314,12134,12131\}$$

and

$$\mathcal{P}_{\leq 2}(abab,\cdot,4,1)=\{1122,1123,1223,1233,1234,1221,1231,1232,1213\}.$$

To give an explicit formula for $p(abab,n,l,k)$ we need first to recall a well known bijection. It matches the elements of the sets $\mathcal{P}_{=2}(abab,n,2n,1)$ and $\mathcal{T}(n+1)$. Here $=2$ indicates partitions with all blocks of size 2 and $\mathcal{T}(n)$ is the set of all rooted plane trees with n vertices. Recursively: one vertex tree corresponds to $\emptyset$ and a general T corresponds to $x_1u_1x_1x_2u_2x_2\ldots x_ju_jx_j$ where u_i corresponds to the ith (counted from left) principal subtree of T and j is the degree of the root of T. The sequences u_i have disjoint alphabets and the symbols x_i are new and mutually different.

Recall that $|\mathcal{T}(n+1)| = c_n = \binom{2n}{n}/(n+1)$ is the nth Catalan number. Recall the formula

$$n(a,b) = n(a,a-b) = \frac{1}{a-b}\binom{a-1}{b}\binom{a-2}{b-1} = \frac{1}{a-1}\binom{a-1}{b}\binom{a-1}{b-1}$$

of Narayana [13] for the number of rooted plane trees with a vertices and b leaves.

Theorem 2.6 *For $k \geq 2$ and $n \leq l \leq \max(2n-k+1, n)$ we have*

$$p(abab, n, l, k) = \sum_{b=1}^{*} \frac{1}{l-n+1-b}\binom{l-n}{b}\binom{l-n-1}{b-1}\binom{l-1-b(k-2)}{2l-2n}$$

where $* = \min(l-n, \lfloor \frac{2n-l-1}{k-2} \rfloor)$ and the empty sum is equal to 1.

Proof. By Theorem 2.5 it is enough to count the number $p_{\leq 2}(abab, n-1, l-1, k-1)$ of partitions $u \in \mathcal{P}_{\leq 2}(abab, n-1, l-1, k-1)$. Each such u has $s = 2n-l-1$ singletons, symbols with one occurrence, and $d = l-n$ doubletons with two occurrences. The doubleton part of u corresponds, by the bijection, to a tree $T \in \mathcal{T}(d+1)$. By the $k-1$-regularity inside of each doubleton of u corresponding to a leaf of T there are at least $k-2$ singletons, in particular $b \leq (2n-l-1)/(k-2)$ for the number b of leaves of T. Besides this requirement singletons may be located arbitrarily in the $2d+1$ gaps of the doubleton part. The number of such u is therefore

$$\sum_{b=1}^{*} n(d+1,b)\binom{2d+1+s-b(k-2)-1}{s-b(k-2)}.$$

This is the general formula. □

In several instances one can give closed formulas.

Theorem 2.7 *For $n, l \geq 1$,*

$$p(abab, n, l, 1) = n(l+1, n) = \frac{1}{l-n+1}\binom{l}{n}\binom{l-1}{n-1},$$

$$p(abab, n, l, 2) = c_{l-n}\binom{l-1}{2l-2n} = \frac{1}{l-n+1}\binom{2l-2n}{l-n}\binom{l-1}{2l-2n},$$

$$p(abab, n, l, 3) = n(n, l-n+1) = \frac{1}{l-n+1}\binom{n-1}{2n-l-1}\binom{n-2}{2n-l-2}.$$

Thus $p(abab, n, l, 1) = p(abab, l-n+1, l, 1)$, $p(abab, n, l, 3) = p(abab, n, 3n-2-l, 3)$, $p(abab, n, l, 3) = p(abab, l-n+1, n-1, 1)$, and

$$p(abab, \cdot, n-1, 1) = p(abab, n, 2n-1, 2) = p(abab, n, \cdot, 3) = c_{n-1} = \frac{1}{n}\binom{2n-2}{n-1}.$$

Proof. The generating function for Narayana numbers $n(a,b)$ is

$$N(x,y) = \sum_{a,b \geq 1} n(a,b)x^a y^b = \frac{1-x+xy-\sqrt{(1-x+xy)^2-4xy}}{2}$$

where we put $n(1,1) = 1$. This formula can be easily derived by considerations similar to those in the proof of Theorem 2.3 and is well known. Consider the first three formulas. The formulas for $k = 1$ and $k = 3$ are consequences of the identities $P(abab, 1)(x,y) = N(y,x)/y - x + 1$ and $P(abab, 3)(x,y) =$

$N(xy,y)/y+1$ which can be readily checked. The formula for $k=2$ is a special case of Theorem 2.6 since for $k=2$

$$\sum_{b=1}^{*} n(d+1,b)\binom{2d+1+s-1}{s} = \binom{l-1}{s}\sum_{b=1}^{d} n(d+1,b) = \binom{l-1}{2l-2n}.c_d.$$

The remaining formulas follow from the symetry $n(a,b)=n(a,a-b)$ and from $\sum_b n(a,b)=c_{a-1}$. □

The formula for $p(abab,n,l,1)$ is contained implicitly already in the Narayana's result since one can prove it by an easy bijection matching partitions with trees. The formula for $p(abab,n,l,2)$ was derived in [5] directly extracting the coefficient from $P(abab,2)$. Although our counting relies on generating functions too, it indicates a bijective proof which is worked out in [9]. We have not seen the formula for $p(abab,n,l,3)$ before.

The closed formulas for $k=2,3$ are indicated by the presence of only small prime factors in the numbers $p(abab,n,l,k)$ when calculated by the general formula of Theorem 2.6. For $k\geq 4$ we get typicly factorizations as $p(abab,20,26,4)=2.13.330641$ or $p(abab,20,30,5)=5.31.2003$ which seems to exclude simple closed forms.

A sequence of numbers is called *unimodal* if it can be split into two parts, the initial one nondecreasing and the final one nonincreasing. The sequences $\{p(abab,n,l,1)\}_{n=1}^{l}$ and $\{p(abab,n,l,3)\}_{l=n}^{2n-2}$ are unimodal and symmetric. Examining the ratio $p(abab,n,l,2)/p(abab,n,l+1,2)$ one can prove easily that $\{p(abab,n,l,2)\}_{l=n}^{2n-1}$ is also unimodal and attains its maximum for $l=\lfloor n(1+\sqrt{1-1/n}/\sqrt{2})\rfloor$. Similarly, $\{p(abab,n,l,k)\}_{n=*}^{l}$, $*=\lceil (l+k-1)/2\rceil$, $k=2,3$, are unimodal for any $l\geq 2$.

Conjecture 2.8 *We conjecture that the sequences* $\{p(abab,n,l,k)\}_{l=n}^{2n-k+1}$ *and* $\{p(abab,n,l,k)\}_{n=*}^{l}$ *are unimodal for any* $n,l\geq k-1$ *and* $k\geq 2$.

3 *abba*-free partitions

Theorem 3.1 *Let* $k\geq 2$. *For* $1\leq n\leq k-1$ *again* $Ex(abba,n,k)=n$. *For* $n\geq k$ *we have* $Ex(abba,n,k)=2n+\lfloor\frac{n-1}{k-1}\rfloor-1$. *The longest partition is unique iff* $n-1$ *is divisible by* $k-1$. *In particular* $Ex(abba,n,2)=3n-2$ *and the longest partition*

$$1212323434545\ldots(n-1)n(n-1)n$$

is unique for any $n\geq 1$.

Proof. We prove first by induction on n the general upper bound. It is true for $n=k$ giving the value $2k$. Let $v\in\mathcal{P}(abba,n,\cdot,k)$ and $n>k$.

Claim 1 *One can suppose that no symbol appears in* v *more than three times.*

In the contrary case take four occurrences of a symbol a and consider the second and the third of them. A symbol $b\neq a$ must appear between them and b may have only one occurrence in v, for otherwise v is not *abba*-free. We delete the b-appearance plus possibly one a-appearance, the k-regularity is not violated. By induction $|v|\leq 2(n-1)+\lfloor\frac{n-2}{k-1}\rfloor-1+2\leq 2n+\lfloor\frac{n-1}{k-1}\rfloor-1$ and we are done in this case.

Let S_2 be the set of the symbols which appear in v at most twice and let S_3 consist of those appearing exactly three times. Let $|S_2|=n_2$ and $|S_3|=n_3$. Thus $n=n_2+n_3$.

Claim 2 $n_3(2k-4)+2\leq 2n_2-2(k-1)$

By a 3-*interval* we mean an interval I in v which begins and ends with an a-occurrence and which has one a-occurrence inside. There are n_3 3-intervals, one for each $a\in S_3$, no two of them are comparable by inclusion and no three of them intersect.

For any 3-interval I corresponding to an $a\in S_3$ there are at least $2k-2$ distinct symbols appearing in I which are distinct to a. Only at most 2 of those symbols can belong to S_3 and hence any I contributes

by at least $2k-4$ elements to S_2. On the other hand any $x \in S_2$ can appear only in at most two 3-intervals. This gives roughly the inequality in Claim 2, the corrections $+2$ and $-2(k-1)$ are caused by the first and by the last 3-interval — each contributes by at least $2k-3$ elements to S_2 and for each there are at least $k-1$ elements of S_2 which appear only in it.

Therefore $n_2 \geq n_3(k-2)+k = (n-n_2)(k-2)+k$ and $n_2 \geq n - \frac{n-1}{k-1} + 1$. Finally,

$$|v| \leq 3n_3 + 2n_2 = 3n - n_2 \leq 2n + \frac{n-1}{k-1} - 1.$$

To prove that this cannot be improved we express $n \geq k$ in the form $n-1 = m(k-1)+i, 0 \leq i < k-1$, and we consider the sequence (partition) $v(n,k) = B_1 B_2 \dots B_{m-1} B_m$ where the jth segment B_j, $1 \leq j \leq m-1$, is of the form

$$B_j = j\ x_1^j x_2^j \dots x_{k-2}^j\ (j+1)j\ x_1^j x_2^j \dots x_{k-2}^j$$

and the mth segment is of the form

$$B_m = m\ x_1^m \dots x_{k-2}^m\ (m+1)m\ y_1 y_2 \dots y_i x_1^m \dots x_{k-2}^m\ (m+1) y_1 y_2 \dots y_i.$$

The n element alphabet here is

$$\{1, 2, \dots, m+1, y_1, y_2, \dots, y_i\} \cup \{x_q^p \mid p = 1 \dots m, q = 1 \dots k-2\}.$$

An easy check reveals that the k-regular $v(n,k)$ is $abba$-free and that the length of v is

$$m(2k-1) + 2i + 1 = 2(n-1) + m + 1 = 2n + \lfloor \frac{n-1}{k-1} \rfloor - 1.$$

Thus $Ex(abba, n, k) = 2n + \lfloor \frac{n-1}{k-1} \rfloor - 1$. If $i > 0$ then the symbols $y_1, \dots, y_i$ can be placed in $v(n,k)$ differently than it is indicated above and we get several longest partitions.

It remains to prove that for $n-1$ divisible by $k-1$ there is no other longest partition than $v(n,k)$. For $n = k$ this is true. Let $n-1 > k-1$ be divisible by $k-1$ and let $u \in \mathcal{P}(abba, n, \cdot, k)$ be of the maximum length and in the canonical form. Since the length is maximum we have only symbols appearing two times or three times and no singletons. The sequence u starts with $u = 12 \dots k \dots$ and each of the symbols $1, 2, \dots, k-1$ appears in u only twice, in the contrary case we would have singletons. Thus $u = 12 \dots k-1\ k \dots 1 \dots 2 \dots$. The second 1 must follow immediately after k, in the contrary case we could delete 1's without violating k-regularity and get a sequence longer than $Ex(abba, n-1, k)$. The case $u = 12 \dots k1x \dots 2 \dots$ reduces by the switching $u = 12 \dots kx1 \dots 2 \dots$ to the previous case. So $u = 123 \dots k123 \dots k \dots$. Now k must appear three times for otherwise by deleting the initial segment of length $2k$ we would decrese n by k but l only by $2k$. Deleting the intial segment of length $2k-1$ and applying the induction assumption on the rest we conclude that $u = v(n,k)$. □

To enumerate the sets $\mathcal{P}(abba, n, l, k)$ we start with definitions and with an analogy of Lemma 2.1. Again, the subscript ≤ 2 indicates partitions with no block of size 3 or more. The set $\mathcal{I}(k)$ (resp. $\mathcal{E}(k)$) of *initial segments* (resp. *end segments*) consists of all partitions u where $u \in \mathcal{P}_{\leq 2}(abba, \cdot, \cdot, k)$ and the last (resp. the first) element of u is a doubleton. *Middle segments* $\mathcal{M}(k)$ are partitions $u \in \mathcal{P}_{\leq 2}(abba, \cdot, \cdot, k)$ such that the first and the last elements of u differ and are doubletons. Finally, *simple segments* $\mathcal{S}(k)$ are k-regular partitions u beginning and ending with a in which no symbol, except for a, repeats. Consider the mapping

$$G : \mathcal{I}(k) \times \mathcal{S}(k) \times \bigcup_{j \geq 1} (\mathcal{M}(k) \times \mathcal{S}(k))^{j-1} \times \mathcal{E}(k) \to \mathcal{P}(abba, \cdot, \cdot, k) \backslash \mathcal{P}_{\leq 2}(abba, \cdot, \cdot, k)$$

defined by $G(u_1, u_2, \dots, u_{2j+1}) = u = u_1 u_2 \dots u_{2j+1}+$ identification. This means that u_is are concatenated as sequences with disjoint alphabets and then the neighboring end elements of these segments are identified.

Lemma 3.2 *G is a bijection and $\sum |u_i| = |u| + 2j$, $\sum \|u_i\| = \|u\| + 2j$.*

Proof. The mapping G is defined correctly and preserves lengths and numbers of symbols in the stated manner. Take a $u \in \mathcal{P}(abba, \cdot, \cdot, k) \backslash \mathcal{P}_{\leq 2}(abba, \cdot, \cdot, k)$. Consider the splitting $u = v_1 a v_2 a \dots a v_m, m \geq 4$, of u by the occurrences of the first symbol a which appears more than twice. Obviously $v_1 a v_2 a \in \mathcal{I}(k)$ and $a v_3 a \dots a v_{m-2} a \in \mathcal{S}(k)$. If in $a v_{m-1} a v_m$ no symbol appears more than twice we are done since then $a v_{m-1} a v_m \in \mathcal{E}(k)$. Otherwise let $a v_{m-1} a v_m = a w_1 b w_2 b \dots b w_r$ be the splitting where b is the first symbol appearing $r \geq 3$ times and w_1 contains one a-appearance and one b-appearance. Then $a w_1 b \in \mathcal{M}(k)$ and $b w_2 b \dots b w_{r-2} b \in \mathcal{S}(k)$. Now we are left with the last segment $b w_{r-1} b w_r$. Continuing this way until the last segment falls into $\mathcal{P}_{\leq 2}(abba, \cdot, \cdot, k)$ we get a unique decomposition of u into segments. These segments have disjoint alphabets, except for the symbols $a, b, \dots$, and decompose u as described in the definition of G. Therefore G is bijective. □

We introduce the generating functions $S(k)(x,y)$, $I(k)(x,y)$, $E(k)(x,y)$, and $M(k)(x,y)$ which count the numbers of simple segments, initial segments, end segments, and middle segments with a given length and number of blocks, respectively. Clearly $I(k) = E(k)$.

Lemma 3.3 *For any $k \geq 1$,*

$$P(abba, k) = \frac{I^2(k) S(k)}{x^2 y^2 - M(k) S(k)} + P_{\leq 2}(abba, k).$$

Proof. Translating the decomposition Lemma 3.2 we get

$$P(abba, k) = P_{\leq 2}(abba, k) + I(k) S(k) [\sum_{j \geq 1} (M(k) S(k))^{j-1} (xy)^{-2j}] I(k).$$

The rest is a routine simplification using the geometric series formula. □

Lemma 3.4 *For any $k \geq 1$,*

1. $S(k)(x,y) = \frac{xy(1-xy)}{1-xy-y(xy)^{k-1}}$.
2. $I(k)(x,y) = E(k)(x,y) = (1-xy) P_{\leq 2}(abba, k)(x,y) - 1$.
3. $M(k)(x,y) = (1-xy)^2 P_{\leq 2}(abba, k)(x,y) - \frac{y(xy)^k}{1-xy} - 1 + xy$.

Proof. To build up a simple segment means to take a sequence of $m \geq 1$ a's, to put $k-1$ (mutually different) singletons into each of the $m-1$ gaps and then to add $r \geq 0$ new singletons into these gaps. Hence

$$S(k) = \sum_{m \geq 1} x y^m (xy)^{(m-1)(k-1)} \sum_{r \geq 0} \binom{m-1+r-1}{r} (xy)^r.$$

The inner sum equals, by a well known identity, $1/(1-xy)^{m-1}$. Using the geometric series formula we get the expression.

The number of initial segments of length l with n blocks equals to $p_{\leq 2}(abba, n, l, k) - p_{\leq 2}(abba, n-1, l-1, k)$, we are subtracting the partitions ending with a singleton. We have to subtract also the empty partition.

Similarly, the number of middle segments of length l with n blocks is $p_{\leq 2}(abba, n, l, k) - 2p_{\leq 2}(abba, n-1, l-1, k) + p_{\leq 2}(abba, n-2, l-2, k) - 1$ (modulo some adjustment for very small numbers n, l) which corresponds to the subtraction of the partitions beginning or ending with a singleton and the only partition beginning and ending with the same symbol. □

Putting it all together we get the following unexpected result.

Theorem 3.5 *For any $k \geq 1$,*

$$P(abba, k) = \frac{(1-2xy)P_{\leq 2}(abba, k) - 1}{(1-xy)^2 P_{\leq 2}(abba, k) - 1}.$$

Proof. Just substitute the expressions from Lemma 3.4 into the equation of Lemma 3.3. The terms with k will disappear during simplifications. □

It is surprising that the relation between $P_{\leq 2}(abba, k)$ and $P(abba, k)$ is independent on k. Theorem 3.5 is a counterpart of the relation $xyP_{\leq 2}(abab, k-1) = P(abab, k) - 1$ of Theorem 2.5.

We proceed to determine the functions $P_{\leq 2}(abba, k)$ and $P(abba, k)$ for $k = 1, 2, 3$. We know $P_{\leq 2}(abba, 1)$ already:

Lemma 3.6

$$P_{\leq 2}(abba, 1) = P_{\leq 2}(abab, 1) = \frac{P(abab, 2) - 1}{xy} = \frac{1 - xy - \sqrt{(1-xy)^2 - 4xy^2}}{2xy^2}.$$

Proof. The ultimate equality is a consequence of Theorem 2.3 and the penultimate equality is an instance of Theorem 2.5. We show by a simple bijection that $p_{\leq 2}(abba, n, l, 1) = p_{\leq 2}(abab, n, l, 1)$ for any $n, l \geq 0$ which proves the first equality.

We start with a bijection between $\mathcal{P}_{=2}(abba, n, 2n, 1)$ and $\mathcal{T}(n+1)$. Empty sequence is represented by a single vertex. Let $u \in \mathcal{P}_{=2}(abba, n, 2n, 1)$. The root of the tree T representing u will have degree m where $v = 12 \ldots m$, $u = vw$, is the maximal initial interval of u without repetitions. Consider the same decomposition $u' = v'w'$, $v' = m+1 \ldots m+r$, of the sequence u' that arises from u by deleting the $2m$ appearances of $1, \ldots, m$. Note that w starts with 1 and decomposes into $w = 1w_1 2w_2 \ldots mw_m$.

T is defined as follows. Suppose that the tree U representing u' has the principal subtrees, from left to right, $U_1, U_2, \ldots, U_r$, with roots $r(1), r(2), \ldots, r(r)$. Let $|v' \cap w_i| = l_i$, $l_1 + \ldots + l_m = r$, and let $l_0 = 0$. We delete the root of U and we join the l_j vertices $r(l_0 + \ldots + l_{j-1} + 1), \ldots, r(l_0 + \ldots + l_{j-1} + l_j)$, $j = 1, 2, \ldots, m$, to a new vertex v_j. Finally, we join the vertices v_j to a common vertex, the root of T. It is not difficult to check that this is indeed a bijection.

Now it is easy to give a bijection between $\mathcal{P}_{\leq 2}(abba, n, l, 1)$ and $\mathcal{P}_{\leq 2}(abab, n, l, 1)$. Let u lie in the former set. Consider the doubleton part of u and the tree T corresponding to it by the bijection we have just described. Replace the doubleton part by the sequence $v \in \mathcal{P}_{=2}(abab, \cdot, \cdot, 1)$ corresponding to T by the bijection described before Theorem 2.6. □

Theorem 3.7

$$P(abba, 1) = \frac{(1-xy)^2 - y - x^2y^3 P_{\leq 2}(abab, 1)}{(1-xy)^3 - y} = \frac{2 - 2y - 5xy + 3x^2y^2 + xy\sqrt{(1-xy)^2 - 4xy^2}}{2(1-xy)^3 - 2y}$$

$$P(abba, 1)(1, y) = \frac{1 - 3y + y^2 - y^3 P_{\leq 2}(abab, 1)(1, y)}{1 - 4y + 3y^2 - y^3} = \frac{-2 + 7y - 3y^2 - y\sqrt{1 - 2y - 3y^2}}{-2 + 8y - 6y^2 + 2y^3}$$

Proof. By the proof of Theorem 2.5 and by the previous lemma, the function $P_{\leq 2}(abba, 1)$ satisfies the quadratic equation $xy^2P^2 + (xy-1)P + 1 = 0$. Thus the identity

$$((1-xy)^2 P - 1)\left(P\ \frac{xy^2}{(1-xy)^2} + \frac{xy^2}{(1-xy)^4} + \frac{1}{xy-1}\right) = -1 - \frac{1}{xy-1} - \frac{xy^2}{(1-xy)^4}$$

by which we rationalize the denominator of the expression in Theorem 3.5. Simplifying and substituting the explicit form of $P_{\leq 2}(abba, 1)$ we get the final result. The second formula arises by specialization. □

$P(abba, 1)(1, y)$ generates the sequence $\{p(abba, \cdot, l, 1)\}_{l \geq 1} = \{1, 2, 5, 14, 41, 123, 374, \ldots\}$ which seems new.

Lemma 3.8

$$P_{\leq 2}(abba, 2) = \frac{P_{\leq 2}(abba, 1) + 1}{2 + xy^2 - xy}$$

Proof. Take a $u \in \mathcal{P}_{\leq 2}(abba, \cdot, \cdot, 1) \backslash \mathcal{P}_{\leq 2}(abba, \cdot, \cdot, 2)$ and consider the first violation of the 2-regularity $u = vaaw$. Thus $v \in \mathcal{P}_{\leq 2}(abba, \cdot, \cdot, 2)$ and v and w have disjoint alphabets. Translated to generating functions, $P_{\leq 2}(abba, 1) = P_{\leq 2}(abba, 2).xy^2.P_{\leq 2}(abba, 1) + P_{\leq 2}(abba, 2)$. The solution for $P_{\leq 2}(abba, 2)$ is

$$P_{\leq 2}(abba, 2) = \frac{P_{\leq 2}(abba, 1)}{xy^2 P_{\leq 2}(abba, 1) + 1}.$$

Rationalizing the denominator as in the proof of Theorem 3.7 we get the desired relation. □

Setting $y = 1$ in the previous lemma we get the following identity.

Consequence 3.9 *For any $n \geq 1$ it is true that $p_{\leq 2}(abba, n, \cdot, 2) = p_{\leq 2}(abba, n, \cdot, -2)$. The minus sign indicates partitions which are* not *2-regular.*

Example

$$\mathcal{P}_{\leq 2}(abba, 3, \cdot, 2) = \{123, 1213, 12123, 12132, 121323, 1231, 1232, 12312, 12313, 123123, 12323\}$$

and

$$\mathcal{P}_{\leq 2}(abba, 3, \cdot, -2) = \{1123, 1223, 1233, 11233, 12233, 11223, 112233, 12133, 121233, 11232, 112323\}.$$

Theorem 3.10

$$P(abba, 2) = \frac{1 - x(2y + 3y^2 + y^3) + x^2(y^2 + y^3) - x^2y^3 P_{\leq 2}(abab, 1)}{1 - x(3y + 3y^2 + y^3) + x^2(3y^2 + 2y^3) - x^3y^3}$$

$$P(abba, 2)(1, y) = \frac{1 - 2y - 2y^2 - y^3 P_{\leq 2}(abab, 1)(1, y)}{1 - 3y}$$

$$P(abba, 2)(x, 1) = \frac{1 - 6x + 2x^2 - x^2 P_{\leq 2}(abab, 1)(x, 1)}{1 - 7x + 5x^2 - x^3}$$

Proof. The expression for $P_{\leq 2}(abba, 2)$ from the previous lemma is substituted in the formula of Theorem 3.5. The denominator of the resulted fraction is rationalized as in Theorem 3.7. Specializations lead to the other two formulas. □

The function $P(abba, 2)(x, 1)$ generates $\{p(abba, n, \cdot, 2)\}_{n \geq 1} = \{1, 3, 15, 85, 501, 3007, 18235, \ldots\}$ which seems new. The sequence $\{p(abba, \cdot, l, 2)\}_{l \geq 2} = \{1, 2, 5, 13, 35, 96, 267, \ldots\}$ generated by $P(abba, 2)(1, y)$ is the sequence A5773 in [E]. Recall that a *directed animal with one root* is a finite set X of lattice points in the plane containing the origin and such that each point of X can be reached from the origin by a path lying completely in X and making only east or north unit steps. For more details consult [6].

Consequence 3.11 *For any $l \geq 2$ it is true that $p(abba, \cdot, l, 2)$ is the same as the number of directed animals with one root and $l - 1$ points.*

Proof. Simplifying the formula for $P(abba,2)(1,y)$ further we get a compact expression

$$P(abba,2)(1,y) = 1 + \frac{y}{2}\ \left(1 + \sqrt{\frac{1+y}{1-3y}}\right)$$

which equals $yQ + 1 + y$ where Q is the generating function for directed animals with one root, see [6]. □

Lemma 3.12

$$P_{\leq 2}(abba,3) = \frac{P_{\leq 2}(abba,2)}{(1-xy^2)^2 + xy^2(2 - xy + x^2y^3 - x^2y^4)P_{\leq 2}(abba,2)}$$

Proof. The idea is the same as in Lemma 3.8. Take a $u \in \mathcal{P}_{\leq 2}(abba,\cdot,\cdot,2)\backslash\mathcal{P}_{\leq 2}(abba,\cdot,\cdot,3)$ and consider the first violation of the 3-regularity by $u = vabaw$. Thus $v \in \mathcal{P}_{\leq 2}(abba,\cdot,\cdot,3)$ and v and w have disjoint alphabets. Now we have to distinguish three possibilities. For the sake of brevity we use P for $P_{\leq 2}(abba,3)$ and Q for $P_{\leq 2}(abba,2)$.

1) b is a singleton. The number of such u is counted by the coefficient in Px^2y^3Q.

2) b appears once more in w. The number of such u is counted by the coefficient in $P(x^2y^4Q + xy^2E(2))$. The first term counts the u's with the structure $u = vababw'$. If the second b does not follow immediately after the second a then bw is an end segment (see the beginning of Section 3) and such u's are counted by the second term.

3) b appears in v. Consider the interval I spanned by the two b appearances. Clearly $|I| \geq 4$. In the case $|I| > 4$ we are done as well as in the case when $|I| = 4$ but the other symbol in I different from a, say c, is a singleton. The bad situation is when $u = v'bcabaw$ and c appears in v'. Then consider the interval J spanned by the two c's. The bad situation is when $u = v''cdbcabaw$ and d appears in v''. Continuing this way we get a unique decomposition $u = v^*a_1sa_2a_1a_3a_2a_4a_3 \ldots abaw$ where either $|s| \geq 2$ or s is a singleton. In the former case $v^*a_1sa_1$ is an initial segment in $\mathcal{I}(3)$ and such u's are accounted for in $I(3)[\sum_{m\geq 1}(xy^2)^m]Q$. In the latter case we have the splitting $v^*\ a_1sa_2a_1a_3a_2a_4a_3 \ldots aba\ w$ of u into three segments with disjoint alphabets and so we account for such u in $P[\sum_{m\geq 2}(xy^2)^m]xyQ$.

We have the equation $Q = P[1 + x^2y^3Q + x^2y^4Q + xy^2(1-xy)Q - xy^2 + \frac{x^3y^5}{1-xy^2}Q + (1-xy)\frac{xy^2}{1-xy^2}Q] - \frac{xy^2}{1-xy^2}Q$ which solves for P by the stated formula. □

Theorem 3.13

$$P(abba,3) =$$

$$\frac{1 - x(2y+4y^2) + x^2(y^2+2y^4-y^5) + x^3(y^4-y^5+2y^7) - x^4(y^7-y^8+y^9) - (x^2y^3 - 2x^3y^5 + x^4y^7)F}{1 - x(3y+4y^2) + x^2(3y^2+3y^3+2y^4-y^5) - x^3(y^3+3y^5-2y^7) + x^4(y^6-y^7+y^8-y^9)}$$

where $F = P_{\leq 2}(abab,1) = (1 - xy - \sqrt{(1-xy)^2 - 4xy^2})/2xy^2$. *The specializations are*

$$P(abba,3)(x,1) = \frac{1 - 6x + 2x^2 + 2x^3 - x^4 - (x^2 - 2x^3 + x^4)P_{\leq 2}(abab,1)(x,1)}{1 - 7x + 7x^2 - 2x^3}\ \textit{and}$$

$$P(abba,3)(1,y) = \frac{1 - 2y - 3y^2 + 3y^4 - 2y^5 + y^7 + y^8 - y^9 - (y^3 - 2y^5 + y^7)P_{\leq 2}(abab,1)(1,y)}{1 - 3y - y^2 + 2y^3 + 2y^4 - 4y^5 + y^6 + y^7 + y^8 - y^9}$$

Proof. This is again only a manipulation with rational functions. First we substitute in the expression of Lemma 3.12 the formula for $P_{\leq 2}(abba,2)$ from Lemma 3.8 and express this way $P_{\leq 2}(abba,3)$ in terms of $P_{\leq 2}(abab,1)$:

$$P_{\leq 2}(abba,3) = \frac{m_1(x,y) + m_2(x,y)P_{\leq 2}(abab,1)}{m_3(x,y) + m_4(x,y)P_{\leq 2}(abab,1)}$$

where $m_1(x,y) = 1 + xy - xy^2 + x^2y^3$, $m_2(x,y) = -1 + 2xy + 2xy^2 - x^2y^3 + x^3y^5 - x^3y^6$, $m_3(x,y) = m_1(x,y) - x^2y^2$, and $m_4(x,y) = m_2(x,y) - x^2y^2$. Rationalizing the denominator we get the stated formula. □

The first specialization generates the sequence $\{p(abba, n, \cdot, 3)\}_{n\geq 2} = \{1, 4, 19, 95, 448, 2553, 13537, \ldots\}$ and the second one the sequence $\{p(abba, \cdot, l, 3)\}_{l\geq 3} = \{1, 2, 5, 14, 38, 102, 276, \ldots\}$, both of them seem new. Now we list the beginnings of the expansions of the functions $P(abba, k)(x, y)$ for $k = 1, 2, 3$.

$$P(abba,1)(x,y) = 1 + xy + (x+x^2)y^2 + (x+3x^2+x^3)y^3 + (x+6x^2+6x^3+x^4)y^4 +$$
$$+(x+9x^2+20x^3+10x^4+x^5)y^5 + (x+12x^2+44x^3+50x^4+15x^5+x^6)y^6 +$$
$$+(x+15x^2+77x^3+154x^4+105x^5+21x^6+x^7)y^7 + (x+18x^2+119x^3+350x^4+434x^5+196x^6+28x^7+x^8)y^8 +$$
$$+(x+21x^2+170x^3+663x^4+1260x^5+1050x^6+336x^7+36x^8+x^9)y^9 +$$
$$+(x+24x^2+230x^3+1120x^4+2907x^5+3822x^6+2268x^7+540x^8+45x^9+x^{10})y^{10} + \ldots$$

$$P(abba,2)(x,y) = 1 + yx + (y^2+y^3+y^4)x^2 + (y^3+3y^4+6y^5+4y^6+y^7)x^3 + (y^4+6y^5+20y^6+29y^7 +$$
$$+21y^8+7y^9+y^{10})x^4 + (y^5+10y^6+50y^7+119y^8+154y^9+111y^{10}+45y^{11}+10y^{12}+y^{13})x^5 +$$
$$+(y^6+15y^7+105y^8+364y^9+714y^{10}+837y^{11}+605y^{12}+274y^{13}+78y^{14}+13y^{15}+y^{16})x^6 +$$
$$+(y^7+21y^8+196y^9+924y^{10}+2520y^{11}+4257y^{12}+4642y^{13} +$$
$$+3354y^{14}+1638y^{15}+545y^{16}+120y^{17}+16y^{18}+y^{19})x^7 + \ldots$$

$$P(abba,3)(x,y) = 1 + yx + y^2x^2 + (y^3+y^4+y^5+y^6)x^3 + (y^4+3y^5+6y^6+7y^7+2y^8)x^4 +$$
$$+(y^5+6y^6+20y^7+34y^8+25y^9+8y^{10}+y^{11})x^5 + (y^6+10y^7+50y^8+124y^9+157y^{10}+106y^{11}+36y^{12}$$
$$+4y^{13})x^6 + (y^7+15y^8+105y^9+364y^{10}+687y^{11}+748y^{12}+465y^{13}+148y^{14}+19y^{15}+y^{16})x^7 + \ldots$$

4 Concluding remarks

We demonstrated in the paper that the structure $\mathcal{P}(p, n, l, k)$ leads to interesting extremal and enumerative results, we emphasized here the latter. Our solution for the pattern $p = abba$ is not completely satisfactory since we gave the explicit formula for $P(abba, k)$ only for the first three values of k.

Problem 1 What can be said about the generating function $P(abba, k)(x, y)$ for $k \geq 4$?

A field for exploration opens when one tries other patterns p. Methods yielding strong upper bounds on $Ex(p, n, k)$ were developed in [8], [10] but we do not know many nontrivial exact values of this function.

Problem 2 What is $Ex(abcabc, n, k), k \geq 3$? It is not too difficult to give the upper bound $6n$ on $Ex(abcabc, n, 3)$ but we do not know the exact value. What can be said about the numbers $p(abcabc, n, l, k)$?

Consider the pattern *ababa*. It contains three appearances of a, thus each partition from $\mathcal{P}_{\leq 2}(\cdot,\cdot,\cdot)$ avoids it. In consequence the numbers $p(ababa,\cdot,l,k)$ and $p(ababa,n,\cdot,k)$ grow superexponentially for any fixed k and exponential rather than ordinary generating function is in place. The function $Ex(ababa,n,2)$ grows superlinearly (see [7]) and it seems very difficult to describe completely the structure of *ababa*-free sequences. Any enumerative result concerning $p = ababa$ would be of great interest.

Problem 3 What can be said about the numbers $p(ababa,n,l,k,)$?

We omitted here the first order asymptotics of the numbers $p(p,n,\cdot,k)$ and $p(p,\cdot,l,k)$, $p = abab, abba$. Knowing the explicit form of the generating function, the asymptotics can be found more or less routinely by methods described in [2]. The reader may wish to consult [17] where the asymptotics of the numbers $p(abab,\cdot,l,k)$, $k = 1,2,3$ is worked out this way.

Acknowledgments The work on this paper was done during the author's stay as a TA in the Department of Mathematics of Arizona State University, Tempe. I want to thank for the possibility to use the computer and other facilities. I thank prof. H. Kierstead for his support during my stay. Last but not least, the phenomenal database [E] of N. J. A. Sloane was very helpful.

Abstract

The average number of (1) antichains, (2) maximal antichains, (3) chains, (4) infima closed sets, (5) connected sets, (6) independent sets, (7) maximal independent sets, (8) brooms, (9) matchings, (10) maximal matchings, (11) linear extensions, and (12) drawings in (of) a rooted plane tree on n vertices is investigated. Using generating functions we determine the asymptotics and give some explicit formulae and identities. In conclusion we discuss the extremal values of the above quantities and pose some problems.

1 Rooted plane trees

A *rooted plane tree*, a classical enumerative structure, is a quadruple $T = (r, V, E, L)$ such that

- (V, E) is a nonempty finite directed tree, as usual V is the *vertex set* and E is the *edge set*,
- where all edges are directed away from the *root* $r \in V$,
- and $L = \{(\{w : \ vw \in E\}, <_v) : \ v \in V\}$ is a collection of $|V|$ linear orders.

We call the elements of the set $ch(v) = \{w : \ vw \in E\}$ *children* of v, v is their *parent*. A *leaf* is a vertex with no child. Rooted plane trees will be called shortly *trees*. A tree T is visualized by embedding it in the plane (see Figure 1) so that the root is at the lowest position, all edges are straight segments directed up, and the orders $<_v$ coincide with the natural left-right order.

By $\mathcal{T}$ we denote the collection of all substantially different trees and by $\mathcal{T}_n$ the collection of those having n vertices. The aim of the paper is, given a *weight* $w : \mathcal{T} \to \{0, 1, 2, \ldots\}$, to count the total weight $w(n) = \sum_{T \in \mathcal{T}_n} w(T)$ of trees on n vertices. We consider twelve combinatorial weights w and for the first ten of them we determine the *generating function*

$$F_w(x) = \sum_{\mathcal{T}} w(T) x^{|V(T)|} = \sum_{n \geq 1} w(n) x^n.$$

For the eleventh and twelfth weight n stands for $|E|$ and the *exponential generating function* will be determined.

For instance, setting $w(T) = 1$ for all T one gets the celebrated *Catalan function*

$$C = C(x) = \sum_{n \geq 1} |\mathcal{T}_n| x^n = \sum_{n \geq 1} c_{n-1} x^n = \frac{1}{2} \left(1 - \sqrt{1 - 4x}\right) = x + x^2 + 2x^3 + 5x^4 + 14x^5 + 42x^6 + \ldots$$

counting the number of trees on n vertices. $c_n = \frac{1}{n+1}\binom{2n}{n}$ is the nth *Catalan number*. Catalan function satisfies the quadratic equation $C^2 - C + x = 0$.

What are the weights? Mostly the numbers of subsets of V or E with special properties. The first four of them appear by understanding a tree T as a poset. The standard partial ordering $(V, \leq)$ is defined by $u \leq v$ iff u lies on the path joining r and v. A *chain* in T is then a subset $X \subset V$ of pairwise comparable vertices. On the contrary an *antichain* X consists of mutually incomparable vertices. A tree with n vertices may have as many as $2^n - 1$ nonempty chains and as few as $2n - 1$. As for the antichains, there may be as few as n and as many as 2^{n-1} of them. These are extremes but what is going on in average? One would expect that in average antichains are much more numerous than chains, is this really the case? How fast the average numbers grow? Seeking answers to this sort of questions and led by the joy of counting by generating functions we investigated twelve weights of this kind. Our arguments are more or less standard but, except for w_8 and w_{11} which we discuss later, we failed to find any reference to results of this type in [5], [8], and [12], or to localize the sequences $\{w(n)\}_{n\geq 1}$ in [11].

We need to review some more definitions. We say that $X \subset V$ is *infima closed* (in a tree T) if X contains with any two vertices $u, v \in X$ also the merging point of the paths joining r and u, and r and v (i.e., the infimum $u \wedge v$). Six weights arise from graph-theoretical considerations. A set $X \subset V$ is *independent* if $uv \in E$ for no two $u, v \in X$. A set $X \subset V$ is *connected* if any two vertices of X can be joined by an undirected path lying completely in X. A *matching* $X \subset E$ is a set of pairwise disjoint edges. A *broom* $X \subset E$ is a set of pairwise intersecting edges, all directed up. Single vertex is also a broom. Two more weights arise from the concept of drawing trees. Suppose $T = (r, V, E, L)$ is a tree. A *simple drawing* of T is a permutation of edges $(e_1, e_2, \ldots, e_{|E|})$ of T such that $r \in e_1$ and, for any $i = 2, \ldots, |E|$, e_i intersects some of the edges $e_1, e_2, \ldots, e_{i-1}$. A *drawing* of T is a sequence of trees $(T_1, T_2, \ldots, T_n)$, $n = |V|$, such that $T_n = T$ and T_{i-1} arises from T_i by deleting a leaf of T_i.

Now we list the weights. Maximality is meant to inclusion and maximal sets are nonempty by definition. For a given tree T, $w_1(T)$ is the number of nonempty antichains in T, $w_2(T)$ is the number of maximal antichains, $w_3(T)$ is the number of nonempty chains, $w_4(T)$ counts the number of nonempty infima closed sets, $w_5(T)$ counts nonempty connected sets, $w_6(T)$ counts all independent sets (including $\emptyset$), $w_7(T)$ counts maximal independent sets, $w_8(T)$ counts the number of brooms in T, $w_9(T)$ counts matchings (including $\emptyset$), $w_{10}(T)$ counts maximal matchings, $w_{11}(T)$ is the number of simple drawings of T, and $w_{12}(T)$ is the number of drawings of T.

The paper is organized as follows. In the next section we summarize the results — explicit formulae or equations for generating functions, asymptotics — for the first ten weights. In Section 3 we give proofs or sketches of proofs to these results. Applications of the Lagrange inversion formula to the weights w_6, w_7, and w_9 are given in Section 4. In particular, we derive a closed formula for $w_6(n)$. Weights w_{11} and w_{12} are handled in Section 5. In Section 6 we give some concluding comments and open problems, and we determine $\max_{T\in\mathcal{T}_n} w_2(T)$.

2 Subset countings — results

First we list the closed formulae for the generating functions F_1, F_2, F_3, F_4, F_5, and F_8, $F_i(x) = \sum_{n\geq 1} w_i(n)x^n$.

$$F_1(x) = \frac{1 + \sqrt{1-4x} - \sqrt{2}\sqrt{\sqrt{1-4x} + 1 - 10x}}{4} \tag{1}$$

$$F_2(x) = \frac{3 - 2x - \sqrt{1-4x} - \sqrt{2}\sqrt{(1+2x)\sqrt{1-4x} + 1 - 8x + 2x^2}}{4} \tag{2}$$

$$F_3(x) = \frac{x\,\left(1 + 3\sqrt{1-4x}\,\right)}{4\left(1 - \frac{9}{2}x\right)} \quad F_4(x) = \frac{\left(1 + \sqrt{1-4x}\,\right)\left(1 - \sqrt{3 - 2/\sqrt{1-4x}}\,\right)}{4} \tag{3}$$

$$F_5(x) = \frac{x}{x - C^2(x)} F_1(x) = \frac{1}{8}\left(1 + \frac{1}{\sqrt{1-4x}}\right)\left(1 + \sqrt{1-4x} - \sqrt{2}\sqrt{1 + \sqrt{1-4x} - 10x}\,\right) \tag{4}$$

$$F_8(x) = \frac{x}{2(1-4x)} + \frac{x}{2\sqrt{1-4x}} \tag{5}$$

The four functions F_6, F_7, F_9, and F_{10} satisfy the following algebraic equations.

$$F_6^3 - 2F_6^2 + (1+2x)F_6 + x^2 - 2x = 0 \tag{6}$$

$$F_7^4 - 3F_7^3 + (3+x)F_7^2 - (1+x)^2 F_7 - x^3 + x^2 + x = 0 \tag{7}$$

$$F_9^4 - 3F_9^3 + (3+x)F_9^2 - (1+2x)F_9 + x^2 + x = 0 \tag{8}$$

$$\begin{gathered} F_{10}^7 - (6+x)F_{10}^6 + (15+6x)F_{10}^5 + (x^2 - 15x - 20)F_{10}^4 - (2x^2 - 20x - 15)F_{10}^3 - \\ -(15x+6)F_{10}^2 + (2x^2 + 6x + 1)F_{10} + x^4 - x^2 - x = 0 \end{gathered} \tag{9}$$

In the first order asymptotics we use the notation $f(n) \sim g(n)$ for $\lim_{n\to\infty} f(n)/g(n) = 1$.

$$w_1(n) \sim \frac{1}{\sqrt{15\pi}}\,\frac{1}{n\sqrt{n}}\,\left(\frac{25}{4}\right)^n \quad w_2(n) \sim 0.16584\; n^{-3/2}\;(4.80261)^n \quad w_3(n) \sim \frac{1}{9}\,\left(\frac{9}{2}\right)^n \tag{10}$$

$$w_4(n) \sim \frac{5}{16}\,\sqrt{\frac{5}{6\pi}}\,\frac{1}{n\sqrt{n}}\,\left(\frac{36}{5}\right)^n \quad w_5(n) \sim \frac{4}{3}\,w_1(n) \sim \frac{4}{3\sqrt{15\pi}}\,\frac{1}{n\sqrt{n}}\,\left(\frac{25}{4}\right)^n \tag{11}$$

$$w_6(n) \sim \frac{4}{9\sqrt{3\pi}}\,\frac{1}{n\sqrt{n}}\,\left(\frac{27}{4}\right)^n \quad w_7(n) \sim \frac{\sqrt{5731 - 4635/\sqrt{17}}}{256\sqrt{\pi}}\,\frac{1}{n\sqrt{n}}\,\left(\frac{107 + 51\sqrt{17}}{64}\right)^n \tag{12}$$

$$w_8(n) \sim \frac{1}{8}\,4^n \tag{13}$$

$$w_9(n) \sim \frac{\sqrt{5 - 1/\sqrt{13}}}{4\sqrt{6\pi}}\,\frac{1}{n\sqrt{n}}\,\left(\frac{70 + 26\sqrt{13}}{27}\right)^n \quad w_{10}(n) \sim 0.12075\; n^{-3/2}\;(5.22159)^n \tag{14}$$

The constants in the asymptotics of w_2 and w_{10} are just approximations but, as we shall see in the next section, in principle we can give closed algebraic expressions for them as well. Numerically the asymptotics read as follows. $w_1(n) \sim 0.14567\; n^{-3/2}\; 6.25^n$, $w_2(n) \sim 0.16584\; n^{-3/2}\; 4.80261^n$, $w_3(n) \sim 0.11111\; 4.5^n$, $w_4(n) \sim 0.16095\; n^{-3/2}\; 7.2^n$, $w_5(n) \sim 0.19423\; n^{-3/2}\; 6.25^n$, $w_6(n) \sim 0.14477\; n^{-3/2}\; 6.75^n$,

$w_7(n) \sim 0.14958\ n^{-3/2}\ 4.95747^n$, $w_8(n) \sim 0.125\ 4^n$, $w_9(n) \sim 0.12514\ n^{-3/2}\ 6.06460^n$, $w_{10}(n) \sim 0.12075\ n^{-3/2}\ 5.22159^n$. A remarkable fact is that all the ten linear constants lie in the interval $(0.1, 0.2)$.

In the left table below we list the first eight values $w_i(n), n = 1, 2, \ldots, 8$, for each $i = 1, 2, \ldots, 10$. For this and other heavy calculations we used MATHEMATICA and MAPLE. For $i = 1, 2, 3, 4, 5, 8$ we took directly the generating function. For $i = 6, 7, 9, 10$ we started with $F_i(0) = 0$ and then, differentiating the equation, we applied the relations $w_i(n) = F_i^{(n)}(0)/n!$. For $i = 6, 7, 9$ one can apply alternatively the Lagrange inversion formula — see Section 4. In the right table we sort the weights by their exponential growth rates.

w_1	1	2	7	19	131	625	3099	15818
w_2	1	2	5	15	50	178	663	2553
w_3	1	3	12	51	222	978	4338	19323
w_4	1	3	13	63	326	1769	9964	57843
w_5	1	3	12	52	236	1109	5366	26639
w_6	2	3	10	42	198	1001	5304	29070
w_7	1	2	4	13	44	164	636	2559
w_8	1	3	11	42	163	638	2510	9908
w_9	1	2	6	23	98	447	2134	10530
w_{10}	1	1	4	12	44	175	718	3052

w_8	brooms	4^n
w_3	chains	4.5^n
w_2	max. antichains	4.80261^n
w_7	max. ind. sets	4.95747^n
w_{10}	max. matchings	5.22159^n
w_9	matchings	6.06460^n
w_1	antichains	6.25^n
w_5	connected sets	6.25^n
w_6	independent sets	6.75^n
w_4	infima closed sets	7.2^n

We conclude the section with a few comments. Note the relation between w_1 and w_5. From (5) it follows at once a closed formula for $w_8(n)$, see (24). In Section 4 we derive a closed formula (29) for $w_6(n)$ and a nice recurrent formula (30) for $w_7(n)$. Expressions and equations (1)–(9) yield effective procedures calculating for a given n the numbers $w_i(n)$, $1 \leq i \leq 10$. A natural question is whether one can calculate effectively, given a tree T, the numbers $w_i(T)$. This turns out to be possible for each of the weights, in the next section we give the corresponding recurrent relations.

Thus, indeed, the average tree has asymptoticly much more antichains than chains in spite the tendency shown by the first nine values. For $n \geq 10$ we have, in accordance with the asymptotics, $w_1(n) > w_3(n)$. Even maximal antichains beat asymptoticly chains but now $w_2(n) < w_3(n)$ for $n = 2, 3, \ldots, 99$. Only from 100 vertices on the asymptotics prevails and the average tree starts to have more maximal antichains than chains.

3 Subset countings — proofs

Let $T = (r, V, E, L)$ be a tree and $v \in V$ be a vertex. A *subtree* T_v of T rooted in v is the subtree spanned by the upset $\{x \in V : \ x \geq v\}$. A *degree* $deg(v)$ of v is the number $|ch(v)|$ of children of v. A *principal subtree* of T is a subtree T_v such that $v \in ch(r)$. T is determined uniquely by the list $ps(T) = (T_v : \ v \in ch(r))$ of its principal subtrees. A *singleton* s is the trivial one vertex tree. Let us remind the Catalan function C satisfying $C^2 - C + x = 0$, see Section 1.

To determine the generating function F_w we use arguments of two kinds. In the *recurrence argument* we take the decomposition $ps(T) = (T_1, T_2, \ldots, T_k)$ and find, for a weight w, the recurrent relation that transforms the list $(w(T_1), w(T_2), \ldots, w(T_k))$ into the number $w(T)$. The relation can be often translated to an equation for F_w. This way we obtain both the *individual count* (the recurrence for $w(T)$) and the *collective count* (the function F_w that counts $w(n)$). An alternative approach via another decomposition is indicated in the concluding section.

The *extension argument* is basically counting in two ways. We count the number of extensions of a fixed set $X \subset V$ with a special property to a tree. See Figure 1. Draw a tree $T = (r, V, E, L)$ in the plane. The *gaps* of $v \in V$ are the wedge-shaped areas into which the edges incident with v split v's neighborhood. Thus v has $deg(v) + 1$ gaps. All gaps of all vertices form the set $g(T)$ with $2|V| - 1$ elements. In the *gap extension* we take a tree $T \in \mathcal{T}_m$ and into each gap $g \in g(T)$ we insert a tree T_g. The root $r(T_g)$ and the vertex of g are identified. A moment of thought reveals that the number of choices for which a tree from $\mathcal{T}_n$ arises is the coefficient at x^n in $x^m(C(x)/x)^{2m-1}$. In the *edge extension* we mark on a fixed oriented edge $e \in \mathcal{T}_2$ from top to bottom $k \geq 0$ points $p_1, \ldots, p_k$ and we put a tree T_i to the left and a tree U_i to the right of p_i, identifying p_i with the roots $r(T_i)$ and $r(U_i)$. A tree from $\mathcal{T}_n$ (we do not count the endpoints of e) is obtained for $[x^n]\ \sum_{k\geq 0}(C^2/x)^k = [x^n]\ x/(x - C^2)$ choices. Here and further on $[x^n]\ f$ denotes the coefficient at x^n in the power series f. In the *l edges extension* we extend this way independently l edges. While saying nothing about the individual count this method is usually more elegant than the recurrence argument.

gap extension edge extension

Figure 1: Extensions.

1 Antichains by extension. Consider an antichain $X \subset V(T)$ and the tree T^* spanned by the downset $\{v \in V(T) :\ v \leq x \in X\}$. Obviously T is a gap extension of T^* and therefore

$$F_1(x) = \sum_{m\geq 1} c_{m-1}x^m \left(\frac{C(x)}{x}\right)^{2m-1} = \frac{x}{C(x)} \sum_{m\geq 1} c_{m-1} \left(\frac{C^2(x)}{x}\right)^m = \frac{C(C^2(x)/x)}{C(x)/x}.$$

The rest is a matter of simplifications.

Antichains by recurrence. For singleton we have $w_1(s) = 1$. For a nonsingleton T with $ps(T) = (T_1, T_2, \ldots, T_k)$ we have the recurrence

$$w_1(T) = \prod_{i=1}^{k}(1 + w_1(T_i)) \tag{15}$$

whose proof is immediate. It translates to $F_1 = x\sum_{k\geq 0}(F_1 + C)^k = x/(1 - F_1 - C)$ which simplifies to $F_1^2 + (C - 1)F_1 + x = 0$. Solving this we get again the formula (1).

2 Maximal antichains by recurrence. Similarly to (15) we get $w_2(s) = 1$ and, $ps(T) = (T_1, T_2, \ldots, T_k)$,

$$w_2(T) = 1 + \prod_{i=1}^{k} w_2(T_i). \tag{16}$$

This translates to $F_2 = C + x\sum_{k\geq 1} F_2^k = C + xF_2/(1-F_2)$, i.e. to $F_2^2 + (x - C - 1)F_2 + C = 0$. The quadratic formula yields (2).

3 Chains by extension. Consider a chain $X = (x_1, \ldots, x_m) \subset V$ in T and think of the x_{i-1}–x_i path as an edge, $i = 1, \ldots, m$, $x_0 = r$. Then T is a gap extension and m edges extension of X. Hence

$$F_3(x) = \sum_{m\geq 1} x^m \left(\frac{C(x)}{x}\right)^{2m-1} \left(\frac{x}{x - C^2(x)}\right)^m = \frac{xC(x)}{x - 2C^2(x)}.$$

After further simplifications we obtain the formula for F_3 in (3).

Chains by recurrence. The recurrence for chains is $w_3(s) = 1$, $ps(T) = (T_1, T_2, \ldots, T_k)$,

$$w_3(T) = 1 + 2\sum_{i=1}^{k} w_3(T_i). \tag{17}$$

Consider the generating function

$$G(x, y) = \sum_{\mathcal{T}} x^{w_3(T)} y^{|V(T)|}.$$

Then (17) reads as

$$G(x, y) = xy \sum_{k\geq 0} G(x^2, y)^k = \frac{xy}{1 - G(x^2, y)}.$$

Clearly $G(1, y) = C(y)$ and $F_3(y) = G_x(1, y)$. Taking the partial derivative by x of the equation for G and evaluating it at $(1, y)$ we find

$$F_3(y) = y\frac{1 - C(y) + 2F_3(y)}{(1 - C(y))^2} \quad \text{that solves as } F_3(y) = y\frac{1 - C(y)}{(1 - C(y))^2 - 2y}.$$

Simplifications lead again to the formula in (3).

4 Infima closed sets by extension. Consider a nonempty infima closed set $X \subset V(T)$, $|X| = m$. By replacing all u–v paths, $u, v \in X$, not containing other vertices of X by an edge we produce a tree T^* on m vertices. Clearly T is a gap and m edges extension of T^*, in the same way as for chains. Only now we are extending all trees on m vertices, not only the path. Thus

$$F_4(x) = \sum_{m\geq 1} c_{m-1} x^m \left(\frac{C(x)}{x}\right)^{2m-1} \left(\frac{x}{x - C^2(x)}\right)^m = \frac{x}{C(x)}\, C\left(C^2(x)/(x - C^2(x))\right).$$

Simplifications lead to the formula in (3).

For the sake of completeness we mention the recurrent formula. Let $ps(T) = (T_1, \ldots, T_k)$. Then $w_4(s) = 1$,

$$w_4(T) = \sum_{i=1}^{k} w_4(T_i) + \prod_{i=1}^{k} (1 + w_4(T_i)). \tag{18}$$

5 Connected sets by extension. Consider a connected set $X \subset V$. It is easy to see that T is a gap and (one) edge extension of X. The edge corresponds to the path $r(T)$–$r(X)$. Thus the additional factor $x/(x - C^2(x))$ in (4) compared to antichains.

Again, given a T, we can effectively calculate $w_5(T)$:

$$w_5(T) = \sum_{v \in V} w_1(T_v) \tag{19}$$

where T_v is the subtree rooted in v.

6 Independent sets by recurrence. We need an auxiliary weight $z(T)$ counting $\emptyset$ and the independent sets in T not containing r. Let $ps(T) = (T_1, \dots, T_k)$. A moment of thought reveals that $z(s) = 1$, $w_6(s) = 2$,

$$z(T) = \prod_{i=1}^{k} w_6(T_i) \text{ and } w_6(T) = \prod_{i=1}^{k} w_6(T_i) + \prod_{i=1}^{k} z(T_i). \tag{20}$$

Translated to generating functions,

$$F_z = x \sum_{k \geq 0} F_6^k = \frac{x}{1 - F_6} \text{ and } F_6 = x \sum_{k \geq 0} F_z^k + x \sum_{k \geq 0} F_6^k = \frac{x}{1 - F_z} + \frac{x}{1 - F_6}. \tag{21}$$

Eliminating F_z from the system we get the cubic equation (6).

7 Maximal independent sets by recurrence. So far we always calculated the number at a vertex from the numbers at its children, now we need to consider also the numbers at grandchildren. We define two auxiliary weights t and q. Let $t(T) = \#$ of ind. sets in T not containing r which are maximal or extendable only by the root r. Further $q(s) = 1$, and $q(T) = t(T_1)t(T_2)\dots t(T_k)$ where $ps(T) = (T_1, \dots, T_k)$. Then $w_7(s) = t(s) = q(s) = 1$ and, $ps(T) = (T_1, \dots, T_k)$,

$$t(T) = \prod_{i=1}^{k} w_7(T_i) \text{ and } w_7(T) = \prod_{i=1}^{k} t(T_i) + \prod_{i=1}^{k} w_7(T_i) - \prod_{i=1}^{k} (w_7(T_i) - q(T_i)). \tag{22}$$

The first equality is easy — to take an r-free ind. set in T extendable at most by r is the same as to take a max. ind. set in each T_i. In the second equality in (22) we count first by the product $\prod t(T_i)$ the number of max. ind. sets containing the root. To take a max. ind. set in T not containing r is the same as to take a max. ind. set in each T_i, not all of them avoiding $r(T_i)$. There are $q(T_i)$ max. ind. sets in T_i containing $r(T_i)$. This gives the rest of the second equation. (22) expressed in generating functions is

$$F_t = \frac{x}{1 - F_7} \text{ and } F_7 = \frac{x}{1 - F_t} + \frac{x}{1 - F_7} - \frac{x}{1 - F_7 + x/(1 - F_t)} \tag{23}$$

because the generating function corresponding to q is $x/(1 - F_t)$. The elimination of F_t yields the quartic (7).

8 Brooms by extension. Fix a broom B with m vertices in a tree T. T is a gap extension and one edge extension (as for connected sets) of B and therefore

$$F_8(x) = \frac{x}{x - C^2(x)} \sum_{m \geq 1} x^m \left(\frac{C(x)}{x} \right)^{2m-1} = \frac{x^2}{C.(x - C^2)} \frac{C^2/x}{1 - C^2/x} = \frac{x^2 C}{(x - C^2)^2} = \frac{x^2 C}{(2x - C)^2} =$$

$$= \frac{1}{1 - 4x} \frac{x^2 C}{C - x} = \frac{x}{1 - 4x} \frac{x}{C} = \frac{x}{1 - 4x} \frac{1 + \sqrt{1 - 4x}}{2} = \frac{x}{2(1 - 4x)} + \frac{x}{2\sqrt{1 - 4x}}.$$

It is easy to extract the coefficient by the binomial formula. On the other hand clearly $w_8(T) = \sum_{v \in V} 2^{deg(v)}$ and we have the identity

$$w_8(n) = \sum_{T \in \mathcal{T}_n} \sum_{v \in V(T)} 2^{deg(v)} = \frac{4^{n-1} + \binom{2n-2}{n-1}}{2}. \tag{24}$$

In our derivation we used only that for any $m \geq 1$ there is exactly one broom on m vertices. Thus more generally:

Theorem 3.1 *Suppose $\mathcal{S} \subset \mathcal{T}$ is a family of trees such that $|\mathcal{S} \cap \mathcal{T}_n| = 1$ for any $n \geq 1$. Let $w(T)$ count the total number of ways to embed a member of $\mathcal{S}$ into T. Then $w(n) = \sum_{T \in \mathcal{T}_n} w(T) = w_8(n) = (4^{n-1} + \binom{2n-2}{n-1})/2$.*

If $\mathcal{S}$ is the family of all paths we obtain the identity

$$\sum_{T \in \mathcal{T}_n} |\{(u,v) \in V(T) \times V(T) : \ u \text{ and } v \text{ are comparable in } T\}| = 4^{n-1}$$

because the left hand side is $2w_8(n) - nc_{n-1}$. We remark that a quantity similar to w_8, namely the average vertex altitude, was counted by D. E. Knuth, see [8].

9 Matchings by recurrence. We set $z(T)$ to be the number of matchings in T not covering the root, the empty set included. Let $ps(T) = (T_1, \ldots, T_k)$. Then $z(s) = w_9(s) = 1$,

$$z(T) = \prod_{i=1}^{k} w_9(T_i) \text{ and } w_9(T) = \prod_{i=1}^{k} w_9(T_i).\left(1 + \sum_{i=1}^{k} \frac{z(T_i)}{w_9(T_i)}\right). \tag{25}$$

The first relation follows from the fact that a matching in T avoiding r arises simply by taking in each T_i either a matching or the empty set. In the second relation we add the numbers of matchings using the edge $r(T)r(T_i)$. To translate this to generating functions we use the identity $\sum_{k \geq 0}(k+1)x^k = 1/(1-x)^2$. Thus

$$F_z = \frac{x}{1 - F_9} \text{ and } F_9 = \frac{x}{1 - F_9} + \frac{xF_z}{(1 - F_9)^2}.$$

Eliminating F_z we obtain the quartic equation (8).

10 Maximal matchings by recurrence. From technical reasons we set $w_{10}(s) = 1$. Consider two auxiliary weights z and q. $z(s) = 0$ and $z(T)$ counts the number of max. matchings in T covering the root, $q(s) = 1$ and $q(T) = w_{10}(T_1)w_{10}(T_2)\ldots w_{10}(T_k)$ where $ps(T) = (T_1, \ldots, T_k)$. Then $z(s) = 0$ and $q(s) = w_{10}(s) = 1$,

$$z(T) = \prod_{i=1}^{k} w_{10}(T_i).\sum_{i=1}^{k} \frac{q(T_i)}{w_{10}(T_i)} \text{ and } w_{10}(T) = z(T) + \prod_{i=1}^{k} z(T_i). \tag{26}$$

In the first relation we count the number of max. matchings using the edge $r(T)r(T_i)$. Those arise by taking a max. matching in each $T_j, j \neq i$, (or $\emptyset$ if $T_j = s$, that's why we set $w_{10}(s) = 1$) and an $r(T_i)$-free matching in T_i (or $\emptyset$ if $T_i = s$) extendable eventually only by some edge going up from $r(T_i)$. Such matchings are counted by $q(T_i)$. In the second relation we add to $z(T)$ the number of max. matchings avoiding $r(T)$. Algebraicly,

$$F_z = \frac{xF_q}{(1 - F_{10})^2} \text{ and } F_{10} = F_z + \frac{x}{1 - F_z} \text{ where } F_q = \frac{x}{1 - F_{10}}.$$

From this one obtains the relation $F_{10} = x^2/(1-F_{10})^3 + x/(1 - x^2/(1-F_{10})^3)$ which simplifies to the equation of degree 7 in (9).

The asymptotics of the numbers $\mathbf{w_1(n), \ldots, w_{10}(n)}$. We start with the simple cases and proceed to more complicated ones. Catalan numbers have the asymptotics

$$c_n \sim \frac{4^n}{n\sqrt{\pi n}}. \tag{27}$$

This follows by Stirling formula.

$w_8(n)$. The asymptotics (13) for $w_8(n)$ is immediate from (24).

When F_i is given by square roots the next theorem of Bender, p. 496 in [2], is useful. We need also binomial and Stirling formulae and basic concepts of analytic functions.

Theorem 3.2 *Let $A(x) = \sum a_n x^n$, $B(x) = \sum b_n x^n$, and $C(x) = A(x)B(x) = \sum d_n x^n$ be three power series, and let A and B have radii of convergence $\alpha > \beta \geq 0$. Suppose $b_{n-1}/b_n \to \beta$ as $n \to \infty$, and $A(\beta) \neq 0$. Then*

$$d_n \sim A(\beta) b_n.$$

$w_3(n)$. For $F_3(x)$ we use Theorem 3.2 with $A(x) = x(1 + 3\sqrt{1-4x})/4$, $B(x) = 1/(1-9x/2)$, $\alpha = 1/4$, $\beta = 2/9$, and $A(2/9) = 1/9$. The asymptotics (10) for $w_3(n)$ follows.

$w_4(n)$. To obtain the asymptotics (11) for $w_4(n)$ we write $F_4(x) = (1+\sqrt{1-4x})/4 - A(x)B(x)$ where

$$A(x) = \frac{\sqrt{5}}{4} \frac{1+\sqrt{1-4x}}{\sqrt{(3\sqrt{1-4x}+2)\sqrt{1-4x}}} \text{ and } B(x) = \sqrt{1 - \frac{36x}{5}}.$$

Theorem 3.2 is applied with $\alpha = 1/4$, $\beta = 5/36$, and $A(5/36) = (5/8)\sqrt{5/6}$. The coefficient b_n in $B(x) = \sum b_n x^n = (1-36x/5)^{1/2}$ can be estimated by means of binomial and Stirling formulae.

$w_1(n)$. We observe that the expresion under the big radical in (1) determines a function that is analytic in the 1/4 circle and that is nonzero there except for the simple zero 4/25. Thus we can write $F_1(x) = (1+\sqrt{1-4x})/4 - A(x)B(x)$ with $B(x) = \sqrt{1-25x/4}$ and $A(x)$ a function analytic in the 1/4 circle. Further, $A(4/25) = 2/\sqrt{15}$. Theorem 3.2 implies the first asymptotics in (10).

$w_5(n)$. Here $A(x) = (1/2)(1+1/\sqrt{1-4x})$, $B(x) = F_1(x)$, $\alpha = 1/4$, $\beta = 4/25$, and $A(4/25) = 4/3$. The second asymptotics in (11) follows.

$w_2(n)$. The expression under the big radical in (2) is analytic in the 1/4 circle and is nonzero there except for the simple zero $\beta = 0.20821\ldots$ (the only real root of $x^3 - 4x^2 + 20x - 4$). Thus we have again $F_5(x) = (3 - 2x - \sqrt{1-4x})/4 - A(x)B(x)$ with $B(x) = \sqrt{1-x/\beta}$ and $A(x)$ a function analytic in the 1/4 circle. One can calculate that

$$A(\beta) = \sqrt{\frac{\beta}{2}} \sqrt{\frac{3\beta}{\sqrt{1-4\beta}} - \beta + 2}.$$

The second asymptotics in (10) is obtained.

To resolve the remaining cases when F_i satisfies an equation of degree > 2 we use the following result, found on p. 502 in [2].

Theorem 3.3 *A power series $f(x) = \sum a_n x^n$ with nonnegative coefficients satisfying $F(x, f(x)) = 0$ and two real numbers $\alpha > 0$ and $\beta > a_0$ are given. Suppose that*

(a) *for some $\delta > 0$, $F(x,y)$ is analytic whenever $|x| < \alpha + \delta$, $|y| < \beta + \delta$,*

(b) *$F(\alpha, \beta) = F_y(\alpha, \beta) = 0$,*

(c) *$F_x(\alpha, \beta) \neq 0$ and $F_{yy}(\alpha, \beta) \neq 0$, and*

(d) *if (κ, λ) is another solution of the system in (b) then $|\kappa| > \alpha$ or $|\lambda| > \beta$.*

Then

$$a_n \sim \sqrt{\frac{\alpha F_x(\alpha,\beta)}{2\pi F_{yy}(\alpha,\beta)}} \frac{1}{n\sqrt{n}} \left(\frac{1}{\alpha}\right)^n. \tag{28}$$

This is exactly what we need but the difficulty is that the theorem is incorrect, as pointed out by Canfield [3]. However, the conclusion (28) still holds if we can present positive reals (α, β), $f(\alpha) = \beta$, such that (01) (α, β) lies inside the analyticity domain of F (i.e., (a) holds), (02) the condition (c) holds, (03) α is the radius of convergence of $f(x)$, and (04) $f(x)$ has no other singularity on the boundary than α.

We know, by implicit function theorem, that the pair (α, β) we look for (as well as and any other singularity on the boundary) is hidden among the solutions of the simultaneous equations (b). In general it may be difficult to determine which solution is the right one or even to find all solutions. Therefore several conditions for F making (α, β) unique or localizing it among the solutions were proposed, see [9] and [10], p. 1162–3.

For the four functions F_6, F_7, F_9, and F_{10} we can always find (α, β) meeting the conditions (01)–(04). Indeed, $F(x, y)$ is a bivariate polynomial, thus analytic everywhere, and it is not too difficult to find all solutions of the algebraic system (b). Notice that $c_{n-1} \le w_i(n) \le 2^n c_{n-1}$. By (27) we know that the radius of convergence of any $F_i(x)$, $i = 1 \dots 10$, lies in $[1/8, 1/4]$. In all four cases there is only one (complex) solution (α, β) such that $1/8 \le |\alpha| \le 1/4$. Thus (01)–(04) holds and (28) is true.

$\mathbf{w_6(n)}$. $F_6(x)$ satisfies the cubic equation (6). The system (b) has four solutions: $(0, 1)$ (with multiplicity 3) and $(\alpha, \beta) = (4/27, 5/9)$. Plugging in the formula (28) we obtain the first bound in (12).

$\mathbf{w_7(n)}$. The equation for $F_7(x)$ is given by (7). The solutions of (b) are: $(0, 1)$ (with multiplicity 4), $((-51\sqrt{17} - 107)/512, (33 - 7\sqrt{17})/128)$, and $(\alpha, \beta) = ((51\sqrt{17} - 107)/512, (33 + 7\sqrt{17})/128)$. The second bound in (12) follows.

$\mathbf{w_9(n)}$. The equation for $F_9(x)$ is (8). The solutions of (b) are: $(0, 1)$ (multiplicity 2), $((-13\sqrt{13} - 35)/72, (1 - \sqrt{13})/12)$, and $(\alpha, \beta) = ((13\sqrt{13} - 35)/72, (1 + \sqrt{13})/12)$. The first bound in (14) follows.

$\mathbf{w_{10}(n)}$. $F_{10}(x)$ satisfies (9). The system (b) has 12 solutions: $(0, 1)$ (multiplicity 8), $(-0.26689 \pm 0.51782i, 0.01231 \pm 0.40950i)$, $(11.67188, 8.47407)$, and $(\alpha, \beta) = (0.19151, 0.38840)$. The four y solutions different from 1 are roots of the quartic $248y^4 - 2204y^3 + 912y^2 - 389y + 137$. x appears in $F_{yy}(x, y) = 0$ only in the second degree. Thus α and β still express in radicals. The second bound in (14) follows.

4 Applications of the LIF

The generating functions F_6, F_7, F_9, and F_{10} satisfy an algebraic equation of degree > 2. Such an equation is often very hard, if not impossible, to solve explicitly. Nevertheless, sometimes we can find easily the inverse to the solution. Then the *Lagrange inversion formula* applies.

Theorem 4.1 (LIF) *Suppose $f(x)$ is a power series with $[x^0]f = 0$ and $[x^1]f \neq 0$. Then*

$$[x^n]f(x)^{<-1>} = n^{-1}[x^{n-1}](f(x)/x)^{-n}.$$

For more details see [14], [10] (p. 1106), and [7] (p. 1032).

Theorem 4.2 *Let $n \ge 1$. Recall that $w_6(n)$ is the total number of all independent sets in all $T \in \mathcal{T}_n$ (the empty set counted) and $z(n)$ is the number of those avoiding the root. Then*

$$w_6(n) = \frac{1}{n-1}\binom{3n-3}{n} \text{ and } z(n) = \frac{1}{n}\binom{3n-2}{n-1}. \tag{29}$$

Proof. We start with $z(n)$. Eliminating F_6 from (21) we obtain $F_z(1 - F_z)^2 = x$. Thus $F_z(x)^{<-1>} = x(1 - x)^2$. The formula for $z(n)$ follows readily by the LIF.

To determine $w_6(n)$ we observe that

$$3xF_6' - 2F_6 - 4xF_z' + 2F_z = 0.$$

This is not difficult to check by means of the relations (21). We leave the straightforward calculations to the reader as an exercise. In terms of coefficients:

$$(3n-2)w_6(n) = (4n-2)z(n).$$

Substituting the formula for $z(n)$ we finish the proof. □

Theorem 4.3 *Let $n \geq 1$. Recall that $w_7(n)$ is the total number of all maximal independent sets in all $T \in \mathcal{T}_n$ and $t(n)$ is the number of independent sets avoiding the root and extendable at most by it. Then*

$$t(n) = \frac{1}{n}\sum_{k=0}^{n-1}(-1)^k\binom{n+k-1}{k}\binom{3n-k-2}{n-k-1} = \frac{1}{n}\sum_{k=0}^{\lfloor (n-1)/2\rfloor}\binom{2n-2-2k}{n-1-2k}\binom{n+k-1}{k}$$

and

$$w_7(n) = t(n+1) - \sum_{k=2}^{n} t(k).w_7(n-k+1). \tag{30}$$

Proof. Eliminating F_7 from (23) we find that $F_t(1-F_t)(1-F_t^2) = F_t(1+F_t)(1-F_t)^2 = x$. Thus $F_t(x)^{<-1>} = x(1-x)(1-x^2) = x(1+x)(1-x)^2$. The LIF yields the formula for $t(n)$. The recurrence for $w_7(n)$ follows from the relation $F_t(1-F_7) = x$. □

As to the values of w_9, the LIF helps here too. $F_9(x)^{<-1>}$ is easily found by solving (8) for x. We obtain a more comfortable way to calculate $w_9(n)$ (instead of taking derivatives) but no nice explicit formula seems to arise here. The details are omitted. We did not succed in applying the LIF to w_{10}.

5 Drawing countings

The calculations for the weights w_{11} and w_{12} are more elegant when the main parameter n is $|E|$ rather than $|V|$. We use exponential instead of ordinary generating function. We determine

$$F_i(x) = \sum_{n\geq 0}\frac{w_i(n)}{n!}\,x^n$$

where $i = 11, 12$ and in $w_i(n) = \sum_T w_i(T)$ we sum over the trees with n edges.

A simple drawing $(e_1, e_2, \ldots, e_n)$ of a tree T with n edges is a way of planting T from the root. To look on it differently consider the vertices $(v_1, v_2, \ldots, v_n)$ where v_i is the endpoint of e_i. Obviously, $(r, v_1, \ldots, v_n)$ is a linear extension of the tree as a poset. And vice versa, any linear extension determines a simple drawing of T. Thus $w_{11}(T)$ is the number of linear extensions of T. This notion and the results below (Theorems 5.1 and 5.2) seem be frequently rediscovered, as we learned after proving the theorems.

Theorem 5.2 is close in statement and proof to Lemma 2.1 in [1]. Theorem 5.1 is proved, in a more complicated manner, in [13]. Another proof of Theorem 5.1, much the same as the one below, can be found in [6]. There the authors point to the thesis [4] as to an older reference for this result and mention that R. P. Stanley proved it before as well. We join in and include, for the readers convenience, our (independent) proofs. As to the notation, $(2n-1)!!$ stands, as usual, for $1.3.5\ldots(2n-1)$. For triple and quadruple factorials see [6]!!

Theorem 5.1 *Let $n > 0$. Then*

$$w_{11}(0) = 1,\ w_{11}(n) = (2n-1)!! \text{ and } F_{11}(x) = \frac{1}{\sqrt{1-2x}}. \tag{31}$$

Proof. So $w_{11}(T)$ counts the labelings of vertices by $0, 1, \ldots, n$ such that the label of u is smaller than that of v whenever $u < v$. Thus r is always labeled by 0. Clearly $w_{11}(0) = 1$. For $T \in \mathcal{T}_{n+1}$, $n \geq 1$, in any of the labelings n sits at a leaf l and deleting l we get a proper labeling of a $T^* \in \mathcal{T}_n$. From each labeled T^* we can get, adding l back, exactly $2n-1$ different labeled T's since each T^* has $2n-1$ gaps to place l. Hence $w_{11}(n) = (2n-1).w_{11}(n-1)$ and we obtain the first formula in (31). The second formula follows from the first one after rewriting $(2n-1)!!$ as $n!\binom{2n}{n}/2^n$. □

The asymptotics

$$w_{11}(n) \sim \sqrt{2}\ \left(\frac{2n}{e}\right)^n$$

follows by Stirling formula.

We show now how to perform for w_{11} the individual count.

Theorem 5.2 *Recall that T_v stands for the subtree of T rooted in $v \in V$. We abbreaviate $|V(T_v)|$ by $|T_v|$. Then, for a tree T with $|V| = n+1$ vertices,*

$$w_{11}(T) = \frac{(n+1)!}{\prod_{v \in V} |T_v|} = \frac{n!}{\prod_{v \in V, v \neq r} |T_v|}. \tag{32}$$

Proof. By induction on the height of T. Clearly $w_{11}(s) = 1$. For a nonsingleton tree T with $ps(T) = (T_1, T_2, \ldots, T_k)$ we have

$$w_{11}(T) = \binom{n}{|T_1|\ |T_2| \ldots |T_k|} \prod_{i=1}^{k} w_{11}(T_i)$$

because for each of the choices $\{1, 2, \ldots, n\} = X_1 \cup X_2 \cup \ldots \cup X_k$, $|X_i| = |T_i|$, X_i mutually disjoint, of the sets of labels for vertices $V(T_i)$ (r is labeled by 0) we have exactly $\prod w_{11}(T_i)$ labelings. Plugging in the formulae for $w_{11}(T_i)$ and canceling the factorials we get (32). □

The counting of $w_{12}(n)$ is more interesting. Note that $w_{12}(T)$ counts different ways to plant T from its root too but "different" has other meaning compared to w_{11}. For instance, if T_0 is the V-shaped tree on 5 vertices then $w_{11}(T_0) = 6$ but $w_{12}(T_0) = 4$. The key fact is that the insertion of a new leaf in T in different gaps may produce the same tree. More precisely:

Lemma 5.3 *Suppose T has $n \geq 1$ edges and l leaves. Adding the new leaf in all $2n+1$ gaps yields $2n+1-l$ new different trees with $n+1$ edges, l of them have l leaves and $2n+1-2l$ have $l+1$ leaves.*

Proof. Consider the trees $X = \{T_g :\ g \in g(T)\}$ where T_g arises by adding the new leaf in the gap g. T_g and T_h coincide iff g and h share the same vertex v and all edges between g and h going up from v lead to leaves. Thus $|X| = 2n+1-c$ where c is the number of gaps whose left edge leads to a leaf. Clearly $c = l$. The number of leaves does not change iff we add the new leaf to a leaf and then we produce l new trees. Otherwise the number of leaves increases by one. □

Theorem 5.4

$$F_{12}(x) = \sum_{\mathcal{T}} \frac{w_{12}(T)}{|E(T)|!} x^{|E(T)|} = \sum_{n\geq 0} \frac{w_{12}(n)}{n!} x^n = \frac{1}{\sqrt{2e^{-x}-1}}. \tag{33}$$

Proof. Consider the bivariate exp. gen. function ($l(T)$ is the number of leaves of T)

$$F^*(x,y) = \sum_{T\in\mathcal{T}} \frac{w_{12}(T)}{|E(T)|!}\, x^{|E(T)|} y^{l(T)} = 1 + xy + \frac{x^2 y}{2} + \frac{x^2 y^2}{2} + \dots$$

Lemma 5.3 translates to generating functions as

$$\int_x (y\,\frac{\partial}{\partial y} + 2xy\,\frac{\partial}{\partial x} + y - 2y^2\,\frac{\partial}{\partial y})\; F^* = F^* - 1.$$

This yields the partial differential equation

$$(\frac{1}{y} - 2x)\,\frac{\partial F^*}{\partial x} + (2y-1)\,\frac{\partial F^*}{\partial y} = F^*. \tag{34}$$

(34) is of the type $a(x,y)F_x + b(x,y)F_y = f(x,y,F)$ that reduces to two ordinary diff. equations. We review briefly the standard resolution and apply it to (34). First one solves the equation

$$\frac{dy}{dx} = \frac{b(x,y)}{a(x,y)} \tag{35}$$

which gives the system of *characteristic curves* $\{y_c(x) :\ c \in D\}$ (D is a set of real parameters). Along each of the curves F turns into a univariate function $F_c(x) = F(x, y_c(x))$ that satisfies

$$\frac{dF_c}{dx} = \frac{f(x, y_c(x), F_c(x))}{a(x, y_c(x))} \tag{36}$$

(this follows by the chain rule for partial derivatives). The value of F at a point $p = (x_0, y_0)$ is then $F_c(x_0)$ where $c = c(p)$ is chosen so that y_c goes through p.

The equation (35) becomes for (34)

$$\frac{dy}{dx} = \frac{2y-1}{1/y - 2x}$$

which is an exact equation $(1/y - 2x)dy + (1-2y)dx = 0$. Solving it in a standard way we get the following equation for characteristic curves:

$$y\; e^{(1-2y)x} = c. \tag{37}$$

(36) turns into a separated variables equation

$$\frac{dF_c^*}{dx} = \frac{y_c'}{2y_c - 1}\; F_c^*$$

whose solution is $F_c^*(x) = d(c).\sqrt{2y_c(x)-1}$. From (37) we have $y_c(0) = c$ and from $F_c^*(0) = 1$ we get $d(c) = 1/\sqrt{2c-1}$. Thus $F_c^*(x) = \sqrt{2y_c(x)-1}/\sqrt{2c-1}$ and, using (37),

$$F^*(x,y) = \sqrt{\frac{2y-1}{2y.e^{x(1-2y)} - 1}}\;.$$

Specializing $y = 1$ we obtain (33). □

Setting in (34) $y = 1/2$ we get for $g(x) = F^*(x, 1/2)$ the ord. diff. equation $2(1-x)g' = g$, thus $(g(0) = 1)$ $g(x) = 1/\sqrt{1-x}$. Hence

$$2^n \sum_{T \in \mathcal{T}_{n+1}} w_{12}(T) \left(\frac{1}{2}\right)^{l(T)} = (2n-1)!!. \tag{38}$$

Let $k(T)$ stand for the number of nonleaves of T. By (38) the sum $\sum w_{12}(T).2^{k(T)-1}$ over all trees with n edges gives the same result as the sum $\sum w_{11}(T)$.

The function $F_{12}(x)$ satisfies $F_{12}(x)'.(2-e^x) = F_{12}(x)$. This provides us with the simple recurrence $w_{12}(0) = 1$,

$$w_{12}(n+1) = w_{12}(n) + \sum_{i=1}^{n} w_{12}(i).\binom{n}{i-1}. \tag{39}$$

The first few numbers are

$$\{w_{12}(n)\}_{n\geq 0} = \{1,\ 1,\ 2,\ 7,\ 35,\ 226,\ 1787,\ 16717,\ 180560,\ 2211181,\ \ldots\}.$$

To determine the asymptotics we proceed as in Section 3. The function $2e^{-x} - 1$ is entire and nonzero, except for the simple zeros $\log 2 + 2k\pi i$. Thus we write $F_{12}(x) = (1 - x/\log 2)^{-1/2} A(x)$ where $A(x)$ is analytic in the $((\log 2)^2 + 4\pi^2)^{1/2}$ circle and $A(\log 2) = 1/\sqrt{\log 2}$. By Theorem 3.2

$$w_{12}(n) = n!\,[x^n]F_{12}(x) \sim n!\,\frac{1}{\sqrt{\pi n \log 2}}\,\left(\frac{1}{\log 2}\right)^n \sim \sqrt{\frac{2}{\log 2}}\,\left(\frac{n}{e\log 2}\right)^n. \tag{40}$$

6 Concluding remarks

1 An alternative decomposition. In all recurrence arguments we used the decomposition $ps(T) = (T_1, T_2, \ldots, T_k)$. However, one can use the decomposition $T = (T_1, T^*)$ where T_1 is the subtree rooted in the leftmost child of r and T^* is the rest. In some cases this leads to easier derivations of equations for generating functions. On the other hand this decomposition is not well suited to do the indiviual count.

We advice the reader to try some individual counts by the formulae (15)–(20), (22), (25), (26), and (32). For instance, to calculate $w_1(T)$ one writes 1 to each leaf of T and then, by (15), recursively assignes to each vertex v the product of by 1 increased numbers assigned to v's children. Then $w_1(T)$ is the number assigned to r. By such calculations we were motivated to some of the problems stated below.

2 The weight $\mathbf{w_{12}}$. The individual count for the weights w_i, $i = 1, 2, \ldots, 11$ can be done by the (recurrent) formulae (15)–(20), (22), (25), (26), and (32) ($w_8(T)$ can be easily calculated from the definition). The question is how to calculate efficiently for any given T the number $w_{12}(T)$. It would be also interesting to give direct combinatorial proofs and interpretations to (39) and (38).

3 Extremal weight values. We define, for $i = 1, 2, \ldots, 12$,

$$m_i(n) = \min w_i(T) \text{ and } M_i(n) = \max w_i(T)$$

where for $i = 1, 2, \ldots, 10$ the extremum is taken over $\mathcal{T}_n$ and for $i = 11, 12$ over $\mathcal{T}_{n+1}$. In many cases it is easy to determine the extremal value. It is trivial that $m_1(n) = n$ (path), $M_1(n) = 2^{n-1}$ (broom), $m_2(n) = 2$ (broom), $m_3(n) = 2n-1$ (broom), $M_3(n) = 2^n - 1$ (path), $M_4(n) = 2^n - 1$

(path), $m_7(n) = 2$ (broom), $m_8(n) = 2n - 1$ (path), $M_8(n) = 2^{n-1}$ (broom), $m_9(n) = n - 1$ (broom), $m_{11}(n) = 1$ (path), $M_{11}(n) = n!$ (broom), and $m_{12}(n) = 1$ (path).

It is not difficult to show that $m_5(n) = \binom{n}{2}+n$ (path), $M_5(n) = 2^{n-1}+n-1$ (broom), $M_6(n) = 2^{n-1}$ (broom), and $(n \geq n_0)$ $m_{10}(n) = n - 1$ (broom). Now we determine $M_2(n)$.

Theorem 6.1 *Let $n = 1+3m+i > 2$, $i \in \{0, 1, 2\}$. Denote by $\mathcal{U}_n \subset \mathcal{T}_n$ the set of trees whose nonroot vertices have only the degrees 1 or 0 and which have only the branches with 3 edges and either 0, 1 or 2 branches with 2 edges or 1 branch with 4 edges. Then*

$$w_2(T) = M_2(n) \text{ for any } T \in \mathcal{U}_n \text{ and } w_2(T) < M_2(n) \text{ for any } T \in \mathcal{T}_n \backslash \mathcal{U}_n \text{ where}$$

$$M_2(n) = 1 + 3^m \text{ for } i = 0, \ = 1 + 3^m + 3^{m-1} \text{ for } i = 1, \quad \text{and } \ = 1 + 2.3^m \text{ for } i = 2.$$

Proof. Suppose T has a nonroot vertex v with $deg(v) = l \geq 2$. Denote by u the parent of v and by x_i the children of v. The tree T^* arises from T by cutting the edge joining v and x_l and joining x_l to u. We write a_i for $w_2(T_{x_i})$, a for the product of a_i's, and b for the product $\prod w_2(T_t)$ where t runs through the children of u different from v ($b = 1$ if there is no such child). By (16)

$$w_2(T_u) = 1 + (1 + a)b = 1 + b + ab \leq 1 + a_l b + ab = 1 + (1 + a_1 \dots a_{l-1})a_l b = w_2(T^*_u).$$

Thus $w_2(T) \leq w_2(T^*)$, the equality holds iff x_l is a leaf. Applying repeatedly the transformation we change T into a tree U with the same number of vertices, with no nonroot vertex of degree > 1, and with w_2 at least as large. Let $d_1, d_2, \dots, d_k$ stand for the number of edges of the branches of U. It holds $w_2(U) = 1 + d_1 d_2 \dots d_k$ and $d_1 + d_2 + \dots + d_k = |V(T)| - 1$. We reduced our problem to a well known riddle asking what is the maximum product of a collection of positive integers with fixed sum. The answer follows by easy splitting arguments and is described above — the maximum is achieved exactly when all d_i's equal to 2 or 3 and there is as many 3's as possible, two 2's may be traded for one 4. The trees U with such d_i's form the set $\mathcal{U}_n$. We see that $w_2(T) = w_2(U)$ implies $T = U$ or $d_i = 1$ for some i. But $d_i = 1$ implies that the maximum product is not attained. Therefore the inequality is strict for the trees outside $\mathcal{U}_n$. □

The problem is to determine the remaining extremal values $m_4(n), m_6(n), M_7(n), M_9(n), M_{10}(n)$, and $M_{12}(n)$ or to give some bounds on them. To single some of them out: what is $m_4(n)$ and what are the trees with few infima closed sets? What is $M_{12}(n)$ and what are the trees with many drawings? For $\varepsilon > 0$ fixed and n large we have the bounds

$$\frac{1-\varepsilon}{4\sqrt{\log 2}} \, \frac{1}{n} \left(\frac{1}{\log 16} \right)^n n! < M_{12}(n) \leq n!$$

The upper bound is trivial and the lower bound follows by the averaging argument from (27) and (40). The problem is how to improve these bounds. The remaining undetermined extremal values can be estimated in a similar way.

4 Two more problems. Is there any tree T different from s for which $w_1(T) = w_3(T)$, i.e., has the same number of chains and antichains? Are there infinitely many of them? We define the *height* of a positive integer m as the minimum height of a tree T such that $w_1(T) = m$. Are there numbers with arbitrary large height? Similarly for w_2.

On numbers of Davenport-Schinzel sequences

Martin Klazar*

Abstract

One class of Davenport-Schinzel sequences consists of finite sequences over n symbols without immediate repetitions and without any subsequence of the type *abab*. We present a bijective encoding of such sequences by rooted plane trees with distinguished nonleaves and we give a combinatorial proof of the formula

$$\frac{1}{k-n+1}\binom{2k-2n}{k-n}\binom{k-1}{2n-k-1}$$

for the number of such normalized sequences of length k. The formula was found by Gardy and Gouyou-Beauchamps by means of generating functions. We survey previous results concerning counting of DS sequences and mention several equivalent enumerative problems.

1 Introduction

The set $DS(n)$ of *Davenport-Schinzel sequences* over n symbols is formed by finite sequences $u = a_1a_2 \dots a_k$ satisfying

1. $a_i \in [n] = \{1, 2, \dots, n\}$ for all i, each integer $j \in [n]$ appears in u.
2. For each pair $i < j$ of $[n]$ the first appearance of i in u precedes that of j.
3. $a_i \neq a_{i+1}$ for all $i = 1, 2, \dots, k-1$.

*During his stay on ASU the author was partially supported by Office of Naval Research grant NOOO14-90-J-1206.

4. $a_{i_1} = a_{i_3} = a \neq b = a_{i_2} = a_{i_4}$ holds for no four indices $1 \leq i_1 < \ldots < i_4 \leq k$.

Condition 3 forbids immediate repetitions while condition 4 does not allow any subsequence of the type $\ldots a \ldots b \ldots a \ldots b \ldots$ where a and b are two distinct numbers. Conditions 1 and 2 normalize sequences for purposes of enumeration.

One can consider *maximal* $DS(n)$ sequences, denoted as $MDS(n)$, which end with 1. For instance,

$$DS(3) = \{123, 1231, 1232, 12321, 1213, 12131\}$$

and

$$MDS(3) = \{1231, 12321, 12131\}.$$

The number of $MDS(n)$ sequences of length k is denoted by $f_{n,k}$ and their total number by f_n. Similarly, $b_{n,k}$ is the number of $DS(n)$ sequences of length k and $b_n = |DS(n)|$. Clearly, $b_1 = f_1 = 1$. The mapping $u \to u1$ is a bijection between $DS(n) \backslash MDS(n)$ and $MDS(n)$, $n > 1$. We see that

$$b_n = 2f_n \text{ and } b_{n,k} = f_{n,k} + f_{n,k+1}. \tag{1}$$

The minimum length of a $DS(n)$ sequence is n and the maximum length is $2n - 1$ (see [4]).

Our aim is to give a combinatorial proof of the formula

$$b_{n,k} = C_{k-n} \cdot \binom{k-1}{2n-k-1} = \frac{\binom{2k-2n}{k-n}\binom{k-1}{2n-k-1}}{k-n+1} \tag{2}$$

established by Gardy and Gouyou-Beauchamps in [6] by means of generating functions. Here $C_n = \binom{2n}{n}/(n+1)$ stands for the n-th *Catalan number* that counts, among other structures, the number of rooted plane trees on $n+1$ vertices.

The paper is organized as follows. In the next section we list several (classical) enumerative problems which are equivalent to counting of $MDS(n)$. In the third section a combinatorial proof of (2) is given. We introduce a new representation of $DS(n)$ by rooted plane trees on n vertices with distinguished nonleaves. To count such trees we encode them bijectively by another tree structure. The bijection is described in the fourth section.

We recall briefly some basic features of a *rooted plane tree* $T = (V, E)$, shortly an *rp tree*. It is a finite rooted tree with edges directed away from the *root* $r \in V$. For an edge $(u, v) \in E$ of T we call u the *parent* of v while v is a *child* of u. The order of children of u matters, we think of T as drawn in the plane with r at the lowest and all edges drawn as straight segments directed up. The number of children of $u \in V$ is denoted by $deg(u)$. A *leaf* is a vertex with no child. The number of leaves of T is denoted by $l(T)$. *Principal subtrees* of T are the trees which arise by deleting the root of T.

To conclude the present section we should say that Davenport-Schinzel sequences were introduced by Davenport and Schinzel [4] in a more general context where alternating subsequences $ababab\ldots$ of length d were excluded. The most important results of the theory of Davenport-Schinzel sequences are upper and lower bounds on their maximum length when d is fixed — [20], [8], and [2]. Applications include both computational and combinatorial geometry. From the enumerative point of view cases $d > 4$ have proven so far intractable. Surveys can be found in [1], [18], [13], and also in [9].

2 The Schröder family

There is an old *Schröder family* of mutually equivalent enumerative problems and the sequence of finite sets $\{MDS(n)\}_{n\geq 1}$ is a relatively new and less known member of it. As such $MDS(n)$ sequences had been enumerated and the generating function had been found well before they were defined. Since this is not articulated in other enumerative papers about $DS(n)$ sequences, it appears useful here to give a brief description of these problems bearing in mind $DS(n)$ sequences. Our list of references is by no means exhaustive.

The sequence of numbers $\{f_n\}_{n\geq 1}$ is the enumerator of the family. There is no closed formula for f_n but it can be computed by a recurrence relation, by a generating function, by sums with positive terms or by alternating sums. We list some of these expressions below.

Special rooted plane maps. The first enumerative paper about $DS(n)$ sequences is due to Mullin and Stanton [11]. They proved, not mentioning so, the membership of the problem to the Schröder family. We describe briefly their bijection between $MDS(n)$ and the set of special rooted plane maps which we will call *fences*.

By a *plane* multigraph we mean a planar multigraph with a specific embedding in the plane. We say it is *totally outerplane* if all edges lie on the boundary of the outer face. A *cut* edge in a connected multigraph G is an edge whose removal disconnects G. A *fence* (F, r, e) is a connected totally outerplane multigraph with no cut edges, with distinguished edge e and vertex r. The vertex r is incident with e and for an observer on r the outer face lies to the left of e.

Note that in a fence no two vertices are connected by three or more edges and that any fence arises from a connected totally outerplane graph by doubling the cut edges.

In F there is a unique closed Eulerian walk C which goes around F clockwise, starts at r, and uses e as its first edge. C produces an $MDS(n)$ sequence. We label r as 1 and we write down the labels of vertices in the order of C. Whenever an unlabeled vertex is encountered, it is given the least unused label.

Counting $MDS(n)$ or fences on n vertices is therefore equivalent. Mullin and Stanton proved the formula

$$b_{n,2n-1} = f_{n,2n-1} = C_{n-1} = \frac{1}{n}\binom{2n-2}{n-1} \tag{3}$$

by observing that fences on n vertices with maximum number of edges are rp trees on n vertices with all edges doubled. They also proved that

$$(n+1)f_{n+1} - (6n-3)f_n + (n-2)f_{n-1} = 0 \quad (n \geq 3), \tag{4}$$

using the generating function

$$\sum_{n=1}^{\infty} f_n x^n = \frac{1 + x - \sqrt{1 - 6x + x^2}}{4}. \tag{5}$$

They derived, for $n \geq 2$, the formula

$$f_n = \sum_{0 \leq k \leq n/2-1} 3^{n-2-2k}\, 2^k \binom{n-2}{2k} C_k. \tag{6}$$

Equation (5) together with the first ten values of f_n appear already in [17]. Interestingly, numbers f_n and equation (4) can also be found (without any combinatorial interpretation) in [15], p. 168.

Dissections of a convex polygon. A *dissection* of a convex polygon P with labeled vertices is a set of diagonals, no two of them crossing. Dissections with various restrictions on the face sizes were enumerated by Etherington [5]. Etherington pointed out that the case when there is no restriction at all is equivalent to Schröder's bracketing problem. Similar problems were investigated by Motzkin [10].

Roselle [16] gave the following bijection that matches dissections of a convex $(n+1)$-gon and $MDS(n)$ sequences. Let D be a dissection of P with vertices labeled by $1, 2, \ldots, n+1$ clockwise. Start with the sequence $12 \ldots n1$. Then insert between $j-1$ and j in the decreasing order the numbers k where $k < j$ and kj is a diagonal of D. Similarly insert between n and 1 the decreasing list of numbers k joined by a diagonal to $n+1$. What you get is an $MDS(n)$ sequence.

In fact, Roselle described this bijection only for the case of triangulations and $MDS(n)$ sequences with maximum length. It is well known that triangulations are counted by Catalan numbers and Roselle gave this way an alternative proof of (3). However, it is easy to see that the bijection works in general and that it matches the elements of $MDS(n)$ of length k with dissections of a convex $(n+1)$-gon with $k-n-1$ diagonals. And this implies already (2) because as early as 1866 Prouhet [14] (see [3], p. 75) counted the number, $r(n,d)$, of dissections of a convex n-gon by d diagonals:

$$r(n,d) = \frac{1}{d+1}\binom{n-3}{d}\binom{n+d-1}{d}. \tag{7}$$

Thus $f_{n,k} = r(n+1, k-n-1)$, and (7) combined with (1) give (2). Since this combination leading to a combinatorial proof of (2) went unnoticed, we take the freedom to present another combinatorial proof.

Bracketings of a product. Schröder [17] discovered the family in 1870 by solving the following problem. Given a noncomutative product of n terms, in how many ways can one bracket them so that each bracket contains at least two factors? The outer bracket is not allowed. The answer is again given by the numbers f_n.

A nice exposition of (4) and (5) is in Comtet [3] on p. 56 who gives the expression, $n > 2$,

$$f_n = \sum_{0 \le k \le n/2} (-1)^k \, \frac{(2n-2k-3)!!}{k!(n-2k)!} \, 3^{n-2k} \, 2^{-k-2}. \tag{8}$$

Here $(2n-2k-3)!!$ denotes the odd factorial $1 \cdot 3 \cdot 5 \cdots (2n-2k-3)$. Standard Lagrange inversion (see Goulden and Jackson [7], problem 2.7.12) yields a simpler alternating expression

$$f_n = \frac{1}{n}\sum_{i=0}^{n-1}(-1)^i 2^{n-1-i}\binom{n}{i}\binom{2n-2-i}{n-1}. \tag{9}$$

Other disguises. There is an obvious tree disguise of the problem. It was noticed already by Etherington that bracketings of n terms can be visualized by rooted plane trees having n leaves and no vertex with degree 1. Two other, less obvious, tree disguises are given in the next two sections.

Besides (2) Gardy and Gouyou-Beauchamps in [6] determined the average length and average number of symbols of a $DS(n)$ sequence and found the bivariate generating function for $b_{n,k}$'s. They gave also a bijection between $DS(n)$ and Schröder words of length $2n-2$. These are words over the alphabet $\{x, \bar{x}, y\}$ given by the language equation

$$X = 1 + yyX + xX\bar{x}X.$$

3 Coding and counting

The first step in our combinatorial proof of (2) is an encoding of $DS(n)$ by the set $CT(n)$ of pairs $\mathcal{T} = (T, S)$, where T is an rp tree on n vertices and S is a subset of nonleaves of T. We call them *circled rooted plane trees*, or shortly *crp trees*, since we visualize the distinguished nonleaves as being circled. See Figure 1. The encoding is easier to describe recursively but the nonrecursive version is easier to perform.

Recursive version. Suppose $u = a_1 a_2 \dots a_k$ is a $DS(n)$ sequence. If $k = 1$ then u is encoded by a single uncircled vertex. Otherwise we use the decomposition $u = 1u_1 1u_2 \dots 1u_l$ of u by all appearances of 1. A moment of thought reveals that the segments u_i are nonempty, except possibly for u_l, they do not share symbols, and each u_i satisfies conditions 3 and 4 of the definition of $DS(n)$. We rename the symbols so that u_i complies with conditions 1 and 2 as well and we encode u_i by $\mathcal{T}_i$. The sequence u is encoded by the crp tree $\mathcal{T}$ with principal subtrees from left to right $\mathcal{T}_1, \mathcal{T}_2, \dots, \mathcal{T}_l$, the

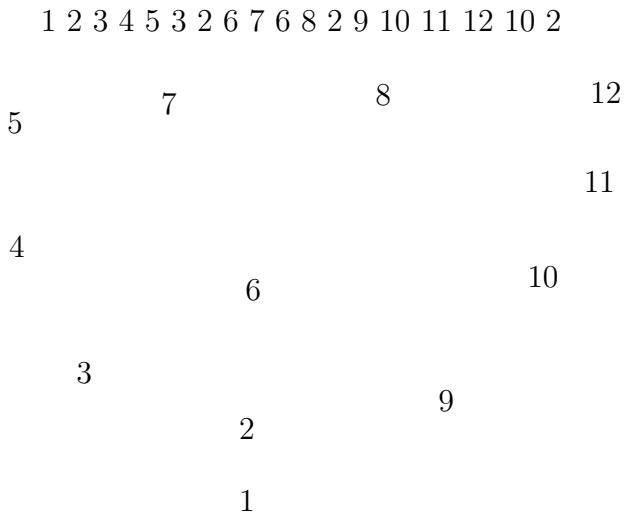

Figure 1: Encoding by crp trees

root of $\mathcal{T}$ is circled iff u_l is empty. We leave the inverse decoding to the reader.

Nonrecursive version. Suppose $u = a_1 a_2 \dots a_k$ is a $DS(n)$ sequence. A crp tree (T, S) on n vertices is generated, the algorithm uses three auxiliary variables: i is the index of the currently processed term of u, v denotes the currently processed vertex, and C is either empty or a singleton set containing a candidate for an element of the set S.

We initialize the variables by setting $i := 1, v := p$, and $S := C := \emptyset$, where p, the root, is an arbitrary point in the plane labeled by $a_1 = 1$. In the general step if $i = k$ we are done. If $i < k$ then there is to distinguish two cases.

1. a_{i+1} has appeared earlier in the sequence. We denote by q the unique vertex on the path joining the root and v which is labeled by a_{i+1}. We put

$$i := i + 1,\ v := q,\ S := S \cup C, \text{ and } C := \{v\} = \{q\}.$$

In the case that now $i = k$ (we did the last step) we add q to S.

2. a_{i+1} is a new symbol. We join to v, above v and to the right of the

children of v, a new child q and give it the label a_{i+1}. Then we put

$$i := i + 1,\ v := q,\ S := S, \text{ and } C := \emptyset.$$

So S consists of vertices which were reached by a jump from above, and from which we jumped down again or for which the procedure terminated. In the end we can discard the labels. Even so it is easy to reconstruct u from the crp tree (T, S). We describe it now.

If (T, S) is a crp tree then the corresponding $DS(n)$ sequence $u = a_1 a_2 \dots a_k$ arises by climbing up and jumping down around T clockwise and writing down the labels of vertices. On the beginning the vertices are unlabeled. We start at the root r and give it the label 1. Whenever an unlabeled vertex is encountered it is given the least unused label. We go up without jumps to the leftmost leaf z. For the crp tree on Figure 1 we produce 12345. Then we jump down on the r-z path P in jumps following elements of $P \cap S$ until we reach a vertex $v \in P$ that has a child to the right of P. In our example we perform the jumps 53 and 32. It is irrelevant now that 2 is circled, we would end in it anyway. From v we continue in consecutive steps upward to the second leftmost leaf and so on. For the rightmost leaf w, which is the last one to be visited, there is no such vertex v and we finish jumping at the lowest element of $Q \cap S$ where Q is the r-w path. If $Q \cap S = \emptyset$ then we finish at w. In our example we finish at 2 and only now it matters that 2 is circled.

We recall that $l(T)$ is the number of leaves in T. The following theorem summarizes the above encoding procedures.

Theorem 3.1 *The above encodings give a bijection between the sets $DS(n)$ and $CT(n)$. It follows that $b_{n,k}$ equals to the number of crp trees (T, S) on n vertices with $2n - k - 1$ uncircled nonleaves, i. e. crp trees (T, S) with $|V(T)| = n$ and $n - l(T) - |S| = 2n - k - 1$.*

Proof. Using our recursive version we can easily prove the bijectivity. If $u \in DS(n)$ has length k then it is encoded by a crp tree (T, S) on n vertices such that $k = n + l(T) + |S| - 1$. So the set of circled nonleaves S has $k - n - l(T) + 1$ elements and the complement S^c (complement in the set of nonleaves) has $n - l(T) - |S| = 2n - k - 1$ elements. □

It is easier to count the pairs (T, S^c) than the pairs (T, S) because the cardinality $|S^c|$ is independent of the structure of T. Therefore (formally we

switch between circled and uncircled nonleaves) it suffices to count crp trees with a fixed number of vertices and circles. The next step is an encoding of crp trees by *rooted plane trees with dots*, shortly *drp trees*. We need few definitions.

Consider an rp tree T with n vertices drawn as a picture in the plane. Let v be a vertex with $d = deg(v)$ children. The $d+1$ edges incident with v, which are drawn as straight segments, split the neighborhood of v into $d+1$ wedge-shaped areas which we call *gaps* of v. For the root of T there is no difference, we imagine an edge joining it to a virtual parent. The set $g(T)$ of all gaps in T has $\sum_V (deg(v)+1) = 2n-1$ elements. A *drp tree* is a pair (T, D) where T is an rp tree and D is a finite multisubset of $g(T)$. This means that we distinguish, possibly with repetitions, some gaps of T. We visualize a drp tree (T, D) as an rp tree T with D determined by dots distributed in the gaps of T. The number of dots in a gap g is then the multiplicity of g in D. Look at the picture on Figure 2.

There is a bijection between crp trees with n vertices and m circles and drp trees with $n-m$ vertices and m dots, the proof is given in the next section. Since it is easy to count drp trees with a given number of vertices and dots, we are done.

Theorem 3.2 *The number of crp trees with n vertices and m circles is*

$$C_{n-m-1} \cdot \binom{2n-m-2}{m}.$$

Proof. From Lemma 4.2 of the next section we know that the number of crp trees with n vertices and m circles is the same as the number of drp trees with $n-m$ vertices and m dots. But this is equal to the number of rp trees on $n-m$ vertices times the number of m element multisubsets of a $2n-2m-1$ element set. □

The proof of (2) is finished, (2) follows immediately from Theorems 3.1 and 3.2 by setting $m = 2n-k-1$.

The total number b_n of $DS(n)$ sequences can be counted in two ways. One can sum (2) for all $k = n, n+1, \ldots, 2n-1$. Changing the summation range the expression found in [6] follows:

$$b_n = \sum_{j=0}^{n-1} \frac{1}{j+1} \binom{2j}{j} \binom{j+n-1}{2j}. \tag{10}$$

The other way is to form groups of crp trees on n vertices with the same number of leaves. The number, $p(n,l)$, of rooted plane trees on n vertices with l leaves is given by the well known formula (first appearing implicitly in [12])

$$p(n,l) = \frac{1}{n-l}\binom{n-1}{l}\binom{n-2}{l-1}.$$

Note that $p(n,l) = p(n,n-l)$. The number of crp trees with the same underlying rp tree is 2^{n-l}. Hence

$$b_n = \sum_{l=1}^{n-1} p(n,l)\cdot 2^{n-l} = \sum_{l=1}^{n-1} \frac{2^l}{n-l}\binom{n-1}{l}\binom{n-2}{l-1}. \tag{11}$$

Well, how many $MDS(n)$ sequences are there then? From either (4), (6), (8), (9), (10) or (11), taking (1) into account, we get

$$\{f_n\}_{n\geq 1} = \{1,1,3,11,45,197,903,4279,20793,103049,\ldots\}.$$

This is the 1163-rd sequence in the phenomenal Sloane's handbook [19].

4 Contractions and expansions

We show that there is a natural bijection between crp trees with n vertices and m circles and drp trees with $n-m$ vertices and m dots. As an example to illustrate our idea we consider first crp and drp trees with one circle and one dot. Let $(T,\{v\})$ be such a crp tree, let e join v to its leftmost child. We put one dot d in the gap of v lying to the right of e and contract e. The drp tree obtained is denoted by $(T^*,\{d\})$. It is easy to see how to recover $(T,\{v\})$ from $(T^*,\{d\})$. Hence the mapping $(T,\{v\}) \to (T^*,\{d\})$ is the desired bijection in the case $m=1$.

To generalize this to $m>1$ we need to define a more general tree structure with both circles and dots and we need to define an order to perform the contractions. First we recall the standard linear order $(V,\prec)$ on the vertex set of an rp tree T. For two distinct vertices $u,v\in V$ one considers the paths P_u and P_v joining the root to u and v. Two cases arise.

1. One path — say P_u — is an initial segment of the other path. Then $u \prec v$.

2. Otherwise there is a branching point and one path — say P_u — branches to the right. Then again $u \prec v$.

Suppose (T, S, D) is a triple where (T, S), resp. (T, D), is a crp tree, resp. a drp tree. We define a partial ordering $(S \cup D, \prec)$. If $x \in S \cup D$ then x is either a circled vertex v or a dot in a gap of a vertex v, in both cases the expression the *vertex of* x refers to v. Let $x, y \in S \cup D$ be two distinct elements, let u be the vertex of x, and let v be the vertex of y.

1. $u \neq v$. We set $x \prec y$ iff $u \prec v$.

2. $u = v$. If x is a dot in a gap g and y is a dot in a gap h, g and h belong to the same vertex, we set $x \prec y$ iff g lies to the right of h. In the two remaining cases — both x and y are dots in the same gap or one of them is a dot and the other is a circled vertex — x and y are set to be incomparable.

A *circled rooted plane tree with dots*, shortly a *cdrp tree*, is a triple $\mathcal{T} = (T, S, D)$ where (T, S), resp. (T, D), is a crp tree, resp. a drp tree, and such that $S \prec D$. In other words, $v \prec d$ for any $v \in S$ and any $d \in D$. In particular, each gap of a circled vertex is empty. We define two mutually inverse operations on $\mathcal{T}$ with an example to illustrate them on Figure 2. The operations preserve the sum $|S| + |D|$. Let v be the largest, with respect to $\prec$, vertex of S and w be its leftmost child. Let d be one of the minimal dots.

Contraction of $\mathcal{T}$ contracts the edge $e = \{v, w\}$, i.e. e is deleted and v and w are identified. The new vertex z created by the identification is not circled. All other circles are preserved. The dots of the leftmost gap of w appear now in the leftmost gap of z and the dots of the rightmost gap of w appear now in what was the second leftmost gap of v. Furthermore we add to the latter one more dot. The distribution of dots in other gaps is preserved. Resulting cdrp tree is denoted by $C(\mathcal{T})$.

Expansion of $\mathcal{T}$ expands d. Suppose d is located in a gap g of a vertex z. We delete d and split z into two vertices w and v. The vertex w is slightly to the left of v and is joined only to those children of z which were to the left of g. Vertex v is joined to the remaining children and to the parent of z. Now w is moved upward a bit with all the dots it bears and is joined to v as its new leftmost child. The dots of g appear now in the rightmost gap of w. All gaps of v are empty. Vertex v is circled, vertex w is not circled. Dots in other gaps and other circles are preserved. Resulting cdrp tree is denoted by $E(\mathcal{T})$.

Lemma 4.1 *$C(\mathcal{T})$ and $E(\mathcal{T})$ are cdrp trees again. Also $C(E(\mathcal{T})) =$*

$E(C(\mathcal{T})) = \mathcal{T}$ *whenever the operations involved are defined.*

Proof. The lemma can be easily proved by an inspection of the above definitions. The proof is left to an interested reader. □

Let $\mathcal{T} = (T, S)$ be a crp tree with n vertices and m circles. We assign to $\mathcal{T}$ a drp tree $\mathcal{U} = C^m(\mathcal{T})$ which arises by m iterations of the contraction operation on $\mathcal{T}$.

Lemma 4.2 *The above assignment is a bijection between crp trees with n vertices and m circles and drp trees with $n - m$ vertices and m dots.*

Proof. It follows immediately from the previous lemma that the mappings $\mathcal{T} \to \mathcal{U} = C^m(\mathcal{T})$ and $\mathcal{U} \to \mathcal{T} = E^m(\mathcal{U})$ are inverses of one another. □

Abstract

We construct a bijection proving that the following two sets have the same cardinality: (i) the set of words over $\{-1, 0, 1\}$ of length $m-2$ which have every initial sum nonnegative, and (ii) the set of partitions of $\{1, 2, \ldots, m\}$ such that no two consecutive numbers lie in the same block and for no four numbers the middle two are in one block and the end two are in another block. The words were considered by Gouyou-Beauchamps and Viennot who enumerated by means of them certain animals. The identity connecting (i) and (ii) was observed by Klazar who proved it by generating functions.

Keywords: set partition; bijection; nonnegative prefix

Let us denote, for $m > 0$, $[m] = \{1, 2, \ldots, m\}$. A sequence $a = a_1 a_2 \ldots a_k$ is a *nonnegative word* if $a_i \in \{-1, 0, 1\}$ for each i and for each initial segment of a the sum of its elements is nonnegative. Recall that $\mathcal{A} = \{A_1, A_2, \ldots, A_n\}$ is a partition of $[m]$ if the A_is (called *blocks*) are nonempty disjoint subsets of $[m]$ and their union is $[m]$. We say that $\mathcal{A}$ is *sparse* if for every $i \in [m-1]$ the elements i and $i+1$ lie in two distinct blocks. $\mathcal{A}$ is called *abba-free* if it does not happen for any four elements $i < j < k < l$ of $[m]$ that i, l lie in a common block and j, k in another common block. For example, $\{\{1, 5, 7\}, \{2, 4\}, \{3, 6\}\}$ is a sparse partition that is not *abba*-free.

[1]Supported by the project LN00A056 of the Ministry of Education of the Czech Republic.

[2]Corresponding author, klazar@kam.mff.cuni.cz

The partition $\{\{1,2,5,7\},\{4\},\{3\},\{6,8\}\}$ is *abba*-free but it is not sparse. We give a direct proof, without using generating functions, for the following theorem originally due to Klazar [2].

Theorem. For every $m \geq 3$ there exists a bijection G between the set of sparse *abba*-free partitions of $[m]$ and the set of nonnegative words of length $m-2$.

Gouyou-Beauchamps and Viennot [1] were interested in counting certain animals (certain sets of plane lattice points) and showed that their animal problem is equivalent to enumeration of nonnegative words (they use slightly different terminology). Klazar [2] was interested in counting set partitions subject to structural restrictions and obtained as a byproduct the above identity. His derivation uses substantially generating functions. Indeed, if r_m is the number of sparse *abba*-free partitions of $[m]$, then ([2])

$$\sum_{m=0}^{\infty} r_m x^m = 1 + \frac{x}{2}\sqrt{\frac{1+x}{1-3x}}.$$

Analogous formula for nonnegative words was derived before in [1]. The sequence

$$(r_m)_{m\geq 2} = (1,2,5,13,35,96,267,750,2123,6046,17303,49721,\ldots)$$

is sequence A005773 of Sloane [3]. Stanley [4, Problem 6.46] and [3] give further information and references on these numbers. Our aim is to avoid the use of generating functions and to give a bijection proving the identity.

We need few more definitions. A nonnegative word is a *correct word* if the first letter is 1, the last letter is -1, the sum of all letters is zero, and each proper initial segment has a positive sum. We say that the letter a_j in a word over $\{-1,0,1\}$ is *dominant* if $a_j = 1$ and the sum of letters in every interval beginning in a_j is positive. For a a correct word of length at least three, a' is obtained from a by deleting the first and the last letter. Obviously, a' is a nonnegative word. For a partition $\mathcal{A} = \{A_1, A_2, \ldots, A_n\}$ of $[m]$ we denote $|\mathcal{A}| = m$. Similarly, for a sequence a we denote $|a|$ its length. We say that $j \in [m]$ is *covered* in $\mathcal{A}$ if there exist $i,k \in [m]$ and $A_r \in \mathcal{A}$ so that $i < j < k$, $i,k \in A_r$, and $j \notin A_r$. If every element of $\{2,\ldots,m-1\}$ is covered in $\mathcal{A}$, we say that $\mathcal{A}$ is a *connected partition*. Any partition $\mathcal{A}$, $|\mathcal{A}| = m$, can be written in a *sequential form*. This is a sequence $b = b_1 b_2 \ldots b_m$ of length m

over some alphabet such that $b_i = b_j$ if and only if i, j lie in the same block of $\mathcal{A}$. A partition has many sequential forms. One of them is the *canonical sequential form* in which the alphabet is $[n]$ (n is the number of blocks in $\mathcal{A}$) and the first occurrence of every $i \in [n]$, $i > 1$, in b is preceded by the first occurrence of $i - 1$. In particular, b starts with 1. Each partition has a unique canonical sequential form. It is convenient to write specific partitions in (canonical) sequential form. For example, the canonical sequential form of

$$\{\{1, 5, 7\}, \{2, 4\}, \{3, 6\}\} \text{ is } 1232131$$

(we will omit commas in the sequential forms of partitions).

Lemma 1. Each block of a connected sparse *abba*-free partition of $[m]$, $m \geq 3$, has at most two elements. Moreover, the block containing 1 and the block containing m have exactly two elements.

Proof. Suppose that $j < k < l$ belong to the same block, say B, of $\mathcal{A}$. Since k is covered, there exist s and t, $s < k < t$, belonging to the same block A that is different from B. It is easy to check that each of the four positions of s, j and t, l leads to the forbidden pattern *abba*. For example, if $j < s$ and $t < l$ then $j < s < t < l$ form the *abba* pattern. If $\{1\}$ were a block, 2 would not be covered. Similarly $\{m\}$ cannot be a block. □

We consider the following mapping F from the set of partitions of $[m]$ with no block with more than two elements to words over $\{-1, 0, 1\}$ with length m. $F(\mathcal{A}) = a_1 a_2 \dots a_m$ where $a_i = 0$ if $\{i\} \in \mathcal{A}$, $a_i = 1$ if i is the first element of the two-element block containing i, and $a_i = -1$ if i is the second element. For example, $F(1234153) = 1, 0, 1, 0, -1, 0, -1$.

Lemma 2. For every $m \geq 3$, F is a bijection between the set of connected sparse *abba*-free partitions of $[m]$ and the set of correct words of length m.

Proof. By the previous lemma, if $\mathcal{A}$ is a connected sparse *abba*-free partition, $F(\mathcal{A})$ is defined and is a word beginning with 1 and ending with -1. Every initial sum of $F(\mathcal{A})$ is nonnegative for else we would have in the corresponding initial segment of $\mathcal{A}$ more second elements of two-element blocks than the first elements, which is impossible. Moreover, for no i, $1 < i < m$, the sum of the first i letters is zero because then i would not be covered. Thus $F(\mathcal{A})$ is a correct word.

We define the inverse mapping F^{-1}. Let $a = a_1 a_2 \dots a_m$ be a correct word and let the partition $F^{-1}(a) = \mathcal{A}$ be defined in the following way. If

$a_i = 0$ then $\{i\}$ is a (singleton) block of $\mathcal{A}$ and if a_i is the kth occurrence of 1 in a and a_j is the kth occurrence of -1, then $\{i, j\}$ is a block of $\mathcal{A}$. Note that always $i < j$ and that the second elements of two-element blocks come in the same order as the first elements. Thus $\mathcal{A}$ is *abba*-free. $\mathcal{A}$ is connected because if an inner element i were not covered, then the sum of the first $i-1$ letters of a would be zero. $\mathcal{A}$ is sparse because $\{i, i+1\} \in \mathcal{A}$ implies that $a_1 + a_2 + \cdots + a_{i-1} = 0$ and $a_1 + a_2 + \cdots + a_{i+1} = 0$. Finally, it is easy to check that F and F^{-1} are inverses of one another and thus F is a bijection. □

For a sparse *abba*-free partition $\mathcal{A}$ of $[m]$, $m \geq 3$, consider the collection $\mathcal{A}^*$ of maximal subintervals $I \subset [m]$ of length at least three for which the induced partition $\mathcal{A}|I$ is connected.

Lemma 3. Every two distinct intervals $I_1, I_2 \in \mathcal{A}^*$ are disjoint or they overlap in one element only.

Proof. Any other position of I_1 and I_2 means that every inner element of $I = I_1 \cup I_2$ is inner in I_1 or in I_2 and thus $\mathcal{A}|I$ is connected. This contradicts the maximality of I_1 or of I_2. □

Thus we can order $\mathcal{A}^*$ as $\mathcal{A}^* = \{I_1, I_2, \ldots, I_n\}_<$ where $I_i = [u_i, v_i]$ and $1 \leq u_1 < v_1 \leq u_2 < v_2 \leq u_3 < \ldots \leq u_n < v_n \leq m$. We define the numbers a_i, $0 \leq i \leq n$, by $a_i = u_{i+1} - v_i - 1$ where we set $v_0 = 0$ and $u_{n+1} = m + 1$. Clearly, $a_i \geq -1$ and a_i is the number of elements strictly between I_i and I_{i+1}, where $a_i = -1$ means that the intervals overlap. Note that every element between I_i and I_{i+1} forms a singleton block.

Now we can define the desired bijection G:

$$G(\mathcal{A}) = 1^{a_0} F(\mathcal{A}_1)' 1^{a_1+2} F(\mathcal{A}_2)' 1^{a_2+2} \ldots 1^{a_{n-1}+2} F(\mathcal{A}_n)' 1^{a_n}.$$

Here $\mathcal{A}$ is a sparse *abba*-free partition of $[m]$, $m \geq 3$, 1^i abbreviates the sequence $1, 1, \ldots, 1$ of i 1s, a_i are the above defined numbers, $\mathcal{A}_i$ is the restriction of $\mathcal{A}$ to I_i (where $\mathcal{A}^* = \{I_1, I_2, \ldots, I_n\}_<$) normalized so that the ground set equals $[|I_i|] = [v_i - u_i + 1]$, F is the mapping of Lemma 2, and $'$ means the deletion of the first and last letter. If $n = 0$, that is if $\mathcal{A}^* = \emptyset$ and $\mathcal{A}$ has only singleton blocks, we set

$$G(\mathcal{A}) = 1^{a_0 - 2} = 1^{m-2}.$$

We prove that G is indeed a bijection between all sparse *abba*-free partitions of $[m]$ and all nonnegative words of length $m-2$. By Lemma 2, $F(\mathcal{A}_i)$ is a correct word. Hence $F(\mathcal{A}_i)'$ is a nonnegative word and the whole $G(\mathcal{A})$ is a nonnegative word. Its length is $m-2$ if $\mathcal{A}^* = \emptyset$ and

$$\sum_{i=1}^{n}(a_{i-1} + |F(\mathcal{A}_i)| - 2) + a_n + 2(n-1) = \sum_{i=1}^{n}(a_{i-1} + |I_i|) + a_n - 2 = m - 2$$

if $\mathcal{A}^* \neq \emptyset$.

We define the inverse mapping G^{-1}. Let $b = b_1 b_2 \dots b_{m-2}$, $m \geq 3$, be a nonnegative word. There is a unique decomposition of b into intervals

$$b = c_0 d_1 c_1 d_2 \dots c_{n-1} d_n c_n$$

such that c_0 is the longest initial interval in which every element is dominant, d_1 is the longest interval starting immediately after c_0 whose elements sum up to zero, c_1 is the longest interval starting immediately after d_1 in which every element is dominant and so on. Note that c_0 and c_n may be empty but the other intervals are nonempty, $c_i = 1^{e_i}$ where e_i is a nonnegative integer, and every d_i is a nonnegative word. If $b = c_0$, b consists only of 1s, and we set $G^{-1}(b)$ to be the partition of $[m]$ having just the singleton blocks $\{1\}, \{2\}, \dots, \{m\}$. If $n > 0$, we define $\mathcal{A}_i = F^{-1}(1, d_i, -1)$ where F^{-1} is the inverse mapping to F of Lemma 2, defined in its proof. The word $1, d_i, -1$ is a correct word and $\mathcal{A}_i$ is a connected sparse *abba*-free partition of some initial interval of positive integers. We define the numbers a_i as $a_0 = e_0$, $a_n = e_n$, and $a_i = e_i - 2$ for $0 < i < n$. Finally, we set

$$G^{-1}(b) = \mathcal{B}_0 \mathcal{A}_1 \mathcal{B}_1 \mathcal{A}_2 \dots \mathcal{B}_{n-1} \mathcal{A}_n \mathcal{B}_n$$

where $\mathcal{B}_i$ is, for $a_i > 0$, a partition consisting of a_i singleton blocks. If $a_i = 0$, $\mathcal{B}_i = \emptyset$ and $\mathcal{A}_i$ and $\mathcal{A}_{i+1}$ are neighbours. If $a_i = -1$, $\mathcal{B}_i = \emptyset$ and $\mathcal{A}_i$ and $\mathcal{A}_{i+1}$ are made to overlap in the last element of $\mathcal{A}_i$ and the first element of $\mathcal{A}_{i+1}$. The two blocks which now intersect merge into one block. We have

$$|G^{-1}(b)| = \sum_{i=0}^{n} a_i + \sum_{i=1}^{n} |\mathcal{A}_i| = \sum_{i=0}^{n} |c_i| - 2(n-1) + \sum_{i=1}^{n} |d_i| + 2n = |b| + 2 = m.$$

The operation of concatenation includes, of course, the appropriate shifting of the ground sets of $\mathcal{A}_i$ and $\mathcal{B}_i$ so that the ground set of the resulting partition $G^{-1}(b)$ equals $[m]$.

It is easy to check that the resulting partition $G^{-1}(b)$ is a sparse *abba*-free partition of $[m]$ and that for every $\mathcal{A}$ and b we have $G^{-1}(G(\mathcal{A})) = \mathcal{A}$ and $G(G^{-1}(b)) = b$. Thus G and G^{-1} are bijections. The theorem is proved.

As an example, we list in the lexicographical order all 13 sparse *abba*-free partitions of [5] in their canonical sequential form and the corresponding nonnegative words with length 3:

$$\begin{aligned}
G(12123) &= F(1212)', 1 = (1,1,-1,-1)', 1 = 1,-1,1.\\
G(12131) &= F(121)', 1, F(131)' = (1,0,-1)', 1, (1,0,-1)' = 0,1,0.\\
G(12132) &= F(12132)' = (1,1,-1,0,-1)' = 1,-1,0.\\
G(12134) &= F(121)', 1^2 = (1,0,-1)', 1, 1 = 0,1,1.\\
G(12312) &= F(12312)' = (1,1,0,-1,-1)' = 1,0,-1.\\
G(12313) &= F(12313)' = (1,0,1,-1,-1)' = 0,1,-1.\\
G(12314) &= F(1231)', 1 = (1,0,0,-1)', 1 = 0,0,1.\\
G(12323) &= 1, F(2323)' = 1, (1,1,-1,-1)' = 1,1,-1.\\
G(12324) &= 1, F(232)', 1 = 1, (1,0,-1)', 1 = 1,0,1.\\
G(12341) &= F(12341)' = (1,0,0,0,-1)' = 0,0,0.\\
G(12342) &= 1, F(2342)' = 1, (1,0,0,-1)' = 1,0,0.\\
G(12343) &= 1^2, F(343)' = 1,1,(1,0,-1)' = 1,1,0.\\
G(12345) &= 1^3 = 1,1,1.
\end{aligned}$$

On Carlitz compositions

Abstract. This paper deals with Carlitz compositions of natural numbers (adjacent parts have to be different). The following parameters are analyzed: Number of parts, number of equal adjacent parts in ordinary compositions, largest part, Carlitz compositions with zeros allowed (correcting an erroneous formula from Carlitz). It is also briefly demonstrated that so--called 1--compositions of a natural number can be treated in a similar style.

What is a Question?

Kevin H. Knuth

NASA Ames Research Center, Computational Sciences Department, Code IC
Moffett Field CA 94035 USA

Abstract. A given question can be defined in terms of the set of statements or assertions that answer it. Application of logical inference to these sets of assertions allows one to derive the logic of inquiry among questions. There are interesting symmetries between the logics of inference and inquiry; where probability describes the degree to which a premise implies an assertion, there exists an analogous measure that describes the bearing or relevance that a question has on an outstanding issue. These have been extended to suggest that the logic of inquiry results in functional relationships analogous to, although more general than, those found in information theory.
