List of Works Citing The Encyclopedia of Integer Sequences

- In order to demonstrate some of the ways in which people have found the **Encyclopedia of Integer Sequences** or **Superseeker** useful, the following is a list of some papers and books that reference the database.
- Papers from the **Journal of Integer Sequences** have been deliberately omitted.
- I have included several papers of my own - well, I too find the database very useful!
- Suggestions for additional references will be welcomed. Send them to me at this address: njas@research.att.com
- Thanks to Antonio Garcia Astudillo for supplying many updates and new items over the past two years.

Welcome to the On-Line Encyclopedia of Integer Sequences

- **Other pages:** Use database | Run demo | Sequence WebCam | Index | FAQ (new) | Format (internal) | Versions in other languages | Recent Additions

- **Contents of this page:** New Users | Description of the Database | Sources | Editorial Board | Arrangement of Sequences in Database | The Full Database | Recent additions | Gzipped Version | Contributing New Sequence or Comment; Helping | Sequences in Classic Books | Papers Citing the Encyclopedia of Integer Sequences | Referencing the OEIS | URLs | Referencing a Particular Sequence | URL for Searching the Database | Policy on Email Addresses | Copyright Notice | Acknowledgments | Links | Awards, etc.

- **New Users:**
  - Let's begin at once with an example of a sequence of great importance:

```
ID Number: A060843
Sequence:  1,6,21,107
Name:      Busy Beaver problem: maximal number of steps that an
n-state Turing
               machine can make on an initially blank tape before
eventually halting.
Comments:  The function Sigma(n) (A028444) denotes the maximal
number of tape
               marks which a Turing Machine with n internal
states and a two-way
               infinite tape can write on an initially empty tape
and then halt. The
               function S(n) (the present sequence) denotes the
maximal number of steps (shifts)
               which such a machine can make (it needs not
produce many tape marks).
           Given that 5-state machines can compute Collatz-like
congruential
               functions (see references), it may be very hard to
find the next term.
           The sequence grows faster than any computable
function of n, and so is
               non-computable.
```

- Most people use this web site to get information about a particular number sequence. If you are a new visitor, then you might ask the database if it can recognize your favorite sequence, if you have one. To do this, go to the **main look-up page**. (Of course, the number sequence should be well-defined, of general interest and ideally it should be infinite. Short sequences such as phone numbers are not appropriate.)

- If your sequence isn't in the database, and if it is interesting, please submit it using the web page for **contributing a new sequence or comment**.

- If you have stumped the database, you can try **Superseeker**, which tries really hard to identify a sequence.

- You can **Browse** the database, to look at the most interesting sequences. This can be quite addictive.

- It is interesting to scan the **Index** to the database to see the variety of topics that are covered. In a way this database can be regarded as an index to all of science. It is like a dictionary or fingerprint file for number sequences.

- Also worth visiting are the pages dealing with **Puzzle sequences**, **Classic sequences** and **Hot sequences**.

- You can run the **demonstration** pages to see more examples of how to use the On-Line Encyclopedia of Integer Sequences.

- Finally, you might like to see a **list of papers that have acknowledged help from the database** and some **comments from readers**.

- **Description of the Database (or, What is the Next Term?)**
  What comes next after 1, 2, 4, 9, 20, 48, 115, 286, 719, ... ? (for example). This is the place to find out!
  The main table is a collection of number sequences arranged in lexicographic order. The entry for each sequence gives:
  - the beginning of the sequence
  - its name or description

- any references or links
- any formulae
- cross-references to other sequences
- the name of the person who submitted it, etc.

For further information about the format of replies received from the database, **click here**. A second file describes the **internal format** in which the sequences are stored in the database. See also the **hints file** for further useful information.

- **Sources:** Since the mid-1960's Neil Sloane has been collecting integer sequences from every possible source. His goal is to have **all** interesting number sequences in the table. At the present time the table contains over 80000 sequences. 5487 of the best of these sequences were published in 1995 in **The Encyclopedia of Integer Sequences**, by Neil Sloane and Simon Plouffe. The book is still useful - and still in print - since it contains many of the most important sequences. The database (which is now more than 75 times the size of the book) is too huge to use except as a reference.

- **Editorial Board:** Beginning in 2002, a group of associate editors has been helping to process new sequences and updates to the database. At present the associate editors are:

  - Henry Bottomley (se16(AT)btinternet.com)
  - Christian G. Bower (bowerc(AT)usa.net)
  - Ray Chandler (RayChandler(AT)alumni.tcu.edu)
  - Patrick De Geest (pdg(AT)worldofnumbers.com)
  - Frank Ellermann (Frank.Ellermann(AT)t-online.de)
  - Richard K. Guy (rkg(AT)cpsc.ucalgary.ca)
  - Dean Hickerson (dean(AT)math.ucdavis.edu)
  - Antti Karttunen
  - John W. Layman (layman(AT)math.vt.edu)
  - Marc LeBrun (mlb(AT)well.com)
  - Jud McCranie (j.mccranie(AT)adelphia.net)
  - Simon Plouffe (plouffe(AT)math.uqam.ca)
  - James A. Sellers (sellersj(AT)math.psu.edu)
  - Neil J. A. Sloane (njas@research.att.com) , editor-in-chief
  - Leonard Smiley (smiley(AT)math.uaa.alaska.edu)
  - Michael Somos (somos(AT)grail.cba.csuohio.edu)
  - David W. Wilson (davidwwilson@comcast.net)
  - Robert G. Wilson v (rgwv(AT)rgwv.com)

  Many other volunteers help by sending corrections, comments, links or even completely editing an entry.

- **Arrangement of Sequences in Database.** Most of the sequences are arranged in the database in lexicographic order of absolute values, indexed by the position of the first term that is greater than 1 in absolute value. Sequences that contain only 0's, 1's and -1's are in strict lexicographic order by absolute value at the beginning of the table. Thus there is an essentially unique place to look in order to see if a

sequence is already in the table. (If it isn't, submit it and it will added if it is sufficiently interesting - see **Sending in a new sequence**.) Sequences received in the last few days and not yet placed in the lexicographic ordering will be found at the **end of the table**.

- **Format used in replies from the database**. **Internal format used in the database**.

- **Short index** to the most important sequences. **Search for a word** in the database.

- **The Full Database** (arranged lexicographically, as explained above) is contained in the following files. Note that these are all very large files! Recent arrivals are at the end of the last file. The list of files and the first sequence in each file are as follows:
Part 0 : 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0, ...
Part 1 : 1,1,1,0,1,0,0,0,0,0,0,0,1,0,0,1,1,1,1,1,1,1,1,0,0,0,1,0,0,0,1,1,1,1,1, ...

- **Recent Additions**

- A **gzipped file** containing just the sequences and their A-numbers (about 5 megs)

- **Contributing a new sequence** (or a comment on an existing sequence, or more terms for an existing sequence).
  Want to help? See the lists of **sequences that need extending** and **future projects.**
  Other related pages: **Demos**, **Transformations of sequences**, **Maple** **or** **Mathematica** scripts to format sequences.

- **Sequences in Classic Books.** Comtet's **Advanced Combinatorics**, Graham, Knuth and Patashnik's **Concrete Mathematics**, Harary and Palmer's **Graphical Enumeration**, Stanley's **Enumerative Combinatorics**.

- **Papers Citing the Encyclopedia of Integer Sequences.** Shows some of the ways that people have used the database.

- **Referencing the OEIS.** If the database helped your work and you wish to reference it, the usual citation is something like this:
  N. J. A. Sloane, editor (2003), The On-Line Encyclopedia of Integer Sequences, http://www.research.att.com/~njas/sequences/.
  Or, since that often causes spacing problems with LaTeX (the line is too long and is hard to break):

N. J. A. Sloane, editor (2003), The On-Line Encyclopedia of Integer Sequences, published electronically at http://www.research.att.com/~njas/sequences/.

- **URLs**
  The URL for the main lookup page is
  http://www.research.att.com/~njas/sequences/
  (or **http://www.research.att.com/%7enjas/sequences/**
  if your keyboard lacks the tilde character).

  The URL for this page is
  http://www.research.att.com/~njas/sequences/Seis.html
  (or **http://www.research.att.com/%7enjas/sequences/Seis.html**
  if your keyboard lacks the tilde character).

- **Referencing a Particular Sequence.** If you are writing a paper and wish to refer the Catalan numbers, say (sequence A000108), but don't want to digress to describe them, simply add a link that points directly to that sequence in the database.

  The URL for sequence A000108 (for example) is

  http://www.research.att.com/projects/OEIS?Anum=A000108

  (this is new short URL introduced June 27, 2003).

  In an HTML file one might say something like this:

  ... where the C(n) are the Catalan numbers
  (Sequence A000108 in [OEIS]).

  One can also create active links in PDF or POSTSCRIPT files. From LATEX for example one can use the HYPERREF package. In that case one would say:

  ... where the $C(n)$ are the Catalan numbers (sequence \htmladdnormallink{A000108} {http://www.research.att.com/projects/OEIS?Anum=000108} in \cite{OEIS}).

  For an example of a LATEX file which produces active links in this way, see **"My Favorite Integer Sequences"** in three versions: LATEX, PDF and POSTSCRIPT.

- **URL for Searching the Database**
  To bypass the web page and search for a sequence directly using the cgi program, for instance the sequence 2,5,14,50,233,
  use (with no line break and no internal spaces):

  ```
  http://www.research.att.com/cgi-bin/access.cgi/as/njas/sequences/
  ```

```
eishis.cgi?sequence=2%2C5%2C14%2C50%2C233
```

To put a window on your own page to do lookups, use the following html commands:

```
To look up a number sequence in the
<a href="http://www.research.att.com/~njas/sequences/">
On-Line Encyclopedia of Integer Sequences</a>,
enter it here and click "Submit":
<form
action="http://www.research.att.com/cgi-bin/access.cgi/as/njas/
sequences/eishis.cgi"
method=post>
<input type=text name=sequence SIZE=60 VALUE=
"1,2,3,6,11,23,47,106,235">
<input type=submit VALUE="Submit">
</form>
```

- **Policy on Email Addresses in the OEIS**
  If possible I prefer to give the author's name and email address with each sequence, so that people can get in touch with each other. This is an important feature of the database.

  Email addresses are disguised by replacing @ by (AT).

  Let me know if you don't want your email address to appear in any form. However, if you ask to have your email address removed, try to give me a link to your home page - send me a line that looks like this:

  %H A077001 John Smith, Home Page

  that I can add to each sequence.

  Again, when sending in a sequence or comment using the **Contribute new seq. or comment** web page, if you don't want your email address to be used, say so in one of the windows, and if possible put the URL of your home page into one of the "links" windows.

- **Copyright Notice.** This database and its associated files are copyright 1996-2003 by N. J. A. Sloane.

- **Acknowledgments.** A very large number of people have contributed to the table, and it is impossible to thank them individually. Their names can be seen in the "Author" and "Extension" lines of the entries. The following are some of the people who have made major contributions in recent years. Antonio G. Astudillo (afg_astudillo(AT)hotmail.com), Asher Natan Auel (auela(AT)reed.edu), Lekraj Beedassy (beedassylekraj(AT)hotmail.com), Mira Bernstein (mira(AT)math.Stanford.edu). The On-Line Encyclopedia of Integer Sequences

The Email Servers and Superseeker

There are two automatic email servers for identifying sequences:

- The first, **sequences@research.att.com**, does a simple look-up in the database. Send the message

  lookup 1 2 5 14 42 132 429 [no commas!]

  for example (with no Subject line). Up to 30 sequences can be submitted at the same time. This service is useful when the World Wide Web is congested.

  The email reply will tell you any sequences in the table (up to a limit of 50) that match your sequence.

  If the word "lookup" does not appear in your message, you will be sent the help file for this server.

  You can also retrieve sequences by A-number -- say
  lookup A12
  lookup A45
  lookup A129
  etc

  (However, you can't have both sequence lookups and A-number lookups in the same email message.)

- The second server does not just look up the sequence in the Encyclopedia, it will also apply a large number of algorithms in order to attempt to explain the sequence. Send a message to

  superseeker@research.att.com

containing a line like

lookup 1 3 5 7 9 11 13 15 17 19 21 23 25 27 29 31

(with no Subject line). The program will try VERY hard to find an explanation. Only one request may be submitted at a time, and (since this program does some serious computing), only one request per user per hour please. If there is no lookup line you will receive the help file. A French version of the help file is also available. (This is not as up-to-date as the English version though.)

These servers are described in more detail in an article in the **Electronic Journal of Combinatorics** (Feature #F1 in Volume 1); in **the book**; and in the help files mentioned above. They have also been written up in **several magazines**.

Journal of Integer Sequences

This is the home page for the electronic Journal of Integer Sequences, ISSN 1530-7638.

- The journal is devoted to papers dealing with integer sequences and related topics.
- All submissions should be sent to the editor-in-chief,

Jeffrey O. Shallit
shallit@graceland.uwaterloo.ca

School of Computer Science
University of Waterloo
Waterloo, Ontario N2L 3G1
Canada

Electronic submission is *very* strongly preferred.Please submit your paper in one of the following formats:

- LaTeX (very strongly preferred)
- TeX
- postscript
- pdf
- html

We regret that we cannot handle submissions in Microsoft Word or Word Perfect formats.

In preparing your paper, please follow the guidelines in our LaTeX style guide:

- postscript format
- pdf format
- dvi format
- tex source

- Editorial board:
  - Henry W. Gould (West Virginia Univ., Morgantown, WV USA),

- Papers should be original, of high quality, and should not have been published in any other journal. (However, publication on web sites or e-print servers is explicitly allowed.) All submissions will be refereed. The standards are those of any serious mathematical journal. Papers should be worthy of being reviewed by **Mathematical Reviews**.

J.-P. Allouche

Finite automata and arithmetic

Abstract. The notion of sequence generated by a finite automaton, (or more precisely a finite automaton with output function, i.e., a "uniform tag system") has been introduced and studied by Cobham in 1972. In 1980, Christol, Kamae, Mendès France and Rauzy proved that a sequence with values in a finite field is automatic if and only if the related formal power series is algebraic over the rational functions with coefficients in this field: this was the starting point of numerous results linking automata theory, combinatorics and number theory. Our aim is to survey some results in this area, especially transcendence results, and to provide the reader with examples of automatic sequences. We will also give a bibliography where more detailed studies can be found.

La recherche expérimentale en mathématiques

Jean-Paul Allouche
CNRS, LRI, Bâtiment 490
F-91405 Orsay Cedex
http://www.lri.fr/~allouche

Le mot *expérience* a deux sens différents en français, d'une part *vérification expérimentale*, d'autre part *expertise* : après avoir *fait* des expériences, on *a* de l'expérience. C'est la même différence que l'on a entre *avoir expérimenté* et *être expérimenté*. Notons que cette ambiguïté n'existe pas dans d'autres langues : par exemple on utilise en anglais *experiment* et *experience*, et en allemand *Experiment* et *Erfahrung*.

S'il semble clair qu'il y a des mathématiciens plus ou moins expérimentés, on peut à rebours se demander s'il existe une démarche expérimentale en mathématiques. Nous nous proposons ici de montrer que l'on peut effectuer des expériences dans la recherche en mathématiques, et que ces expériences ont pour rôle essentiel d'être pourvoyeuses de questions (rappelons au passage que le rôle fondamental de la recherche est de *poser* des questions). Nous aborderons la question du ``statut officiel'' de l'expérimentation en mathématiques, puis ses succès et ses dangers.

Qu'est-ce qu'une expérience en mathématiques ?

On peut distinguer plusieurs types d'expériences en mathématiques. Nous donnons quelques exemples ci-dessous.

- Calculer numériquement les valeurs approchées de constantes. Par exemple calculer des milliers (millions) de décimales du nombre pi ou de la racine carrée de 2. Chercher ensuite si des motifs apparaissent ou si, au contraire, le développement semble ``au hasard''. Pour les deux nombres cités on *conjecture* que chacun des chiffres 0, 1, 2, ... 9, apparaît une infinité de fois avec la fréquence 1/10, que chaque couple de chiffres 00, 01, 02, ..., 99 apparaît une infinité de fois avec la fréquence 1/100, que chaque groupe de 3 chiffres apparaît une infinité de fois avec la fréquence 1/1000, etc. Cette conjecture est totalement hors d'atteinte pour le moment : on ne sait même pas si le nombre pi ou la racine carrée de 2 ont une infinité de 4 (disons) dans leur développement décimal.

- Dessiner des figures. Par exemple dessiner un triangle quelconque. Tracer soigneusement les hauteurs issues de chacun des sommets. Constater qu'elles se coupent en un même point. Puis le

démontrer (c'est un théorème ancien).

- Faire des calculs exacts ou formels. Par exemple étudier la fonction *f* définie sur les nombres entiers par *f(n) = n/2* si est pair, et *f(n) = (3n+1)/2* si *n* est impair. Une conjecture stipule qu'en partant de n'importe quel nombre est en appliquant *f* de manière répétée on atteint 1. Par exemple, en partant de 17 on obtient successivement

  17 --> 26 --> 13 --> 20 --> 10 --> 5 --> 8 --> 4 --> 2 --> 1.

  Cette conjecture est encore *ouverte*. Autrement dit on peut la vérifier par ordinateur jusqu'à des valeurs de *n* gigantesques, mais on ne sait pas *démontrer* que la propriété est vraie pour tout entier *n*.

- Énumérer des structures. Par exemple, pour essayer de répondre à la question ``Combien y a-t-il de groupes finis non isomorphes de cardinal *n* ?", on essaie ``à la main" de trouver tous les groupes d'ordre 1, d'ordre 2, d'ordre 3, d'ordre 4 ...

- Faire des calculs numériques (qui peuvent être compliqués) en chaîne. Par exemple rechercher numériquement des solutions approchées d'équations différentielles.

- On peut aussi combiner par exemple des calculs numériques et des figures (que l'on pense aux objets fractals).

L'apparition d'ordinateurs de plus en plus puissants a permis de faire des expériences en mathématiques, que l'on n'aurait ni faites ni pour certaines même imaginées il y a quelques décennies. Il est intéressant de voir la dialectique qui s'est ainsi installée entre informatique et mathématiques, et l'émergence d'une discipline à la croisée de leurs chemins, appelée informatique théorique par les uns et mathématiques discrètes par les autres. (Rappelons au passage que le *discret* -- que l'on peut se représenter comme le tracé en pointillés -- s'oppose en mathématiques au *continu* -- que l'on peut se représenter comme le tracé à main levée ... sans lever la main.)

Le statut officiel de l'expérience dans la recherche en mathématiques

Dans leurs articles les mathématiciens cachent le plus souvent leurs démarches expérimentales, comme s'il s'agissait de quelque chose d'inavouable. La tendance ``bourbakisante" (du nom de cet auteur collectif de traités mathématiques quasi-définitifs) consiste, lors de la rédaction d'un article de recherche pour une revue spécialisée, à taire les pistes qui n'ont pas abouti, les hésitations ou les expérimentations fécondes ou cruciales. La ``bonne" manière de rédiger consiste à enchaîner linéairement les lemmes, propositions, théorèmes et corollaires. Même les intuitions sont le plus souvent tues, voire soigneusement dissimulées. Au mieux donnera-t-on un exemple pour ses qualités pédagogiques supposées, avec la peur d'écrire ainsi des choses trop ``faciles".

Pour être honnête il convient d'ajouter que cet état d'esprit n'est pas celui de tous les mathématiciens, et que les choses changent. Ainsi dans un récent article (A case study in mathematical research: the Golay-Rudin-Shapiro sequence, American Mathematical Monthly **103** (1996) 854-869) J. Brillhart et P. Morton expliquent-ils leurs motivations, pistes en cul-de-sac, espoirs et déceptions lors de leur travail sur une suite ``classique'' une vingtaine d'années plus tôt. Dans le même ordre d'idées on peut signaler qu'il existe depuis 1992 une nouvelle revue spécialisée qui s'appelle ``Experimental Mathematics'' (la version électronique de cette revue se trouve à l'adresse http://www.expmath.org/).

Rappelons néanmoins le rôle important qu'ont toujours joué les *conjectures* en mathématiques : il s'agit d'affirmations que les experts jugent très vraisemblables, mais qui ne sont pas (pas encore ?) démontrées. Les conjectures n'ont donc pas le statut de ``vérités mathématiques'', mais les plus célèbres d'entre elles ont été ou sont encore extrêmement fécondes, en particulier parce qu'elles ont souvent amené les mathématiciens à créer des théories entières avec l'espoir (éventuellement déçu) d'aboutir à des démonstrations. Les théories ainsi fabriquées ont eu ensuite des applications ou retombées inattendues dans d'autres domaines. Un exemple célèbre est le ``théorème'' de Fermat qui n'a été, en fait, qu'une conjecture jusqu'à la démonstration (compliquée et nécessitant la maîtrise de nombreux concepts mathématiques fort éloignés de la simplicité de la formulation de l'énoncé de la conjecture) récente due à A. Wiles. Naturellement une ``conjecture'' n'acquiert ce statut que si ... elle n'est pas démontrée, et que de nombreux cas particuliers sont vérifiés ou démontrés, et l'on voit bien sûr le rôle - pas si clandestin - de l'expérimentation dans ce contexte.

Succès et dangers de la recherche expérimentale en mathématiques

Comme nous l'avons laissé entendre, le premier effet fécond de l'expérimentation dans la recherche en mathématiques est de fournir un vivier de conjectures. Celles-ci soit ont un intérêt immédiat, soit sont à l'origine de nouvelles théories. De toute manière, comme elles sont souvent à la fois d'énoncé relativement simple et de démonstration inaccessible, elles sont un puissant stimulant pour l'imagination des mathématiciens.

L'expérimentation renvoie aussi à des questions d'ordre épistémologique, par exemple *l'effectivité* : certains résultats mathématiques affirment (démontrent) l'existence d'une infinité d'objets ayant une propriété donnée ... sans pouvoir exhiber un seul exemple explicite ! De telles questions (liées à celles soulevées par les constructivistes) sont à nouveau posées avec la complicité des ordinateurs. Dans cette direction, citons une conjecture qui affirmait que tout nombre entier est somme d'au plus 19 bicarrés (c'est-à-dire de puissances quatrièmes comme 1, 16, 81, 256, ...). Le résultat était acquis pour les nombres entiers ``très grands''. Ceci peut signifier les entiers plus grands qu'un certain nombre entier non explicite (résultat existentiel). Ceci peut aussi signifier les nombres entiers plus grands qu'un certain nombre entier explicite mais gigantesque, de sorte que les vérifications numériques pour les nombres entiers plus petits que cette borne monstrueuse *ne sont pas possibles* sur les ordinateurs actuels. La conjecture a été finalement démontrée (par R. Balasubramanian, J.-M. Deshouillers et F. Dress) en

baissant un peu cette borne gigantesque, puis en trouvant un autre seuil en dessous duquel les vérifications soient possibles, enfin en inventant des méthodes astucieuses, mélanges de résultats théoriques ad hoc et de vérifications numériques entre ce seuil et la borne monstrueuse.

Un autre exemple de succès de l'expérimentation est la mise au point de la version électronique de ``l'Encyclopédie des suites de nombres entiers'' de N. J. A. Sloane. Sloane avait écrit un livre (A handbook of integer sequences, Academic Press, New York, 1973) qui est un catalogue de suites de nombres entiers. Ce catalogue répertorie les suites de nombres entiers ``intéressantes'' (celles ayant des propriétés remarquables ayant fait l'objet d'articles dans des revues de mathématiques ou d'informatique). Un mathématicien ou un informaticien théoricien rencontrant une suite de nombres entiers dans ses travaux peut aller consulter ce catalogue. Si les vingt (disons) premiers termes de sa suite sont les mêmes que les vingt premiers termes d'une suite du catalogue, il va calculer (disons) les cinquante premiers termes de sa suite. S'il y a à nouveau coïncidence les présomptions que les deux suites sont égales sont grandes. Il reste bien sûr à le *démontrer* rigoureusement. Une nouvelle version de cette encyclopédie a été mise ``en ligne'' par N. J. A. Sloane et S. Plouffe. On peut la consulter à l'adresse
http://www.research.att.com/~njas/sequences/Seis.html
ou en français
http://www.research.att.com/~njas/sequences/indexfr.html
Une anecdote à la fois amusante et profonde est que, lors de la mise au point de cette nouvelle version, S. Plouffe a passé à la ``moulinette'' électronique de programmes de reconnaissance de suites les suites de nombres entiers de la version papier de cette encyclopédie. Pour certaines d'entre elles, le programme ``a répondu'' quelque chose comme ``je ne peux déterminer quelle est cette suite, mais si on remplace le dix-huitième terme par tel nombre, alors la suite est telle suite classique''. Après vérification il y a avait **en effet** une faute de frappe dans la suite présentée ...

On pourrait penser que tout est conte de fée dans l'utilisation de l'expérimentation. Il n'en est rien comme le sous-entend le titre de ce paragraphe. Plusieurs conjectures en théorie des nombres ont été réfutées alors qu'on peut vérifier qu'elles sont correctes expérimentalement jusqu'à des valeurs gigantesques des nombres entiers impliqués. Ainsi la différence entre le nombre de nombres premiers inférieurs à x et le logarithmique intégral de x est de signe constant jusqu'à de très grandes valeurs de x, mais change de signe une infinité de fois lorsque x tend vers l'infini (voir l'article de J. E. Littlewood aux Comptes-Rendus de l'Académie des Sciences, Paris, **158** (1914) 1869--1872).

En guise de conclusion

La fin du paragraphe précédent suggère les dangers de l'expérimentation, et la **nécessité absolue de la preuve mathématique.** On ne saurait trop insister sur le fait que les ``expériences mathématiques'', pour fécondes qu'elles puissent être, ne peuvent donner qu'une idée non seulement incomplète et partielle, mais encore souvent **fausse** des objets mathématiques étudiés. Alors que le concept même de démonstration mathématique est en train de disparaître des programmes scolaires, nous pensons fermement que, plutôt que de faire des ``expériences mathématiques'', sans même évoquer ou esquisser

des **démonstrations**, il est à la fois infiniment plus intéressant, plus formateur et plus utile de faire de la botanique ou de la géologie par exemple.

Evaluating the "Small Scope Hypothesis" for Code

ABSTRACT

The "small scope hypothesis" argues that a high proportion of bugs in a system can be found by exhaustively checking the system within some small scope. In software testing, this exhaustive checking corresponds to testing the program for all inputs in a given scope. In object-oriented programs, an input is constructed from objects of different classes; a test input is within a scope s if at most s objects of any given class appear in it.

This paper evaluates the hypothesis for several implementations of data structures, including some from the Java Collections Framework. We measure how statement coverage, branch coverage, and rate of mutant killing vary with scope. For systematic input generation and correctness checking, we use the Korat tool. This paper presents Korat extensions that enable faster input generation and correctness checking. This paper also presents the Ferastrau tool that we have developed for mutation testing of Java programs. Experimental results show that exhaustive testing within small scopes can achieve complete coverage and kill most of the mutants, even for intricate methods that manipulate complex data structures. The results also show that Korat can efficiently generate inputs and check correctness for these scopes.

1. INTRODUCTION

The "small scope hypothesis" [16] argues that a high proportion of bugs in a system can be found by exhaustively checking the system within some small scope. This hypothesis is a well-known underlying principle of model checking [11]. For example, several case studies [18, 19] used the Alloy modeling language [15] to build *abstract models* of systems and check them with the Alloy Analyzer [17], an automatic tool for exhaustive checking of Alloy models. These studies revealed bugs in the actual systems, providing empirical evidence in support of the hypothesis. However, the studies did not directly check actual implementation code.

The challenge in evaluating/exploiting the hypothesis for code is doing exhaustive checking of code. Our approach uses systematic testing for all inputs within a given scope. In object-oriented programs, an input is constructed from objects of different classes; a test input is within a scope s if at most s objects of any class appear in it. For test input generation and correctness checking, we use Korat (Section 3), a tool that we have developed for testing Java programs [8].

The heart of Korat is a technique for systematically generating all (non-isomorphic) inputs that satisfy a Java predicate, i.e., inputs for which the predicate returns `true`. We have used this technique for specification-based, black-box testing [7]: given a specification for a method, Korat automatically generates all test inputs (within a given small scope) that satisfy the method precondition; Korat then executes the method on each test input and uses the method postcondition as a test oracle to check the correctness of each output. For specifications, Korat uses the Java Modeling Language (JML) [22], and for checking correctness, Korat builds on the JML tool-set [10]. This paper also presents how our technique can be used for white-box testing (Section 3.4), which can reduce total testing time.

Using tools for systematic testing, we have found bugs in several applications [25], including a networking architecture [2], a constraint solver for first-order logic [17], and a fault-tree analyzer [31]. Korat has been also reimplemented in the AsmL Test Generator tool (AsmLT) [1] and successfully used for testing an XPath compiler [30]. Scalability of systematic testing tools does not depend as much on the complexity/size of the tested code as it depends on the complexity of data that the code operates on. This paper focuses on implementations of several Java data structures, including some from the Java Collections Framework [32]. We evaluate the "small scope hypothesis" for these programs using code coverage and mutation testing.

Code coverage is a common criterion for assessing the quality of a test suite [7]. Measuring code coverage involves executing the program on each input and recording statements and branches that get executed. Statement (branch) coverage is then the ratio of the number of executed statements (branches) to the number of total statements (branches) in the program; *complete coverage* is the ratio of 100%. Since Korat uses executable specifications, we also measure *specification coverage* [9].

Mutation testing is another criterion for assessing the quality of a test suite [14, 27]. Mutation testing determines how many bugs a test suite can find. It proceeds in two steps. In the first step, several *mutant*s are generated from the original program, by performing one or more syntactic modifications as specified by *mutation operators*, e.g., replacing a variable with another variable (of a compatible type), say `n.left` with `n.right`. These operators corresponds to typical bugs that programmers make. For several languages, including Java, possible operators are characterized in [3, 20, 21, 28].

In the second step, the original program and each mutant are executed on each input and the corresponding outputs are compared. If a mutant generates an output different than the original program, the test input is said to *kill* the mutant. For a given set of inputs, the rate of mutant killing is the ratio of the number of killed mutants to the total number of mutants. Mutation testing tools were implemented for some languages, such as Mothra [21] for Fortran and Proteum [13] for C. We have implemented Ferastrau (Section 4) for Java; to the best of our knowledge, this is the first tool for mutation testing of Java programs.

The experimental results show that systematic testing within small scopes can achieve complete coverage and kill almost all of the mutants, even for intricate methods that manipulate complex data structures. We also compare systematic testing with randomly selected test inputs; the results show that systematic testing for all inputs within some scope can be more effective than random testing with bigger inputs. These results provide evidence that the "small scope hypothesis" holds for data structures.

Moreover, evaluating the hypothesis is not only about characterizing benchmarks; it also determines whether a tool for systematic testing can be practically used, i.e., how big a scope it can test in a given time. Once we establish that the "small scope hypothesis" holds for some type of benchmarks (or we cannot establish that), we dispense complex testing metrics, and use the scope itself as a metric. The experimental results show that for all benchmarks and the scopes that give high quality test suites, Korat can generate all inputs and check correctness in less than five minutes, often within a few seconds. We show how Korat can generate inputs even faster using a library of *dedicated generators* (Section 3.2) that also make specifications easier to write.

Previous work [8] has presented the basic ideas of Korat. The new contributions of this paper are:

- Evaluation of the "small scope hypothesis" for several data structure implementations;
- Introduction of dedicated generators, a Korat extension that allows faster input generation and easier specification writing;
- Application of Korat technique to white-box testing;
- Evaluation of the Korat tool;
- Design and implementation of Ferastrau, a tool for mutation testing of Java programs.

2. EXAMPLE

This section illustrates how programmers can use Korat to test their programs. As a running example, we use a method for removing an element from a set implemented as a binary search tree. Figure 1 shows JML-annotated Java code that declares a binary tree and its `remove` method. Each object of the class `SearchTree` represents a binary search tree. The `size` field contains the number of nodes in the tree. Objects of the inner class `Node` represent nodes of the trees. The elements of the set are stored in the `info` fields. The elements implement the interface `Comparable`, which provides the method `compareTo` for comparisons. Appendix A shows the full code for the `remove` method.

```
class SearchTree {
    Node root; // root node
    int size;  // number of nodes in the tree
    static class Node {
        Node left;  // left child
        Node right; // right child
        Comparable info; // data
    }

    /*@ normal_behavior // non-exceptional specification
      @     // precondition
      @     requires repOk();
      @     // postcondition
      @     ensures repOk() && !contains(info) &&
      @             \result == \old(contains(info));
      @*/
    boolean remove(Comparable info) { ... }

    boolean repOk() {
        // checks that empty tree has size zero
        if (root == null) return size == 0;
        // checks that the input is a tree
        if (!isAcyclic()) return false;
        // checks that size is consistent
        if (numNodes(root) != size) return false;
        // checks that data is ordered
        if (!isOrdered(root)) return false;
        return true;
    }
}
```

Figure 1: Example code and specification.

The JML annotations specify partial correctness for the example `remove` method. The `normal_behavior` annotation specifies that if the precondition (annotation `requires`) is satisfied at the beginning of the method, then the method must satisfy the postcondition (annotation `ensures`) at the end, and it must return without raising an exception. The method `repOk` is a Java predicate that checks the *representation invariant* [24] of the corresponding data structure. For illustrative purposes, we put `repOk` in the precondition and postcondition; in practice, it is usually given as a class invariant (annotation `invariant`) that is implicitly conjoined with the precondition and postcondition [22]. Good programming practice [24] suggests that implementations of abstract data types provide these predicates, as they are useful for checking correctness of the implementations.

In this example, `repOk` checks if the input is a valid binary search tree with the correct `size`. First, `repOk` checks if the tree is empty. If not, `repOk` checks that there are no undirected cycles along `left` and `right`, that the number of nodes reachable from `root` is `size`, and that all elements in the left (right) subtree of a node are smaller (larger) than the element in that node. Appendix A shows the full code for `repOk` (and the methods it invokes). The same `repOk` is also used for `add` and other methods in `SearchTree`. Manually developing a high-quality test suite for all methods in a data structure is typically much harder than writing `repOk` invariant that Korat uses to automatically generate test inputs.

The method `contains` checks that the tree contains the given element. The JML keyword `\result` denotes the return value of the method. In this example, `remove` returns `true` iff it removes an element from the tree. The JML keyword `\old` denotes that its expression should be evaluated in the pre-state, i.e., the state immediately before the method's invocation.

To test the `remove` method in a black-box setting, Korat first generates valid inputs for the method. Each input is a

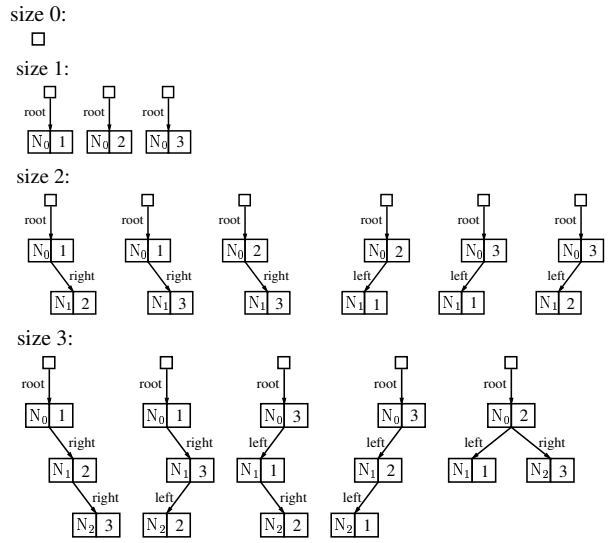

Figure 2: Trees generated for scope three.

pair of a tree and an element. The precondition defines valid inputs: the tree satisfies `repOk`, and the element is unconstrained. To limit the number of inputs, Korat uses a *finitization* (Section *3.1.1*) that specifies bounds on both the number of objects to be used to construct data structures and the values stored in the fields of these objects. For trees, finitization specifies the maximum number of nodes and the possible elements; a tree is in scope s if it has at most s nodes and s elements. Two trees are *isomorphic* if they have the same branching structure and isomorphic elements, irrespective of the identity of the actual nodes or elements in the trees.

Given a finitization and bounds, Korat generates all non-isomorphic input pairs that satisfy the precondition. For example, in scope three, Korat generates 45 input pairs that are the Cartesian product of the 15 trees shown in Figure 2 and the three elements. For the `SearchTree` benchmark, we use Korat to generate inputs and check correctness of `remove` and `add` methods. As another example, in the scope seven, Korat generates 41300 input pairs for both these methods in less than ten seconds. With dedicated generators (Section 3.2), it takes less than three seconds to generate these inputs.

Korat uses the JML tool-set [10] to translate method postconditions (and JML assertions) into Java runtime assertions. After generating the inputs, Korat invokes the method, with assertions, on each input and reports a counterexample if the method fails to satisfy the postcondition. This process checks the correctness of the method for the given scope. For example, for scope seven, Korat takes less than two seconds to check both `remove` and `add` for all 41300 inputs.

We evaluate the "small scope hypothesis" by measuring how coverage and the rate of mutant killing vary with the scope. We use our Ferastrau framework for mutation testing. The "output" for `remove` consists of both its `boolean` return value and the value of the receiver tree in the post-state, i.e., the state immediately after the method's invocation. Figure 3 shows the variation for the `SearchTree` benchmark; a certain small scope is sufficient to achieve complete coverage and kill most of the mutants. Korat generates inputs and checks

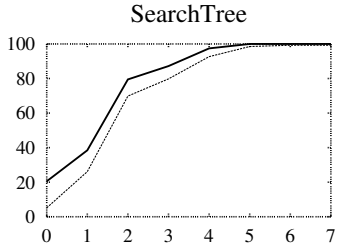

Figure 3: Variation of statement coverage (thick line) and rate of mutant killing (thin line) with scope.

correctness for these scopes in less than 15 seconds.

3. KORAT

This section describes Korat [8], a tool that automates both test-input generation and correctness checking for Java programs. The heart of Korat is a technique for generating inputs that satisfy a Java predicate (Section 3.1). We show how to apply this technique to black-box (Section 3.3) and white-box (Section 3.4) testing by constructing appropriate predicates from method preconditions and postconditions.

3.1 Valid input generation

Given a Java predicate and a bound on its input, Korat automatically generates all non-isomorphic inputs that are *valid*, i.e., inputs for which the predicate returns `true`. Korat uses a *finitization* (Section *3.1.1*) to bound the *state space* (Section *3.1.2*) of predicate inputs. Korat uses backtracking (Section *3.1.3*) to systematically explore this state space. Korat generates *candidate inputs* and invokes the predicate on them to check their validity. Naive checking of all possible candidate inputs would prohibit searching very large state spaces. Korat uses two optimizations: 1) pruning based on accessed fields and 2) generating only non-isomorphic candidates. These optimizations speed up the search without compromising its soundness and completness.

Korat prunes the search based on the following observation: if the predicate returns without reading some fields of a candidate input, the validity of the candidate must be independent of the values of those fields. Korat monitors accesses that the predicate makes for each execution to determine which fields it reads. To monitor the accesses, Korat instruments the predicate and all the methods that the predicate transitively invokes.

Each candidate that Korat generates has one root object; a tuple of objects is essentially one object of a tuple class (Section 3.3). In Java, structure isomorphism is defined based on object identity; two candidates are isomorphic if the parts of their object graphs reachable from the root are isomorphic:

Definition: Let $O_1, \ldots, O_n$ be some sets of objects from n classes. Let $O = O_1 \cup \ldots \cup O_n$, and suppose that candidates consist only of objects from O, i.e., pointer fields of objects in O can either be `null` or point to other objects in O. Let P be the set consisting of `null` and all values of primitive types, such as `int`. Let $r \in O$ be a root object, and let $R_C(r)$ be the set of all objects reachable from r in C. Two candidates, C and C', are *isomorphic* iff there exists a

```
Finitization finSearchTree(int numNode,
    int minSize, int maxSize, int minInfo, int maxInfo) {
  Finitization f = new Finitization(SearchTree.class);
  ObjSet nodes = f.createObjects("Node", numNode);
  nodes.add(null);
  f.set("root", nodes);
  f.set("size", new IntSet(minSize, maxSize));
  f.set("Node.left", nodes);
  f.set("Node.right", nodes);
  f.set("Node.info", new IntegerSet(minInfo, maxInfo));
  return f;
}
Finitization finSearchTree(int scope) {
  return finSearchTree(scope, 0, scope, 1, scope);
}
```

Figure 4: Two finitizations for the `repOk` method.

permutation π on $O \cup P$ that is identity on P and that maps objects from O_i to objects from O_i for all $1 \leq i \leq n$, such that:

$$\forall o \in R_C(r).\ \forall f \in fields(o).\ \forall v \in O \cup P.$$
$$o.f{==}v \text{ in } C \Leftrightarrow \pi(o).f{==}\pi(v) \text{ in } C',$$

where the operator == is Java's comparison by object identity. Isomorphism between candidates partitions the state space into *isomorphism partitions*. Since candidates and valid inputs are rooted and edge-labeled, it is easy to check isomorphism. However, Korat does not do that explicitly; instead, it avoids generating isomorphic valid inputs by not even considering isomorphic candidates.

In summary, Korat generates all non-isomorphic valid inputs within specified bounds; the search has these properties:

- **Soundness:** Korat does not generate any input for which the predicate returns `false`.
- **Completness:** Korat generates at least one input from each isomorphism partition for which the predicate returns `true`.
- **Optimality:** Korat generates at most one input from each isomorphism partition for which the predicate returns `true`.

We next desribe the most relevant parts of Korat, which allows us to present recent extensions; more details on Korat can be found in [8]. For illustration, we consider that the predicate is the `repOk` method from `SearchTree`, and we show how Korat generates valid trees. (Section 3.3 presents how Korat generates valid test inputs for the `remove` method.)

3.1.1 Finitization

To generate a finite state space for predicate's inputs, the search algorithm needs a finitization, i.e., a set of bounds that limits the size of the inputs. The inputs can consist of objects from several classes, and the finitization specifies the number of objects for each of those classes. A set of objects from one class forms a *class domain*. The finitization also specifies a set of values for each field; this set forms a *field domain*, which is a union of some class domains.

In the spirit of Extreme Programming [5] that uses the implementation language familiar to programmers for testing and specification, Korat provides a `Finitization` class that allows finitizations to be written in Java. Korat automatically generates a finitization *skeleton* from the type declarations in the Java code. The AsmLT [1] additionally provides a GUI for generating skeletons. Testers can further specialize or generalize this skeleton.

Figure 4 shows two finitizations for the example `repOk` method. For `finSearchTree(s)`, Korat generates all valid

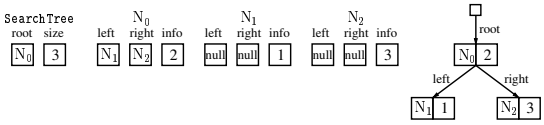

Figure 5: Candidate that is a valid `SearchTree`.

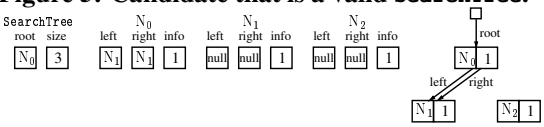

Figure 6: Candidate that is not a valid `SearchTree`.

inputs within scope `s`. The `createObjects` method specifies that the input contains at most `numNode` objects from the class `Node`. The `set` method specifies a field domain for each field.

3.1.2 State space

Korat uses the finitization presented in Figure 4 to construct the state space of inputs to the `repOk` method. Consider the case for `finSearchTree(3)`. Korat first allocates one `SearchTree` object and three `Node` objects. These `Node` objects form the `Node` class domain. Korat then assigns a field domain and a unique *identifier* to each field. The identifier is the index into the *candidate vector*. In this example, the vector has length 11: the single `SearchTree` object has two fields (`root` and `size`) and the three `Node` objects have three fields each (`left`, `right`, and `info`).

A *candidate* input is represented by a valuation of the candidate vector. The state space of inputs consists of all possible valuations of the candidate vector, i.e., it is the Cartesian product of the field domains for all fields. In this example, the domain for `root`, `left`, and `right` has four elements (`null` and three `Node` objects), the domain for `size` has four elements, and the domain for `info` has three elements. Therefore, the state space has $4 \cdot 4 \cdot (4 \cdot 4 \cdot 3)^3 = 1769472 > 2^{20}$ potential candidates. For `scope`$= n$, the state space has $(n+1)^{2(n+1)} \cdot n^n$ potential candidates. Figure 5 shows an example candidate tree that is a valid binary search tree with three nodes. Not all valuations represent valid binary search trees. Figure 6 shows an example candidate tree that is not a tree; `repOk` returns `false` for this candidate.

3.1.3 Search

To systematically explore the state space, Korat orders all the elements in every class domain and every field domain. The ordering in each field domain is consistent with the orderings in the class domains, and all the values that belong to the same class domain occur consecutively in the ordering of each field domain.

Each candidate input is a vector of *field domain indices* into the corresponding field domains. For our running example with scope 3, assume: the `Node` class domain is ordered [N_0,N_1,N_2]; the field domain for `root`, `left`, and `right` is ordered [`null`,N_0,N_1,N_2] (`null` by itself forms a class domain); the domain for `size` is ordered `[0,1,2,3]`; and the domain for `info` is ordered [`Int(1)`,`Int(2)`,`Int(3)`]. According to this ordering, the candidate in Figure 5 (Figure 6) corresponds to the valuation `[1,3,2,3,1,0,0,0,0,0,2]` (`[1,3,2,2,0,0,0,0,0,0,0]`) for candidate vector.

The search starts with the candidate vector set to all zeros. For each candidate, Korat sets fields in the objects according to the values in the vector. Korat then executes the predicate to check the validity of the current candidate. During the execution, Korat monitors the fields that the predicate accesses. Specifically, Korat builds a *field-ordering*: a list of the field identifiers ordered by the first time the predicate accesses the corresponding field. As an illustration, consider the invocation of `repOk` on the candidate shown in Figure 6. In this case, `repOk` accesses only the fields [`root`,N_0`.left`,N_0`.right`] (in that order) before returning `false`. Hence, the field-ordering that Korat builds is `[0,2,3]`.

After the predicate returns, Korat generates the next candidate vector backtracking on the accessed fields. Korat first increments the field domain index for the last field in the field-ordering. If the index exceeds the domain size, Korat resets the index to zero, increments the domain index of the previous field in the field-ordering, and so on. Continuing with our example, the next candidate takes the next value for N_0`.right`, which is N_2 by the above order; the other fields do not change. This prunes from the search $4^5 \cdot 3^3 = 27648$ candidate vectors of the form `[1,_,2,2,_,_,_,_,_,_,_]` that have the (partial) valuation: `root`=N_0, N_0`.left`=N_1, N_0`.right`=N_1. The pruning does not rule out any valid data structure because `repOk` did not read the other fields, and it would have returned `false` irrespective of the values of those fields. If the predicate returns `true`, Korat outputs all (non-isomorphic) candidates that have the same values for the accessed fields as the current candidate. The search then backtracks to the next candidate.

Recall that Korat orders the values in the class and field domains. Additionally, each execution of the predicate on a candidate imposes an order on the fields in the field-ordering. Together, these orders induce a lexicographic order on the candidates. The Korat search algorithm generates inputs in the lexicographical order. Moreover, Korat avoids generating multiple candidates that are isomorphic to one another: for each isomorphism partition, Korat generates only the lexicographically smallest candidate in that partition. Conceptually, Korat avoids generating isomorphic candidates by incrementing field domain indices by more than one. This optimization is presented in detail in [8].

3.2 Dedicated generators

Korat provides a library of *dedicated generators* that make it easier to write spefications and also enable faster generation of valid inputs. Certain checks are common in class invariants (`repOk` methods), e.g., that a linked data structure is acyclic along some fields or that an array has all elements different or ordered. The library provides methods for these checks. The specifications, as well as any other code, can use these library methods; in regular execution, these methods behave like other Java methods. However, when Korat generates valid inputs, it uses the special knowledge about these methods to further optimize its search.

In `SearchTree`, `repOk` invokes the method `isAcyclic` that checks that the nodes reachable from the `root` field form a tree along the `left` and `right` fields. Appendix A shows one way to write `isAcyclic`; it has about 20 lines of code. Instead, we could just use the library method `korat.isTree(root, new String[]{"left", "right"})`. This method is parametrized over the root node and the names of the fields. Given a root node, `isTree` checks that the reachable nodes form a tree; essentially, it means that no node repeats in the traversal of the nodes reachable from the root. The search for the library method is implemented to take into account this fact.

When Korat generates an input that satisifes `isTree` along some fields, it does not try all (non-isomorphic) possibilities for those fields. Instead, each field is either `null` or points to a node that is not already in the tree. In our example `finSearchTree(s)`, this reduces the number of possiblities for one field from `s`+1 to 2. In the library, the implementation of `isTree` uses the basic dedicated generator `korat.isIn(field, set)` that, while searching, assigns to the `field` only the values from the `set`, and while checking, checks that the value of `field` is in the `set`.

The library includes the basic dedicated generators for checking: that a value is in a set, that two values are equal, that a value is less/greater than another value, and that a value is of a certain class (`instanceof`). The library also includes generators for combining other generators for checking: negation, conjunction, and disjunction. Finally, the library includes several higher-level generators, implemented using basic generators, which check structural constraints such as acyclicity or that elements of an array are sorted.

It is easy to add new generators; in theory, we could even add for each data structure that we consider a special-purpose generator that generates all valid inputs without any backtracking. For example, such a generator for red-black trees was developed and used for testing in [4]. However, we do not do that; the library that we use in the experiments has only generators that are applicable for several data structures. In practice, we do not expect Korat users to extend the library, but instead to use Korat as general-purpose search.

3.3 Black box Testing

In black-box testing, Korat tests a method without considering the method's code. Korat systematically generates inputs that satisfy the method precondition, executes the method on each of the inputs and checks the output using a *test oracle*. To generate test inputs for a method m, Korat first constructs a Java class corresponding to the m's inputs and a predicate corresponding to the m's precondition. Korat then generates valid inputs for that predicate; each of these inputs corresponds to a valid test input for m. For the `remove` method from Section 2, the corresponding class and the predicate `removePre` are shown in Figure 7. The predicate simply invokes `repOk` on the (implicit) `this` parameter of `remove`; the parameter `info` is unconstrained.

3.3.1 Checking correctness

After generating all valid test inputs for a method, Korat invokes the method on each input and checks each output with a test oracle. A simple test oracle could check partial correctness of a method by invoking `repOk` in the post-state to check if the method preserves its class invariant. If the result is `false`, the method under test is incorrect, and the

```
class SearchTree_remove {  // inputs to "remove"
    SearchTree This;       // (implicit) "this" parameter
    Comparable info;       // "info" parameter

    // for black-box testing of "remove"
    boolean removePre() {  // precondition for "remove"
        return This.repOk();
    }

    // for white-box testing of "remove"
    boolean removeFail() { // failure for "remove"
        if (!removePre()) return false;
        try { // invoke "remove" with JML assertions
            This.remove(info);
        } catch (JMLAssertionException e) {
            return true;   // postcondition not satisfied
        }
        return false;
    }
}
```

Figure 7: Class for inputs to the `remove` method.

	testing framework

generating test oracle		√	√
running tests	√	√	√

Table 1: Comparison of several testing frameworks for Java. Automated testing activities are indicated with '√'; jmlunit generates inputs using directly the Cartesian product, which cannot handle very large input spaces.

input provides a concrete counterexample.

The Korat tool currently uses the JML tool-set to automatically generate test oracles from method postconditions (and method assertions in general), as in the jmlunit framework [10]. The JML tool-set translates JML postconditions (and assertions) into runtime Java assertions. If an execution of a method violates such an assertion, an exception is raised. Test oracle catches these exceptions and reports correctness violations. These exceptions are different from the exceptions that the method specification allows, and Korat leverages JML to check both normal and exceptional behavior of methods. More details on the JML tool-set and translation can be found in [22].

Korat can also use jmlunit to combine JML test oracles with JUnit [6], a popular framework for unit testing of Java modules. JUnit automates test execution and error reporting, but requires programmers to provide test inputs and test oracles. In jmlunit, the Cartesian product is directly used to generate test inputs, which cannot handle very large input spaces. Additionally, jmlunit does not generate complex data structures, but requires users to create and provide them. Korat further automates and optimizes generation of test inputs, thus automating the entire testing process. Table 1 summarizes the comparison of these testing frameworks.

3.4 White box Testing

In white-box testing, Korat tests a method considering the method's code. To test a method m, Korat first constructs a predicate corresponding to the negation of m's correctness. If a valid input is found for this predicate, m is incorrect, and the input provides a counterexample. For the `remove` method, the corresponding predicate `removeFail` is shown in Figure 7. This predicate first invokes `removePre`; if it is not satisfied, the input is not a valid test input for `remove` and cannot be a counterexample. If the input is valid, `remove` is executed, together with the JML-translated assertions. If this execution raises a JML exception, `remove` failed to satisfy its specification.

The difference between predicates for white-box and black-box testing is in the invocation of the method under test; in our example, `removeFail` invokes `remove`, but `removePre` does not. This means that for generating valid inputs to `removeFail`, Korat instruments `remove`, among other methods, and monitors the accesses that `remove` makes to the candidate. This by itself makes one execution of `remove` slower. But it "opens" the body of `remove` for the optimizations that Korat performs to prune the search. In general, this can significantly reduce the time to test the method.

4. MUTATION TESTING

This section presents design and implementation of Ferastrau, a tool for mutation testing of Java programs. *Mutation testing* is a criterion for assessing the quality of a set of test inputs [14, 27]. Mutation testing proceeds in two steps. In the first step, a set of *mutant*s is generated from the original program by applying *mutation operators* to perform one or more syntactic modifications. Section 4.1 presents mutant generation in Ferastrau. In the second step, the original program and each mutant are executed on each input and the corresponding outputs are compared. If a mutant generates an output different than the original program, the test input is said to *kill* the mutant. Section 4.2 presents how Ferastrau executes mutants and compares the outputs.

4.1 Mutant generation

We have implemented mutant generation by changing the Sun's `javac` compiler. Ferastrau performs a source-to-source translation: it parses each class of the original program into an abstract syntax tree, applies some mutation operators to the trees, and outputs the source of the mutants. Ferastrau applies the following mutation operators:

- Mutate a Java operator to another operator (of the same type), e.g., '`+`' to '`-`', '`==`' to '`!=`', '`<`' to '`<=`' etc.
- Mutate a variable to another variable (of a compatible type), e.g., a local variable `i` to `j` or an instance variable `n.left` to `n.right`.
- Mutate an invocation of a method to another method (of a compatible signature). (Ferastrau does not replace some special methods, such as `notify`; programmers typically do not make such mistakes.)

The above operators modify only the code of methods, and not classes, i.e., do not add/remove a method or a field. These operators correspond to subtle mistakes that manifest only for non-trivial inputs, as the results in Section 5.3 show. It is easy to add new operators to Ferastrau to test different kind of mistakes.

Ferastrau generates mutant classes that have the same name as the corresponding original classes. For reasons explained below, Ferastrau provides two approaches: 1) generate the same classes with both the original program and the mutants or 2) generate different classes. Suppose that the original programs contains `temp.right` that is to be

mutated to `left.right`. The first approach uses *metamutants* [33]: the mutations are guarded by boolean variables that are appropriately set during mutant execution; it generates one class with `(MUT ? left : temp).right`. The second approach simply generates `left/*temp*/.right` in another class.

4.2 Mutant execution

After generating the mutants, Ferastrau uses a set of test inputs to perform mutation testing. Our experiments use inputs generated by Korat. Ferastrau executes the original program and the mutants for each input and compares their respective outputs. Ferastrau assumes that the original program terminates for all test inputs; mutation testing tools for other languages [13, 21] make the same assumption. Since Ferastrau operates on Java and has to handle potentially large number of inputs, additional questions arise:

- How to compare outputs and name mutated classes?
- Whether to execute the original program and the mutants in a single run or in separate runs?
- How to handle non-termination and exceptional termination of the original program and the mutants?

We next describe how Ferastrau addresses these questions and then list the criteria that Ferastrau uses to kill a mutant.

Recall that the "output" of a method refers to both the return value and the objects in the post-state. Comparison is easy when these are primitive values, but the objects can represent complex structures. Ferastrau by default uses `equals` methods to compare outputs, following Java convention of using `equals` for equality comparisons of objects. This allows comparisons based on *abstract* values; for example, two binary search trees that implement sets may be structurally different at the *concrete* level of the implementation, but if they represent the same set, they are equal according to the `equals` method. The use of `equals` requires that Ferastrau generates mutant classes that have the same name as the corresponding original classes.

Ferastrau executes the original program and the mutants in a single run; otherwise, it would need to serialize all the outputs, which could produce very large files for inputs exhaustively generated by Korat. When Ferastrau generates the original program and the mutants in different classes, it needs to execute several classes with the same name in a single Java Virtual Machine (JVM). Ferastrau then uses a different `ClassLoader` [32] to load in the classfiles of the original program and each mutant. To compare objects, Ferastrau uses serialization through a buffer in memory. This approach works better for large code with small data. When Ferastrau uses metamutants, the guarding boolean variables slow down the execution. This approach works better for small code with large data.

Ferastrau assumes that the original program terminates for all test inputs, either normally or exceptionally. These exceptions are allowed by the specification, and they are not errors. Ferastrau handles non-termination of mutants by running them in a separate thread and setting a time limit for execution. The mutants can terminate either normally or exceptionally. Ferastrau catches all exceptions (in terms of Java, all `Throwable` objects) that the executions raise. This allows Ferastrau to compare the outputs, even when they are exceptional, as well as to catch all errors in the mutants. This handles the situations when the mutant runs out of stack or heap memory and JVM raises `StackOverflowError` or `OutOfMemoryError`.

Ferastrau uses the following criteria to kill a mutant:

- The mutant's output does not satisfy some class invariant (`repOk`), which is a precondition for `equals`.
- The mutant's output differs from the output of the original program; any of the outputs can be normal or exceptional.
- The mutant's execution exceeds the time limit.
- The mutant's execution runs out of memory.

5. EXPERIMENTAL RESULTS

This section presents the experiments that evaluate the "small scope hypothesis" and the Korat tool. We first discuss Korat's performance for test input generation and checking method correctness. We then discuss how the coverage and the rate of mutant killing vary with the scope. We finally compare exhaustive testing with randomly selected test inputs. We performed all timed experiments on a Linux machine with a 1.8GHz Pentium 4 processor using Sun's Java 2 SDK1.3.1 JVM.

5.1 Benchmarks and methods

Table 2 lists the benchmarks and methods that we use to measure Korat's performance. We use Korat to generate inputs and check the correctness of outputs for the *target* methods. These methods implement the standard operations on their corresponding data structures [12]. Executing these methods also tests some *helper* methods because they are invoked either when executing the target methods or when checking their correctness (e.g., from postconditions).

`SearchTree` is presented in Section 2. `DisjSet` is an array-based implementation of the fast union-find data structure [12]; this implementation uses both path compression and rank estimation heuristics to improve efficiency. `HeapArray` is an array-based implementation of the heap (priority queues) data structure. `BinomialHeap` and `FibonacciHeap` are dynamic data structures that also implement heaps, but differ in complexity for certain operations [12].

`LinkedList` is the implementation of linked lists in the Java Collections Framework, a part of the standard Java libraries [32]. This implementation uses doubly-linked, circular lists. This benchmark is also representative for linked data structures such as stacks and queues. The elements in `LinkedList` are arbitrary objects; `SortedList` is structurally identical to `LinkedList`, but the elements are sorted. This benchmark is similar to the examples used in some shape analyses [23, 26]. `TreeMap` implements the `Map` interface using red-black trees [12]. `HashSet` implements the `Set` interface, backed by a hash table [12].

`AVTree` implements the *intentional name* trees that describe properties of services in the Intentional Naming System (INS) [2], an architecture for service location in dynamic networks. The original implementation of INS had errors that we revealed with exhaustive testing [25] and corrected. We use the corrected version as the original program in these experiments, but (some of) the mutants have errors.

benchmark	"target" methods	some "helper" methods	# ncnb lines	# branches	# mutants
SearchTree	add, remove	contains	85	20	272
DisjSet	union, find	compressPath	29	8	243

BinomialHeap	insert, extractMin union, delete	contains, decrease merge, findMin	182	33	292
FibonacciHeap	insert, extractMin union, delete	contains, decrease cascadingCut, cut, consolidate	171	31	297
LinkedList	add, remove, reverse	contains, ListIterator.next	102	16	244
SortedList	insert, remove sort, merge	contains	176	29	231
TreeMap	put, remove	get, fixAfterInsertion containsKey, fixAfterDeletion rotateLeft, rotateRight	230	47	293
HashSet	add, remove	contains, HashMap.containsKey HashMap.put, HashMap.remove HashMap.rehash	113	20	244
AVTree	lookup	extract	199	26	205

Table 2: Benchmarks and target methods. Each benchmark is named after the main class; Korat generates data structures that also contain objects from other classes. Korat generates inputs and checks outputs for the target methods, thereby also testing helper methods. We tabulate the number of non-comment non-blank lines of source code in all those methods, the number of branches, and the number of mutants generated by Ferastrau.

5.2 Test generation and correctness checking

Table 3 shows Korat's performance for test generation and correctness checking for some scopes. Appendix B presents the results for many other scopes. For each benchmark, all size parameters and maximum elements are set to the scope value. For each benchmark, the tabulated scope is sufficient to achieve the maximum coverage and kill almost all the mutants. We tabulate the time Korat takes to generate all valid test inputs (without and with dedicated generators) and to check the correctness of methods. All times are elapsed real times in seconds from the start of Korat to its completion, without the JVM initialization that takes around 0.5 seconds.

Number of inputs that is generated is the sum of numbers of inputs for *all* target methods. Similarly, the generation and checking times are sums of times for all target methods. We use Korat to separately generate inputs for each method. However, when two methods have the same precondition (e.g., `remove` and `add` for `SearchTree`), we could reuse the inputs and thus reduce the generation time. The postconditions for all methods specify typical partial correctness properties; they require resulting data structures to be valid and to (not) contain the input elements, depending on the method.

For scopes in Table 3, the size of the search space is between 2^{25} and 2^{150}. The actual size of search spaces for several data structures can be found in [8]; for some scopes in those experiments, as well as for some scopes in Appendix B, Korat explores search spaces with size over 2^{250}. In all cases, Korat completes in less than two minutes, often in just a few seconds. The use of dedicated generators reduces the generation times for up to 75% (for `SearchTree`). Since dedicated generators have a higher overhead, their use sometimes increases the generation time, specially for small scopes. But in all cases, dedicated generators make it easier to write specifications.

These results show that Korat can efficiently generate all inputs even for very large search spaces, primarily because the search pruning allows Korat to explore only a tiny fraction of these spaces. The key to effective pruning is backtracking based on fields accessed during `repOk`'s executions. Without backtracking, and even with isomorphism optimization, Korat would consider infeasibly many candidates. Isomorphism optimization further reduces the number of considered candidates, but it mainly reduces the number of valid inputs. As shown in [8], Korat generates exactly the number of non-isomorphic data structures given in the Sloane's On-Line Encyclopedia of Integer Sequences [29].

5.3 Coverage and mutant testing

Table 3 also shows specification/code coverage and the rate of mutant killing. Since Korat uses executable specifications, we measure *specification coverage* [9] as code coverage for the predicate that corresponds to the method's precondition (e.g., `removePre`). We measure this coverage while Korat generates valid inputs for the predicate, i.e., valid test cases for the method. For most benchmarks, the tabulated scopes achieve complete coverage, both for statements and branches. It is not always 100%, because finitizations do not even put for fields some values that do not satisfy the predicate (e.g., `finSearchTree` does not put `null` for `info`). Specification coverage typically reaches maximum before code coverage (Appendix B).

Figure 8 shows graphs that relate scope with the statement coverage of code and the rate of mutant killing. The code coverage is measured for all target and helper methods, since they are all executed. For most benchmarks, Korat generates inputs that achieve complete coverage, both for statements and branches. For other benchmarks, the coverage is not complete because no input for target methods could trigger some exceptional behavior of helper methods.

For example, the (target) `reverse` method for lists creates a `ListIterator` and invokes some (helper) methods on it. In general, these helper methods could raise exceptions, such as `ConcurrentModificationException` or `NoSuchElementException`, but the target methods never invoke the helper methods in such a way. In terms of JML specifications, the target methods invoke the helper methods in pre-states that satisfy the precondition for `normal_behavior`, and not for `exceptional_behavior`.

		generation					checking			
		gen.	ded.	spec. coverage		#	time	code coverage		mutants
benchmark	scope	[sec]	[sec]	st. [%]	br. [%]	inputs	[sec]	st. [%]	br. [%]	killed [%]
SearchTree	7	9.03	2.19	94.74	96.67	41300	1.25	100.00	100.00	99.26
DisjSet	5	10.91	9.87	100.00	100.00	1246380	19.93	100.00	100.00	95.06
HeapArray	7	7.09	6.21	90.00	92.86	1175620	17.58	100.00	100.00	96.71
BinomialHeap	7	35.60	28.06	97.67	98.00	2577984	75.96	100.00	100.00	96.91

SortedList	7	22.68	21.13	100.00	100.00	1047608	37.91	92.50	89.66	97.40
TreeMap	7	3.28	1.75	100.00	100.00	12754	0.73	100.00	91.49	89.76
HashSet	7	3.38	2.88	89.47	92.31	54844	1.55	100.00	100.00	92.21
AVTree	5	87.13	43.41	96.67	96.88	417878	134.51	94.12	92.31	93.65

Table 3: Korat's performance for test generation (with regular and dedicated generators), specification coverage (statement and branch), correctness checking, code coverage (statement and branch), and rate of mutant killing. All times are elapsed real times in seconds from the start of Korat to its completion. For all benchmarks and their sufficient scopes, Korat takes less than five minutes to generate all inputs and check correctness.

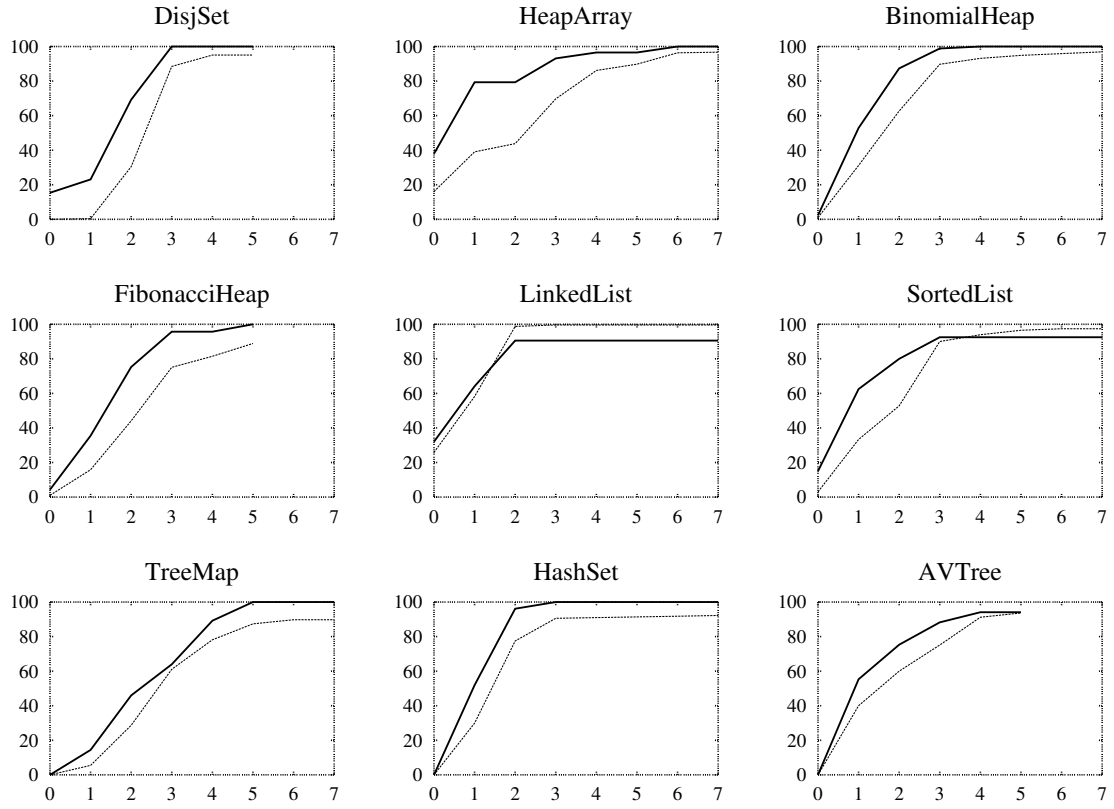

Figure 8: Variation of statement code coverage (thick line) and rate of mutant killing (thin line) with scope. For *all* benchmarks, Korat generates inputs that achieve the maximum coverage that is possible without directly generating inputs for helper methods.

For mutant testing, we use Ferastrau to generate between 200 and 300 mutants for each benchmark. We instruct Ferastrau to mutate the target methods and the helper methods the invoke, but not the helper methods that only specifications invoke. For most benchmarks, Korat generates inputs that kill over 90% of the mutants. We tried to manually inspect if the mutants that are not killed are, although syntactically different from the original program, *semantically* equivalent to it and thus no input could kill them. Due to the complexity of the benchmark methods, we were not able to definitely establish the equivalence for all surviving mutants, but those that we managed to inspect were indeed equivalent.

Notice that for some of the benchmarks the rate of mutant killing increases with scope even after achieving complete coverage. This can be expected because complete statement and branch coverage (or for that matter, any coverage criteria) does not guarantee absence of bugs [7]. Because of this, we take as sufficient the scope for which almost all mutants are killed, and not the scope that just achieves complete coverage. For all benchmarks and their respective sufficient scopes, Korat can generate all inputs and check correctness in less than five minutes, often within a few seconds. Korat can thus be effectively used for systematic testing of these benchmarks and similar data structures.

benchmark	scope	random mutants killed [%]	exhaustive scope-1	exhaustive scope
SearchTree	7	99.26	=	=
DisjSet	5	95.06	=	=

FibonacciHeap	5	86.87	>	<
LinkedList	7	99.59	=	=
SortedList	7	96.40	<	<
TreeMap	7	89.08	<	<
HashSet	7	91.39	<	<
AVTree	5	93.17	>	<

Table 4: Comparison of exhaustive testing with randomly selected test inputs. '=' means that both sets are equally good, '<' that random testing is worse, and '>' that random testing is better.

5.4 Random selection

We next evaluate the importance of exhaustive testing within a scope. Consider one benchmark, and let $T(s)$ be the set of all (non-isomorphic) test inputs within scope s for that benchmark. From $T(s)$, we randomly select a subset $R(s)$ whose cardinality is the same as the cardinality of $T(s-1)$. We then compare the quality of $R(s)$ against $T(s-1)$ and $T(s)$. For comparison, we use the rate of mutant killing. This criterion most directly measures the quality of test suite in detecting faults; the results are similar for code coverage. It is important to notice that randomly selected inputs are also generated with Korat; for complex data structures, it is not possible to simply generate random inputs.

Table 4 shows the comparison for all benchmarks. In most cases, randomly selected test inputs give a lower rate of mutant killing; only for `FibonacciHeap` and `AVTree`, the rate is higher for randomly selected inputs than for all inputs from the smaller scope. This means that the exhaustive testing for all inputs within some scope can be more effective than random testing with bigger inputs.

6. CONCLUSIONS

The "small scope hypothesis" argues that a high proportion of bugs can be found by testing the program for all test inputs within some small scope. In object-oriented programs, a test input is constructed from objects of different classes; a test input is within a scope of s if at most s objects of any given class appear in it. This paper evaluated the hypothesis for several implementations of data structures. We measured how statement coverage, branch coverage, and rate of mutant killing vary with scope. We used Korat and its extensions to perform exhaustive testing. This paper also presented the Ferastrau tool that we developed for mutation testing of Java programs.

The experimental results show that exhaustive testing within small scopes can achieve complete coverage and kill almost all of the mutants for data structure benchmarks, and additionally that exhaustive testing within some scope can be sometimes more effective than random testing with bigger inputs. The results also show that Korat can be used effectively to generate inputs and check correctness for these scopes. These results, together with previous studies that used systematic testing to expose bugs in real application [25], suggest that techniques that rely on exhaustive generation within scope $[1, 8, 34]$ are worth pursuing.

Similarity Submodules and Root Systems in Four Dimensions

Michael Baake and Robert V. Moody

Abstract: *TeX format* Lattices and $\ZZ$-modules in Euclidean space possess an infinitude of subsets that are images of the original set under similarity transformation. We classify such self-similar images according to their indices for certain 4D examples that are related to 4D root systems, both crystallographic and non-crystallographic. We encapsulate their statistics in terms of Dirichlet series generating functions and derive some of their asymptotic properties.

The Electronic Journal of Combinatorics

Abstract for R38 of Volume 7(1), 2000

L. Babai and P. J. Cameron

Automorphisms and Enumeration of Switching Classes of Tournaments.

Two tournaments T_1 and T_2 on the same vertex set X are said to be *switching equivalent* if X has a subset Y such that T_2 arises from T_1 by switching all arcs between Y and its complement $X \setminus Y$.

The main result of this paper is a characterisation of the abstract finite groups which are full automorphism groups of switching classes of tournaments: they are those whose Sylow 2-subgroups are cyclic or dihedral. Moreover, if G is such a group, then there is a switching class C, with $\mathrm{Aut}(C) \cong G$, such that every subgroup of G of odd order is the full automorphism group of some tournament in C.

Unlike previous results of this type, we do not give an explicit construction, but only an existence proof. The proof follows as a special case of a result on the full automorphism group of random G-invariant digraphs selected from a certain class of probability distributions.

We also show that a permutation group G, acting on a set X, is contained in the automorphism group of some switching class of tournaments with vertex set X if and only if the Sylow 2-subgroups of G are cyclic or dihedral and act semiregularly on X. Applying this result to individual permutations leads to an enumeration of switching classes, of switching classes admitting odd permutations, and of tournaments in a switching class.

We conclude by remarking that both the class of switching classes of finite tournaments, and the class of "local orders" (that is, tournaments switching-equivalent to linear orders), give rise to countably infinite structures with interesting automorphism groups (by a theorem of Fraïssé).

On some criteria of irrationality for series of positive rationals : A survey

Catalin BADEA*

URA 751 au CNRS & UFR de Mathématiques
Université de Lille I, F–59655 Villeneuve d'Ascq, France

Dédié à la mémoire de Roger Apéry

Abstract

This paper is an English and expanded version of a talk delivered at the "Rencontre Arithmétique de Caen", June 1995, dedicated to the memory of Roger Apéry. It is a survey of some general irrationality criteria and other irrationality results. The emphasis is on irrationality of reciprocals of binary recursive sequences and on an open problem of P. Erdős concerning the so-called Sylvester sequence.

1991 Mathematical Subject Classification : 11J72, 11J81, 11B37.

Keywords : irrational numbers, irrationality criteria, Fibonacci numbers, linear recurrences, transcendental numbers.

1 Introduction

There are several known conditions for an infinite convergent series of positive rational numbers to have an irrational (or transcendental) sum. There are also other results about the irrationality or transcendence of particular constants expressed as series of positive rationals. In general, it seems to be hopeless to obtain general irrationality criteria which are sufficiently strong to imply the irrationality of many particular constants.

R. Apéry's wonderful proof [2] of the irrationality of $\zeta(3)$ belongs to the second class. The aim of this paper is to survey some of the general criteria of irrationality and to discuss some irrationality and trancendency results, mainly about series of reciprocals of binary recursive sequences. The only place when we will cite again Apéry's name will be in the next section, when we will mention a result due to André-Jeannin [3]. He used Apéry's method in order to prove the irrationality of the series of reciprocals of Fibonacci numbers. Speaking about Apéry's method, it would be fair to see his proof as belonging to the midle class of particular irrationality assertions yielding some new ideas for irrationality proofs, although we cannot speak yet of Apéry's criterion of irrationality. We refer to [8] and [18] for several developments of Apéry's method.

The irrationality and the trancendence of series of reciprocals of binary recursive sequences is discussed in the third section, while the particular case of Fibonacci and Lucas numbers is considered in the next one. In the last section we deal with some general irrationality criteria related to a conjecture of P. Erdős.

We will make two conventions. The first one is that all series which appear are supposed to be convergent. The second one is the following. Let $(a_n), n \geq 0$, be a sequence of complex numbers and $(s_h), h \geq 0$, be a strictly increasing sequence of integers. When writing

$$\sum_{h=0}^{\infty} \frac{1}{a_{s_h}},$$

we will understand that the sum is in fact taken over those h with $s_h \geq 0$ and $c_{s_h} \neq 0$.

2 Sums of reciprocals of Fibonacci and Lucas numbers.

Let $(F_n), n \geq 0$, be the Fibonacci sequence, defined by

$$F_0 = 0, F_1 = 1, F_{n+1} = F_n + F_{n-1} \ (n \geq 1).$$

We define the Lucas sequence by

$$L_n = F_{n-1} + F_{n+1}.$$

Using R. Apéry's method, André-Jeannin [3] proved in 1989 that the series of reciprocals of Fibonacci numbers is an irrational number :

$$\theta_0 = \sum_{n=0}^{\infty} \frac{1}{F_n} \notin \mathbf{Q}.$$

In fact, in [3] there is a more general result implying also the irrationality of reciprocals of more general recursive sequences (cf. the next section). Recently, Bundschuch and Väänänen [14] obtained an irrationality measure for $\sum_{n=0}^{\infty} \frac{1}{F_n}$. Namely, one has :

$$\sum_{n=0}^{\infty} \frac{1}{F_n} = -\frac{5+\sqrt{5}}{2} L_q(\frac{1+\sqrt{5}}{2})$$

where $q = -(3+\sqrt{5})/2 \in \mathbf{Q}(\sqrt{5})$ and

$$zL_q(-z) = \sum_{n=1}^{\infty} \frac{z^n}{q^n - 1} = \sum_{n=1}^{\infty} \frac{z}{q^n - z}$$

and, using this, they obtained $6/(1-(3/\pi^2)) \approx 8.62\ldots$ as a measure of irrationality for θ_0. We refer to [14] for the details. We still don't know if θ_0 is a transcendental number.

Surprising facts are known if the sum is taken not over the whole sequence. For instance, we have

$$\theta_1 = \sum_{n=0}^{\infty} \frac{1}{F_{2^n}} = \frac{7-\sqrt{5}}{2} \in \mathbf{Q}(\sqrt{5})$$

(cf. Good [28] , Hoggatt and Bicknell [34], [35], and Cuculière [19]). Therefore θ_1 is algebraic. The trancendence of

$$\theta_2 = \sum_{n=0}^{\infty} \frac{1}{n! F_{2^n}}$$

was proved independently by Mignotte [44] and Mahler [42].

P. Erdős and R.L. Graham [23, pp. 64-65] have raised, among many problems, the following ones :

A. *What is the character of*

$$\theta_3 = \sum_{n=1}^{\infty} \frac{1}{F_{2^n+1}} \quad \textit{and} \quad \theta_4 = \sum_{n=1}^{\infty} \frac{1}{L_{2^n}} \ ?$$

B. *Is it true that if* $(n(k)), k \geq 1$, *is a sequence of positive integers such that there exists a constant* $c > 1$ *with* $n(k+1)/n(k) \geq c$ *for every* k, *then the sum of the sum of the series* $\sum_{k=1}^{\infty} \frac{1}{F_{n(k)}}$ *is irrational ?*

The author [5] proved that θ_3 and θ_4 are irrational, while Bundschuh and Pethö [13] showed that θ_3 is transcendental. André-Jeannin [4] proved that $\theta_4 \notin \mathbf{Q}(\sqrt{5})$. Recently, Becker and Töpfer [11] proved a general theorem (see later) implying that θ_3 and θ_4 are transcendental.

For the second part of the Erdős-Graham's problem, we know [6] the affirmative answer for $c \geq 2$. We will return to this problem in the next section.

3 Sums of reciprocals of binary recursive sequences

Let P and Q be two coprime integers. Let α and β be the roots of the equation $x^2 - Px + Q = 0$. Consider the binary recursive sequences $U_n = U_n(P, Q)$ and $V_n = V_n(P, Q)$ defined, respectively, by

$$U_n = \frac{\alpha^n - \beta^n}{\alpha - \beta} \quad \textit{and} \quad V_n = \alpha^n + \beta^n \quad , n \geq 0.$$

Then $U_{n+2} = PU_{n+1} - QU_n,\ n \geq 0$, and the same recurrence relation holds for V_n.

The following formula was obtained in 1878 by Lucas [41, p. 225] :

$$\sum_{n=1}^{\infty} \frac{Q^{2^{n-1}r}}{U_{2^n r}} = \frac{\beta^r}{U_r} \ ,\ r \geq 1.$$

This implies that

$$\Theta_0 = \sum_{n=1}^{\infty} \frac{1}{U_{2^n r}} \notin \mathbf{Q}$$

whenever $Q = \pm 1$ and $\Delta = P^2 - 4Q > 0$. Indeed, U_r and V_r are integers, $\alpha - \beta$ is irrational and $\beta^r = (V_r - U_r(\alpha - \beta))/2$ is irrational. Many special cases of this result were re-discovered in the seventies. As we will see a little bit later, Becker and Töpfer [11] showed that algebraic numbers of this kind belong to a explicitely given exceptional set.

In the above section, we mentioned that the second Erdős-Graham's problem for Fibonacci numbers has a positive solution for $c \geq 2$. In fact [6],

$$\Theta_1 = \sum_{n=1}^{\infty} \frac{1}{U_{n(k)}} \notin \mathbf{Q}$$

whenever $n(k+1) \geq 2n(k) - 1$ for all sufficiently large k for $P > 0$ and $Q < 0$. Wayne McDaniel [43] assumed that $\Delta > 0$ and proved that Θ_1 is irrational if $n(k+1) \geq 2n(k)$ for large k, for all sequences U_n with $P > 0, (P, Q) = 1$ and $P^2 - 4Q > 0$. He also proved that if $n(k+1) \geq 2n(k) - 1$ for all large k and $n(k)$ is even, then the result holds for all such positive parameters P and Q. Similar results hold for the sequences V_n. André-Jeannin [4] has shown that, if $P > 0$ and $Q = \pm 1$, then

$$\Theta_2 = \sum_{n=1}^{\infty} \frac{1}{U_n} \notin \mathbf{Q}.$$

The following result was proved recently by Becker and Töpfer [10]: we have

$$\Theta_3 = \sum_{n=0}^{\infty} \frac{\varepsilon^n}{V_{2^n}} \notin \mathbf{Q}$$

whenever $\varepsilon = \pm 1$, the roots α and β are distinct, not necessarily real, $|\alpha| \geq |\beta|$, and α/β is not a root of unity. In fact, if $\Delta > 0$, not a perfect square, Θ_3 is even a trancendental number [11]. In the same paper, the authors were able to carry out a complete study of similar trancendency problems for binary recursive sequences with irreducible companion polynomial of positive discriminant. The proofs are based upon Mahler's method for transcendency.

Theorem 1 (Becker and Töpfer [11]) *Let (R_n), $n \geq 0$, be a sequence of integers which is not eventually periodic and satisfies the recurrence relation*

$$R_{n+2} = PR_{n+1} - QR_n \ (n \geq 0) \ ,$$

with integers P and Q satisfying $P \neq 0$, $\Delta = P^2 - 4Q > 0$. Suppose that Δ is not a perfect square.

Let (b_h), $h \geq 0$, be a periodic sequence of algebraic numbers which is not indentically zero and let d, k, and l be integers with $d \geq 2$ and $k \geq 1$.

Then

$$\Theta_4 = \sum_{h=0}^{\infty} \frac{b_h}{R_{d^h k+l}}$$

is algebraic if and only if (b_h) is a constant sequence, $d = 2$, $|Q| = 1$, and $R_l = 0$. Moreover, if Θ_4 is algebraic, then $\Theta_4 b_0^{-1} \in \mathbf{Q}(\sqrt{\Delta}) \setminus \mathbf{Q}$.

For other results of this type, we refer the interested reader to [38], [40], [45], [13], [31], [10], [11].

4 The Sylvester sequence and a problem of Erdős

In proposition 20 of Book IX of his *Elements*, Euclid gave a proof like the following that there are infinitely many primes. Suppose that $p_1, \ldots, p_n$ are all the primes we know about. Let

$$P_n = \prod_{i=1}^{n} p_i \ .$$

Then $1 + P_n$ is not divisible by any of the primes $p_1, \ldots, p_n$, so the prime factors of $1 + P_n$ are new to us. Hence, the number of primes is unbounded. If we "discover" just the smallest prime factor of $1 + P_n$ and if we begin with 2, then we are lead in a natural way to the sequence

$$2, \ 3, \ 7, \ 43, \ 13, \ \textit{etc.}$$

Shanks [53] has conjectured that this sequence contains all primes and he gave a heuristic argument which makes this conjecture plausible. For this

and other similar Euclid sequences we also refer to Guy and Nowakowski [30] and Wagstaff [58].

If one feels that *all* prime factors of 1 plus the product of those found so far are "discoverd", then one is lead to the sequence

$$S_1 = 2,\ S_{n+1} = 1 + S_1 \cdots S_n.$$

The terms of this sequence can be computed without any factoring since

$$S_{n+1} = S_n^2 - S_n + 1 = S_n(S_n - 1) + 1\ .$$

We refer to Guy and Nowakowski [30] and Odoni [46] (and the references cited therein) for the study of the primes of this sequence.

It seems that this sequence (#331 in [54]) was first mentioned by J.J. Sylvester in 1880 [55], although some authors attribute it to E. Lucas. We will call it the *Sylvester sequence*. It may be worthwile to mention that the Sylvester sequence appears in many different contexts : see the list of references for several of the many papers mentioning the Sylvester sequence.

For irrationality assertions, the following greedy property of the Sylvester sequence may be important : for each N, the first N terms of the Sylvester sequence are known [37], [20], [36] to give the smallest positive value of

$$1 - \sum_{i=1}^{N} \frac{1}{a_i}$$

among all choices of positive integers $a_1, \ldots, a_N$. In particular, the sum

$$\sum_{i=1}^{\infty} \frac{1}{S_n} = 1$$

is rational. The following open problem due to Erdős conjectures that this is essentially the only possibility among sequences satisfying $a_{n+1}/a_n^2 \sim 1$.

Conjecture 2 (Erdős [23]) *Let $(a_n), n \geq 1$, be a sequence of positive integers such that*

$$\lim_{n\to\infty} \frac{a_{n+1}}{a_n^2} = 1.$$

Then,

$$\sum_{n=1}^{\infty} \frac{1}{a_n} \in \mathbf{Q}$$

implies $a_{n+1} = a_n^2 - a_n + 1$ *for all large* n.

The following are some partial results towards this conjecture.

Theorem 3 (Erdős and Straus [24]) *Let* $(a_n), n \geq 1$, *be an increasing sequence of positive integers such that*

1. $\limsup_{n\to\infty} a_n^2/a_{n+1} \leq 1$;
2. *the sequence* $[a_1, \ldots, a_n]/a_{n+1}$ *is bounded.*

Then the same conclusion as in Conjecture 4.1 holds.

In the above theorem, $[a_1, \ldots, a_n]$ denotes the least common multiple of $a_1, \ldots, a_n$.

The following result is a consequence of a more general result [6].

Theorem 4 ([6]) *Let* $(a_n), n \geq 1$, *be a sequence of positive integers such that*

$$a_{n+1} \geq a_n^2 - a_n + 1.$$

Then the same conclusion as in Conjecture 4.1 holds.

A generalization of this result to irrationality of series of rationals can be found in [6], while a generalization of Erdős-Straus's result to more general series was obtained by Oppenheim [48]. A similar result holds for infinite products [47].

The following variation of Theorem 4.2 can be proved.

Theorem 5 ([7]) *Let* $(a_n), n \geq 1$, *be an increasing sequence of positive integers such that*

1. $a_n^2/a_{n+1} \geq 1$;
2. $\sum_{n=1}^{\infty} \left(\frac{a_n^2}{a_{n+1}} - 1\right) < \infty$.

Then the same conclusion as in Conjecture 4.1 holds.

If one admits also alternating series, then we should mention that

$$C_0 = \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{S_n}$$

is transcendental. Therefore, Cahen's [15] constant

$$C = \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{S_n - 1}$$

is also a transcendental number since $2C = C_0 + 1$. These results were first proved by Davison and Shallit [21], [52], who also obtained their continued fractions development. Note that C was also mentioned by Remez [49] and that the transcendency of Cahen's constant was also proved, as a corollary of a more general result, by Becker [9]. A trancendency measure for C was recently obtained by Töpfer [57].

Acknowledgments. The author would like to thank the organizers of the conference for their kind invitation and support. He would also like to thank R. André-Jeannin, P.-G. Becker, F. Beukers, P. Bundschuh and R.W.K. Odoni for their help.

1 Introduction

While extensive usage of high-performance computing has been a staple of other scientific and engineering disciplines for some time, research mathematics is one discipline that has heretofore not yet benefited to the same degree. Now, however, with sophisticated mathematical computing tools and environments widely available on desktop computers, a growing number of remarkable new mathematical results are being discovered partly or entirely with the aid of these tools. With currently planned improvements in these tools, together with substantial increases expected in raw computing power, due both to Moore's Law and the expected implementation of these environments on parallel supercomputers, we can expect even more remarkable developments in the years ahead.

This article briefly discusses the nature of mathematical experiment. It then presents a few instances primarily of our own recent computer-aided mathematical discoveries, and sketches the outlook for the future. Additional examples in diverse fields and broader citations to the literature may be found in [16] and its references.

2 Preliminaries

The crucial role of high performance computing is now acknowledged throughout the physical, biological and engineering sciences. Numerical experimentation, using increasingly large-scale, three-dimensional simulation programs, is now a staple of fields such as aeronautical and electrical engineering, and research scientists heavily utilize computing technology to collect and analyze data, and to explore the implications of various physical theories.

† Borwein's work supported by the Natural Sciences and Engineering Research Council of Canada and the Networks of Centres of Excellence programme.

However, "pure" mathematics (and closely allied areas such as theoretical physics) only recently has begun to capitalize on this new technology. This is ironic, because the basic theoretical underpinnings of modern computer technology were set out decades ago by mathematicians such as Alan Turing and John Von Neumann. But only in the past decade, with the emergence of powerful mathematical computing tools and environments, together with the growing availability of very fast desktop computers and highly parallel supercomputers, as well as the pervasive presence of the Internet, has this technology reached the level where the research mathematician can enjoy the same degree of intelligent assistance that has graced other technical fields for some time.

This new approach is often termed *experimental mathematics*, namely the utilization of advanced computing technology to explore mathematical structures, test conjectures and suggest generalizations. And there is now a thriving journal of *Experimental Mathematics*. In one sense, there is nothing new in this approach — mathematicians have used it for centuries. Gauss once confessed, "I have the result, but I do not yet know how to get it." [2]. Hadamard declared, "The object of mathematical rigor is to sanction and legitimize the conquests of intuition, and there was never any other object for it." [34]. In recent times Milnor has stated this philosophy very clearly:

> If I can give an abstract proof of something, I'm reasonably happy. But if I can get a concrete, computational proof and actually produce numbers I'm much happier. I'm rather an addict of doing things on computer, because that gives you an explicit criterion of what's going on. I have a visual way of thinking, and I'm happy if I can see a picture of what I'm working with. [35]

What is really meant by an *experiment* in the context of mathematics? In *Advice to a Young Scientist*, Peter Medawar [31] identifies four forms of experiment:

> 1. The *Kantian* experiment is one such as generating "the classical non-Euclidean geometries (hyperbolic, elliptic) by replacing Euclid's axiom of parallels (or something equivalent to it) with alternative forms."
> 2. The *Baconian* experiment is a contrived as opposed to a natural happening, it "is the consequence of 'trying things out' or even of merely messing about."
> 3. The *Aristotelian* experiment is a demonstration: "apply electrodes to a frog's sciatic nerve, and lo, the leg kicks; always precede the presentation of the dog's dinner with the ringing of a bell, and lo, the bell alone will soon make the dog dribble."
> 4. The *Galilean* experiment is "a critical experiment – one that discriminates between possibilities and, in doing so, either gives us confidence in the view we are taking or makes us think it in need of correction."

The first three are certainly common in mathematics. However, as discussed in detail in [15], the Galilean experiment is the only one of the four forms which can make experimental mathematics a truly serious enterprise.

3 Tools of the Trade

The most obvious development in mathematical computing technology has been the growing availability of powerful symbolic computing tools. Back in the 1970s, when the first symbolic computing tools became available, their limitations were quite evident — in many cases, these programs were unable to handle operations that could be done by hand. In the intervening years these programs, notably the commercial products such as Maple and Mathematica, have greatly improved. While numerous deficiencies remain, they nonetheless routinely and correctly dispatch many operations that are well beyond the level that a human could perform with reasonable effort.

Another recent development that has been key to a number of new discoveries is the emergence of practical integer relation detection algorithms. Let $x = (x_1, x_2, \cdots, x_n)$ be a vector of real or complex numbers. x is said to possess an integer relation if there exist integers a_i, not all zero, such that $a_1x_1 + a_2x_2 + \cdots + a_nx_n = 0$. By an *integer relation algorithm*, we mean a practical computational scheme that can recover the vector of integers a_i, if it exists, or can produce bounds within which no integer relation exists. The problem of finding integer relations was studied by numerous mathematicians, including Euclid and Euler. The first general integer relation algorithm was discovered in 1977 by Ferguson and Forcade [24]. There is a close connection between integer relation detection and finding small vectors in an integer lattice, and thus one common solution to the integer relation problem is to apply the Lenstra-Lenstra-Lovasz (LLL) lattice reduction algorithm [30]. At the present time, the most effective scheme for integer relation detection is Ferguson's "PSLQ" algorithm [23,6].

Integer relation detection, as well as a number of other techniques used in modern experimental mathematics, relies heavily on very high precision arithmetic. The most advanced tools for performing high precision arithmetic utilize fast Fourier transforms (FFTs) for multiplication operations. Armed with one of these programs, a researcher can often effortlessly evaluate mathematical constants and functions to precision levels in the many thousands of decimal digits. The software products Maple and Mathematica include relatively complete and well-integrated multiple precision arithmetic facilities, although until very recently they did not utilize FFTs, or other accelerated multiplication techniques. One may also use any of several freeware multiprecision software packages [3,22] and for many purposes tools such as Matlab, MuPAD or more specialized packages like Pari-GP are excellent.

High precision arithmetic, when intelligently used with integer relation detection programs, allows researchers to discover heretofore unknown mathematical identities. It should be emphasized that these numerically discovered "identities" are only approximately established. Nevertheless, in the cases we are aware of, the results have been numerically verified to hundreds and in some cases thousands of decimal digits beyond levels that could reasonably be dismissed as numerical artifacts. Thus while these "identities" are not firmly established in a formal sense, they are supported by very compelling numerical evidence. After all, which is more compelling, a formal proof that in its full exposition requires hundreds of difficult pages of reasoning, fully understood by only two or three colleagues, or the numerical verification of a conjecture to 100,000 decimal digit accuracy, subsequently validated by numerous subsidiary computations? In the same way, these tools are often even more useful as a way of *excluding* the possibility of hoped for relationships, as in equation (1) below.

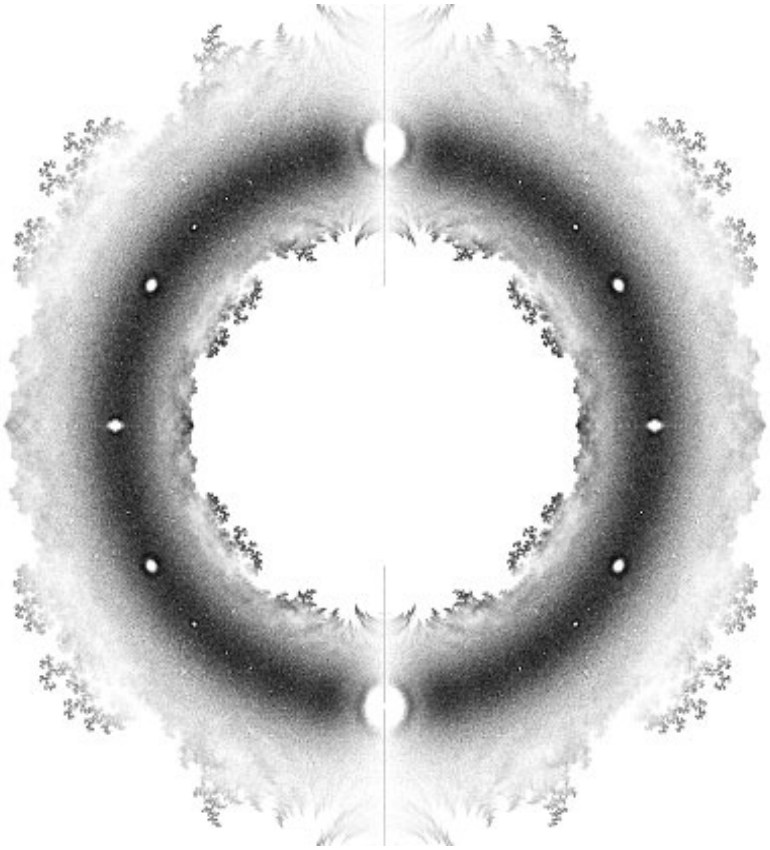

FIGURE 1(A-D): -1/1 POLYNOMIALS (TO BE SET IN COLOR)

We would be remiss not to mention the growing power of visualization especially when married to high performance computation. The pictures

in FIGURE 1 represents the zeroes of all polynomials with ± 1 coefficients of degree at most 18. One of the most striking features of the picture, its fractal nature excepted, is the appearance of different sized "holes" at what transpire to be roots of unity. This observation which would be very hard to make other than pictorially led to a detailed and rigorous analysis of the phenomenon and more [17,27]. They were lead to this analysis by the interface which was built for Andrew Odlyzko's seminal online paper [32].

One additional tool that has been utilized in a growing number of studies is Sloane and Plouffe's *Encyclopedia of Integer Sequences* [36]. As the title indicates, it identifies many integer sequences based on the first few terms. A very powerful on-line version is also available and is a fine example of the changing research paradigm. Another wonderful resource is Stephen Finch's "Favorite Mathematical Constants," which contains a wealth of frequently updated information, links and references on 125 constants, [25], such as the *hard hexagon constant* $\kappa \approx 1.395485972$ for which Zimmermann obtained a minimal polynomial of degree 24 in 1996.[1]

In the following, we illustrate this – both new and old – approach to mathematical research using a handful of examples with which we are personally familiar. We will then sketch some future directions in this emerging methodology. We have focussed on the research of our own circle of direct collaborators. We do so for resaons of fmailiarity and because we believe it is representative of broad changes in the way mathematics is being done rather than to claim primacy for our own skills or expertise.

4 A New Formula for Pi

Through the centuries mathematicians have assumed that there is no shortcut to determining just the n-th digit of π. Thus it came as no small surprise when such a scheme was recently discovered [5]. In particular, this simple algorithm allows one to calculate the n-th hexadecimal (or binary) digit of π without computing any of the first $n-1$ digits, without the need for multiple-precision arithmetic software, and requiring only a very small amount of memory. The one millionth hex digit of π can be computed in this manner on a current-generation personal computer in only about 30 seconds run time.

This scheme is based on the following remarkable formula, whose formal proof involves nothing more sophisticated than freshman calculus:

$$\pi = \sum_{k=0}^{\infty} \frac{1}{16^k} \left[\frac{4}{8k+1} - \frac{2}{8k+4} - \frac{1}{8k+5} - \frac{1}{8k+6} \right]$$

This formula was found using months of PSLQ computations, after corresponding but simpler n-th digit formulas were identified for several

[1] See `http://www.mathsoft.com/asolve/constant/square/square.html`.

other constants, including log(2). This is likely the first instance in history that a significant new formula for π was discovered by a computer.

Similar base-2 formulas are given in [5,21] for a number of other mathematical constants. In [20] some base-3 formulas were obtained, including the identity

$$\pi^2 = \frac{2}{27}\sum_{k=0}^{\infty}\frac{1}{729^k}\quad\left[\frac{243}{(12k+1)^2} - \frac{405}{(12k+2)^2} - \frac{81}{(12k+4)^2}\right.$$
$$- \frac{27}{(12k+5)^2} - \frac{72}{(12k+6)^2} - \frac{9}{(12k+7)^2}$$
$$\left. - \frac{9}{(12k+8)^2} - \frac{5}{(12k+10)^2} + \frac{1}{(12k+11)^2}\right]$$

In [8], it is shown that the question of whether π, log(2) and certain other constants are normal can be reduced to a plausible conjecture regarding dynamical iterations of the form $x_0 = 0$,

$$x_n = (bx_{n-1} + r_n) \bmod 1$$

where b is an integer and $r_n = p(n)/q(n)$ is the ratio of two nonzero polynomials with $\deg(p) < \deg(q)$. The conjecture is that these iterates either have a finite set of attractors or else are equidistributed in the unit interval. In particular, it is shown that the question of whether π is normal base 16 (and hence base 2) can be reduced to the assertion that the dynamical iteration $x_0 = 0$,

$$x_n = \left(16x_{n-1} + \frac{120n^2 - 89n + 16}{512n^4 - 1024n^3 + 712n^2 - 206n + 21}\right) \bmod 1$$

is equidistributed in $[0, 1)$. There are also connections between the question of normality for certain constants and the theory of linear congruential pseudorandom number generators. All of these results derive from the discovery of the individual digit-calculating formulas mentioned above. For details, see [8].

5 Identities for the Riemann Zeta Function

Another application of computer technology in mathematics is to determine whether or not a given constant α, whose value can be computed to high precision, is algebraic of some degree n or less. This can be done by first computing the vector $x = (1, \alpha, \alpha^2, \cdots, \alpha^n)$ to high precision and then applying an integer relation algorithm. If a relation is found for x, then this relation vector is precisely the set of integer coefficients of a polynomial satisfied by α. Even if no relation is found, integer relation detection programs can produce bounds within which no relation can exist. In fact, exclusions of this type are solidly established by integer relation calculations, whereas "identities" discovered in this fashion are only approximately established, as noted above.

Consider, for example, the following identities, with that for $\zeta(3)$ due to Apéry [10,14]:

$$\zeta(2) = 3\sum_{k=1}^{\infty} \frac{1}{k^2\binom{2k}{k}}$$
$$\zeta(3) = \frac{5}{2}\sum_{k=1}^{\infty} \frac{(-1)^{k-1}}{k^3\binom{2k}{k}}$$
$$\zeta(4) = \frac{36}{17}\sum_{k=1}^{\infty} \frac{1}{k^4\binom{2k}{k}}$$

where $\zeta(n) = \sum_k k^{-n}$ is the Riemann zeta function at n. These results have led many to hope that

$$Z_5 = \zeta(5)/\sum_{k=1}^{\infty} \frac{(-1)^{k-1}}{k^5\binom{2k}{k}} \tag{1}$$

might also be a simple rational or algebraic number. However, computations using PSLQ established, for instance, that if Z_5 satisfies a polynomial of degree 25 or less, then the Euclidean norm of the coefficients must exceed 2×10^{37}. Given these results, there is no "easy" identity, and researchers are licensed to investigate the possibility of multi-term identities for $\zeta(5)$. One recently discovered [14], using a PSLQ computation, was the polylogarithmic identity

$$\sum_{k=1}^{\infty} \frac{(-1)^{k+1}}{k^5\binom{2k}{k}} = 2\zeta(5) + 80\sum_{k=1}^{\infty}\left[\frac{1}{(2k)^5} - \frac{L}{(2k)^4}\right]\rho^{2k} - \frac{4}{3}L^5 + \frac{8}{3}L^3\zeta(2) + 4L^2\zeta(3)$$

where $L = \log(\rho)$ and $\rho = (\sqrt{5}-1)/2$. This illuastrates neatly that one can only find a closed form if one knows where to look.

Other earlier evaluations involving the central binomial coefficient suggested general formulas [12], which were pursued by a combination of PSLQ and heavy-duty symbolic manipulation. This led, most unexpectedly, to the identity

$$\sum_{k=1}^{\infty} \zeta(4k+3)z^{4k} = \sum_{k=1}^{\infty} \frac{1}{k^3(1-z^4/k^4)} = \frac{5}{2}\sum_{k=1}^{\infty} \frac{(-1)^{k-1}}{k^3\binom{2k}{k}(1-z^4/k^4)} \prod_{m=1}^{k-1} \frac{1+4z^4/m^4}{1-z^4/m^4}.$$

Experimental analysis of the first ten terms showed that the rightmost above series necessarily had the form

$$\frac{5}{2}\sum_{k=1}^{\infty} \frac{(-1)^{k-1}P_k(z)}{k^3\binom{2k}{k}(1-z^4/k^4)}$$

where

$$P_k(z) = \prod_{j=1}^{k-1} \frac{1 + 4z^4/j^4}{1 - z^4/j^4}.$$

Also discovered in this process was the intriguing *equivalent* combinatorial identity

$$\binom{2n}{n} = \sum_{k=1}^{\infty} \frac{2n^2 \prod_{i=1}^{n-1}(4k^4 + i^4)}{k^2 \prod_{i=1, i\neq k}^{n}(k^4 - i^4)}.$$

This evaluation was discovered as the result of an serendipitous error in an input to Maple[2]— the computational equivalent of discovering penicillin after a mistake in a Petri dish.

With the recent proof of this last conjectured identity, by Almkvist and Granville [1], the above identities have now been rigorously established. But other numerically discovered "identities" of this type appear well beyond the reach of current formal proof methods. For example, in 1999 British physicist David Broadhurst used a PSLQ program to recover an explicit expression for $\zeta(20)$ involving 118 terms. The problem required 5,000 digit arithmetic and over six hours computer run time. The complete solution is given in [6].

6 Identification of Multiple Sum Constants

Numerous identities were experimentally discovered in some recent research on multiple sum constants. After computing high-precision numerical values of these constants, a PSLQ program was used to determine if a given constant satisfied an identity of a conjectured form. These efforts produced empirical evaluations and suggested general results [4]. Later, elegant proofs were found for many of these specific and general results [13], using a combination of human intuition and computer-aided symbolic manipulation. Three examples of experimentally discovered re-

[2] Typing 'infty' for 'infinity' revealed that the program had an algorithm when a formal variable was entered.

sults that were subsequently proven are:

$$\sum_{k=1}^{\infty}\left(1+\frac{1}{2}+\cdots+\frac{1}{k}\right)^2 (k+1)^{-4} = \frac{37}{22680}\pi^6 - \zeta^2(3)$$

$$\sum_{k=1}^{\infty}\left(1+\frac{1}{2}+\cdots+\frac{1}{k}\right)^3 (k+1)^{-6} = \zeta^3(3) + \frac{197}{24}\zeta(9) + \frac{1}{2}\pi^2\zeta(7) - \frac{11}{120}\pi^4\zeta(5) - \frac{37}{7560}\pi^6\zeta(3)$$

$$\sum_{k=1}^{\infty}\left(1-\frac{1}{2}+\cdots+(-1)^{k+1}\frac{1}{k}\right)^2 (k+1)^{-3} = 4\,\mathrm{Li}_5(\tfrac{1}{2}) - \frac{1}{30}\ln^5(2) - \frac{17}{32}\zeta(5) - \frac{11}{720}\pi^4\ln(2) + \frac{7}{4}\zeta(3)\ln^2(2) + \frac{1}{18}\pi^2\ln^3(2) - \frac{1}{8}\pi^2\zeta(3)$$

where again $\zeta(n) = \sum_{j=1}^{\infty} j^{-n}$ is a value of the Riemann zeta function, and $\mathrm{Li}_n(x) = \sum_{j=1}^{\infty} x^j j^{-n}$ denotes the classical polylogarithm function.

More generally, one may define *multi-dimensional Euler sums* (or *multiple zeta values*) by

$$\zeta\begin{pmatrix} s_1,\ s_2\ \cdots\ s_r \\ \sigma_1,\ \sigma_2\ \cdots\ \sigma_r \end{pmatrix} := \sum_{k_1>k_2>\cdots>k_r>0} \frac{\sigma_1^{k_1}}{k_1^{s_1}}\,\frac{\sigma_2^{k_2}}{k_2^{s_2}}\,\cdots\,\frac{\sigma_r^{k_r}}{k_r^{s_r}}$$

where $\sigma_j = \pm 1$ are signs and $s_j > 0$ are integers. When all the signs are positive, one has a multiple zeta value. The integer r is the sum's depth and $s_1 + s_2 + \cdots + s_r$ is the weight. These sums have connections with diverse fields such as knot theory, quantum field theory and combinatorics. Constants of this form with alternating signs appear in problems such as computation of the magnetic moment of the electron.

Multi-dimensional Euler sums satisfy many striking identities. The discovery of the more recondite identities was facilitated by the development of Hölder convolution algorithms that permit very high precision numerical values to be rapidly computed. See [13] and a computational interface at `www.cecm.sfu.ca/projects/ezface+/`. One beautiful general identity discovered by Zagier [37] in the course of similar research is

$$\zeta(3,1,3,1,\ldots,3,1) = \frac{1}{2n+1}\zeta(2,2,\ldots,2) \;=\; \frac{2\pi^{4n}}{(4n+2)!}$$

where there are n instances of '$(3,1)$' and '2' in the arguments to $\zeta(\cdot)$. This has now been proven in [13] and the proof, while entirely conventional, was obtained by guided experimentation. A related conjecture for which overwhelming evidence but no hint of a proof exists is the

"identity"

$$8^n\zeta\begin{pmatrix} 2, & 1, & 2, & 1, \cdots, & 2, & 1 \\ -1, & 1, & -1, & 1, \cdots, & -1, & 1 \end{pmatrix} = \zeta(2,1,2,1,\ldots,2,1).$$

Along this line, Broadhurst conjectured, based on low-degree numerical results, that the dimension of the space of Euler sums with weight w is the Fibonacci number $F_{w+1} = F_w + F_{w-1}$, with $F_1 = F_2 = 1$. In testing this conjecture, complete reductions of all Euler sums to a basis of size F_{w+1} were obtained with PSLQ at weights $w \leq 9$. At weights $w = 10$ and $w = 11$ the conjecture was stringently tested by application of PSLQ in more than 600 cases. At weight $w = 11$ such tests involve solving integer relations of size $n = F_{12} + 1 = 145$. In a typical case, each of the 145 constants was computed to more than 5,000 digit accuracy, and a working precision level of 5,000 digits was employed in an advanced "multi-pair" PSLQ program. In these problems the ratios of adjacent coefficients in the recovered integer vector usually have special values, such as $11! = 39916800$. These facts, combined with confidence ratios typically on the order of 10^{-300} in the detected relations, render remote the chance that these identities are spurious numerical artifacts, and lend substantial support to this conjecture [6].

7 Mathematical Computing Meets Parallel Computing

The potential future power of highly parallel computing technology has been underscored in some recent results. Not surprisingly, many of these computations involve the constant π, underscoring the enduring interest in this most famous of mathematical constants. In 1997 Fabrice Bellard of INRIA used a more efficient formula, similar to the one mentioned in section three, programmed on a network of workstations, to compute 150 binary digits of π starting at the *trillionth* position. Not to be outdone, 17-year-old Colin Percival of Simon Fraser University in Canada organized a computation of 80 binary digits of π beginning at the five trillionth position, using a network of 25 laboratory computers. He an many others are presently computing binary digits at the quadrillionth position on the web [33]. As we write, the most recent computational result was Yasumasa Kanada's calculation (September 1999) of the first 206 billion decimal digits of π. This spectacular computation was made on a Hitachi parallel supercomputer with 128 processors, in little over a day, and employed the Salamin-Brent algorithm [10], with a quartically convergent algorithm from [10] as an independent check.

Several large-scale parallel integer relation detection computations have also been performed in the past year or two. One arose from the discovery by Broadhurst that

$$\alpha^{630} - 1 = \frac{(\alpha^{315}-1)(\alpha^{210}-1)(\alpha^{126}-1)^2(\alpha^{90}-1)(\alpha^3-1)^3(\alpha^2-1)^5(\alpha-1)^3}{(\alpha^{35}-1)(\alpha^{15}-1)^2(\alpha^{14}-1)^2(\alpha^5-1)^6\alpha^{68}}$$

where $\alpha = 1.176280818\ldots$ is the largest real root of Lehmer's polynomial [29]

$$0 = 1 + \alpha - \alpha^3 - \alpha^4 - \alpha^5 - \alpha^6 - \alpha^7 + \alpha^9 + \alpha^{10}.$$

The above cyclotomic relation was first discovered by a PSLQ computation, and only subsequently proven. Broadhurst then conjectured that there might be integers a, b_j, c_k such that

$$a\,\zeta(17) = \sum_{j=0}^{8} b_j\,\pi^{2j}(\log\alpha)^{17-2j} + \sum_{k\in D(\mathcal{S})} c_k\,\mathrm{Li}_{17}(\alpha^{-k})$$

where the 115 indices k are drawn from the set, $D(\mathcal{S})$, of positive integers that divide at least one element of

$$\begin{aligned}\mathcal{S} = \{&29, 47, 50, 52, 56, 57, 64, 74, 75, 76, 78, 84, 86, 92, 96, 98, 108, 110, 118,\\ &124, 130, 132, 138, 144, 154, 160, 165, 175, 182, 186, 195, 204, 212, 240,\\ &246, 270, 286, 360, 630\}.\end{aligned}$$

Indeed, such a relation was found, using a parallel multi-pair PSLQ program running on a SGI/Cray T3E computer system at Lawrence Berkeley Laboratory. The run employed 50,000 decimal digit arithmetic and required approximately 44 hours on 32 processors. The resulting integer coefficients are as large as 10^{292}, but the "identity" nonetheless was confirmed to 13,000 digits beyond the level of numerical artifact [7].

8 Connections to Quantum Field Theory

In another surprising recent development, David Broadhurst has found, using these methods, that there is an intimate connection between Euler sums and constants resulting from evaluation of Feynman diagrams in quantum field theory [18,19]. In particular, the renormalization procedure (which removes infinities from the perturbation expansion) involves multiple zeta values. As before, a fruitful theory has emerged, including a large number of both specific and general results [13].

Some recent quantum field theory results are even more remarkable. Broadhurst has now shown [20], using PSLQ computations, that in each of ten cases with unit or zero mass, the finite part the scalar 3-loop tetrahedral vacuum Feynman diagram reduces to 4-letter "words" that represent iterated integrals in an alphabet of seven "letters" comprising the one-forms $\Omega := dx/x$ and $\omega_k := dx/(\lambda^{-k} - x)$, where $\lambda := (1 + \sqrt{-3})/2$ is the primitive sixth root of unity, and k runs from 0 to 5. A 4-letter word is a 4-dimensional iterated integral, such as

$$U := \zeta(\Omega^2\omega_3\omega_0) = \int_0^1 \frac{dx_1}{x_1}\int_0^{x_1}\frac{dx_2}{x_2}\int_0^{x_2}\frac{dx_3}{(-1-x_3)}\int_0^{x_3}\frac{dx_4}{(1-x_4)} = \sum_{j>k>0}\frac{(-1)^{j+k}}{j^3k}.$$

There are 7^4 such four-letter words. Only two of these are primitive terms occurring in the 3-loop Feynman diagrams: U, above, and

$$V := \text{Real}[\zeta(\Omega^2\omega_3\omega_1)] = \sum_{j>k>0} \frac{(-1)^j \cos(2\pi k/3)}{j^3 k}.$$

The remaining terms in the diagrams reduce to products of constants found in Feynman diagrams with fewer loops. These ten cases as shown in Figure 1. In these diagrams, dots indicate particles with nonzero rest mass. The formulas that have been found, using PSLQ, for the corresponding constants are given in Table 2. In the table the constant $C = \sum_{k>0} \sin(\pi k/3)/k^2$.

V_1	$= 6\zeta(3) + 3\zeta(4)$
V_{2A}	$= 6\zeta(3) - 5\zeta(4)$
V_{2N}	$= 6\zeta(3) - \frac{13}{2}\zeta(4) - 8U$
V_{3T}	$= 6\zeta(3) - 9\zeta(4)$
V_{3S}	$= 6\zeta(3) - \frac{11}{2}\zeta(4) - 4C^2$
V_{3L}	$= 6\zeta(3) - \frac{15}{4}\zeta(4) - 6C^2$
V_{4A}	$= 6\zeta(3) - \frac{77}{12}\zeta(4) - 6C^2$
V_{4N}	$= 6\zeta(3) - 14\zeta(4) - 16U$
V_5	$= 6\zeta(3) - \frac{469}{27}\zeta(4) + \frac{8}{3}C^2 - 16V$
V_6	$= 6\zeta(3) - 13\zeta(4) - 8U - 4C^2$

Table 1. Formulas found by PSLQ for the ten cases of Figure 1

9 A Note of Caution

In spite of the remarkable successes of this methodology, some caution is in order. First of all, the fact that an identity is established to high precision is *not* a guarantee that it is indeed true. One example is

$$\sum_{n=1}^{\infty} \frac{[n \tanh \pi]}{10^n} \approx \frac{1}{81}$$

which holds to 267 digits, yet is not an exact identity, failing in the 268'th place. Several other such bogus "identities" are exhibited and explained in [11].

More generally speaking, caution must be exercised when extrapolating results true for small n to all n. For example,

$$\int_0^{\infty} \frac{\sin(x)}{x}\, dx = \frac{\pi}{2}$$
$$\int_0^{\infty} \frac{\sin(x)}{x} \frac{\sin(x/3)}{x/3}\, dx = \frac{\pi}{2}$$
$$\cdots$$
$$\int_0^{\infty} \frac{\sin(x)}{x} \frac{\sin(x/3)}{x/3} \cdots \frac{\sin(x/13)}{x/13}\, dx = \frac{\pi}{2}$$

yet

$$\int_0^{\infty} \frac{\sin(x)}{x} \frac{\sin(x/3)}{x/3} \cdots \frac{\sin(x/15)}{x/15}\, dx = \frac{467807924713440738696537864469}{935615849440640907310521750000}\pi.$$

When this fact was recently observed by a researcher using a mathematical software package, he concluded that there must be a "bug" in the software. Not so. What is happening here is that

$$\int_0^{\infty} \frac{\sin(x)}{x} \frac{\sin(x/h_1)}{x/h_1} \cdots \frac{\sin(x/h_n)}{x/h_n}\, dx = \frac{\pi}{2}$$

only so long as $1/h_1 + 1/h_2 + \cdots + 1/h_n < 1$. In the above example, $1/3 + 1/5 + \cdots + 1/13 < 1$, but with the addition of $1/15$, the sum exceeds 1 and the identity no longer holds [9]. Changing the h_n lets this pattern persist indefinitely but still fail in the large.

10 Future Outlook

Computer mathematics software is now becoming a staple of university departments and government research laboratories. Many university departments now offer courses where the usage of one of these software

packages is an integral part of the course. But further expansion of these facilities into high schools has been inhibited by a number of factors, including the fairly high cost of such software, the lack of appropriate computer equipment, difficulties in standardizing such coursework at a regional or national level, a paucity of good texts incorporating such tools into a realistic curriculum, lack of trained teachers and many other demands on their time.

But computer hardware continues its downward spiral in cost and its upward spiral in power. It thus appears that within a very few years, moderately powerful symbolic computation facilities can be incorporated into relatively inexpensive hand calculators, at which point it will be much easier to successfully integrate these tools into high school curricula. Thus it seems that we are poised to see a new generation of students coming into university mathematics and science programs who are completely comfortable using such tools. This development is bound to have a profound impact on the future teaching, learning and doing of mathematics.

A likely and fortunate spin-off of this development is that the commercial software vendors who produce these products will likely enjoy a broader financial base, from which they can afford to further enhance their products geared at serious researchers. Future enhancements are likely to include more efficient algorithms, more extensive capabilities mixing numerics and symbolics, more advanced visualization facilities, and software optimized for emerging symmetric multiprocessor and highly parallel, distributed memory computer systems. When combined with expected increases in raw computing power due to Moore's Law — improvements which almost certainly will continue unabated for at least ten years and probably much longer — we conclude that enormously more powerful computer mathematics systems will be available in the future.

We only now are beginning to experience and comprehend the potential impact of computer mathematics tools on mathematical research. In ten more years, a new generation of computer-literate mathematicians, armed with significantly improved software on prodigiously powerful computer systems, are bound to make discoveries in mathematics that we can only dream of at the present time. Will computer mathematics eventually replace, in near entirety, the solely human form of research, typified by Andrew Wiles' recent proof of Fermat's Last Theorem? Will computer mathematics systems eventually achieve such intelligence that they discover deep new mathematical results, largely or entirely without human assistance? Will new computer-based mathematical discovery techniques enable mathematicians to explore the realm, proved to exist by Gödel, Chaitin and others, that is fundamentally beyond the limits of formal reasoning?

11 Conclusion

We have shown a small but we hope convincing selection of what the present allows and what the future holds in store. We have hardly mentioned the growing ubiquity of web based computation, or of pervasive access to massive data bases, both public domain and commercial. Neither have we raised the human/computer interface or intellectual property issues and the myriad other not-purely-technical issues these raise.

Whatever the outcome of these developments, we are still persuaded that mathematics is and will remain a uniquely human undertaking. One could even argue that these developments confirm the fundamentally human nature of mathematics. Indeed, Reuben Hersh's arguments [26] for a humanist philosophy of mathematics, as paraphrased below, become more convincing in our setting:

1. *Mathematics is human.* It is part of and fits into human culture. It does not match Frege's concept of an abstract, timeless, tenseless, objective reality.
2. *Mathematical knowledge is fallible.* As in science, mathematics can advance by making mistakes and then correcting or even re-correcting them. The "fallibilism" of mathematics is brilliantly argued in Lakatos' *Proofs and Refutations* [28].
3. *There are different versions of proof or rigor.* Standards of rigor can vary depending on time, place, and other things. The use of computers in formal proofs, exemplified by the computer-assisted proof of the four color theorem in 1977, is just one example of an emerging nontraditional standard of rigor.
4. *Empirical evidence, numerical experimentation and probabilistic proof all can help us decide what to believe in mathematics.* Aristotelian logic isn't necessarily always the best way of deciding.
5. *Mathematical objects are a special variety of a social-cultural-historical object.* Contrary to the assertions of certain post-modern detractors, mathematics cannot be dismissed as merely a new form of literature or religion. Nevertheless, many mathematical objects can be seen as shared ideas, like Moby Dick in literature, or the Immaculate Conception in religion.

Certainly the recognition that "quasi-intuitive" analogies can be used to gain insight in mathematics can assist in the learning of mathematics. And honest mathematicians will acknowledge their role in discovery as well.

We look forward to what the future will bring.

Latin squares: Equivalents and equivalence

1 Introduction

This essay describes some mathematical structures 'equivalent' to Latin squares and some notions of 'equivalence' of such structures.

According to the *Handbook of Combinatorial Design* [2], Theorem II.1.5, a Latin square of order n is equivalent to

- the multiplication table (*Cayley table*) of a quasigroup on n elements;
- a transversal design of index 1;
- a $(3,n)$-net;
- an orthogonal array of strength 2 and index 1;
- a 1-factorisation of the complete bipartite graph $K_{n,n}$;
- an edge-partition of the complete tripartite graph $K_{n,n,n}$ into triangles;
- a set of n^2 mutually non-attacking rooks on an $n \times n \times n$ board;
- a single error detecting code of word length 3, with n^2 words from an n-symbol alphabet.

We add two further items to this list:

- a strongly regular graph of Latin square type;
- a sharply transitive set of permutations.

The statement is true but not sufficiently precise, since it is not explained what 'equivalent' means. The imprecision of which this is just an example has led to a number of inaccuracies in the literature. This essay will explain how to transform Latin squares into structures of each of these types, what notions of equivalence of Latin squares result from the natural definitions of isomorphism of these structures, and how the confusion may be avoided.

2 Latin squares

A *Latin square* of order n is an $n \times n$ array in which each of the n^2 cells contains a symbol from an alphabet of size n, such that each symbol in the alphabet occurs just once in each row and once in each column.

The alphabet is completely arbitrary, but it is often convenient to take it to be the set $\{1,2,\ldots,n\}$. This has the advantage that the same set indexes the rows and columns of the square.

It is clear that, if we permute in any way the rows, or the columns, or the symbols, of a Latin square, the result is still a Latin square. We say that two Latin squares L and L' (using the same symbol set) are *isotopic* if there is a triple (f,g,h), where f is a row permutation, g a column permutation, and h a symbol permutation, carrying L to L': this means that, if the (i,j) entry of L is k, then the $(f(i),g(j))$ entry of L' is $h(k)$. The triple (f,g,h) is called an *isotopy*. The relation of being isotopic is an equivalence on the set of Latin squares with given symbol set; its equivalence classes are called *isotopy classes*.

The notion of isotopy can be extended to Latin squares L,L' with different alphabets by allowing h to be a bijective map from the alphabet of L to that of L'. In this wider sense, any Latin square of order n is isotopic to one with alphabet $\{1,\ldots,n\}$.

A Latin square with symbol set $\{1,\ldots,n\}$ is *normalised* if the $(i,1)$ and $(1,i)$ entries are both equal to i, for all $i \in \{1,\ldots,n\}$. Given any Latin square, we can obtain from it a normalised Latin square by row and column permutations. So, in particular, every Latin square is isotopic to a normalised Latin square.

Despite the fact that the definition of a Latin square gives different roles to the rows, columns, and symbols, there are extra 'equivalences' connecting them. To each permutation π of the set $\{r,c,s\}$, there is a function on Latin squares. We give two examples (which suffice to generate all six):

- $L^{(r,c)}$ has (j,i) entry k if and only if L has (i,j) entry k (in other words, $L^{(r,c)}$ is the transpose of L);
- $L^{(r,s)}$ has (k,j) entry i if and only if L has (i,j) entry k.

The six Latin squares obtained from L in this way are the *conjugates* of L.

The *main class* or *species* of a Latin square is the union of the isotopy classes of its conjugates. Two Latin squares L,L' are *main class equivalent* if they belong to the same main class; that is, if L is isotopic to a conjugate of L'. Each main class is the union of 1, 2, 3 or 6 isotopy classes.

One of the important properties of main class equivalence is that it preserves various combinatorial properties. Here are some examples. Let L be a Latin square of order n.

- A *subsquare* of L of order k is a set of k rows and k columns in whose cells just k symbols occur. (These k^2 cells form a Latin square of order k if the remaining cells are removed.) A subsquare of order 2 is called an *intercalate*.

- A *transversal* of L is a set T of n cells, such that each row contains one member of T, each column contains one member of T, and each symbol occurs in one member of T. Now the square L possesses an orthogonal mate if and only if the n^2 cells can be partitioned into n transversals. (Associate one symbol of a new alphabet with each transversal, and let L' have (i,j) entry k if cell (i,j) lies in transversal k.)

Now the following is easily checked:

Proposition 1 *If two Latin squares are main class equivalent, then they have the same number of subsquares of each order, the same number of transversals, and the same number of partitions into transversals.*

For example, the two Latin squares shown below belong to different main classes since they have different numbers of intercalates (12 and 4 respectively) and different numbers of transversals (8 and 0 respectively).

1	2	3	4
2	1	4	3
3	4	1	2
4	3	2	1

1	2	3	4
2	3	4	1
3	4	1	2
4	1	2	3

A Web page giving the isotopy classes and main classes of Latin squares of small orders is maintained by McKay [3]. The numbers of Latin squares, isotopy classes, and main classes are given in sequences numbered A002860, A040082, A003090 in the *On-Line Encyclopedia of Integer Sequences* [4].

3 Quasigroups and loops

A *binary system* is a pair $(Q,*)$, where Q is a set and $*$ a binary operation on Q (a function from $Q\times Q$ to Q). We usually write the image of the operation on the pair (a,b) as $a*b$.

A *quasigroup* is a binary system $(Q,*)$ satisfying the two conditions

- for any $a,b \in Q$, there is a unique $x \in Q$ satisfying $a*x = b$;
- for any $a,b \in Q$, there is a unique $y \in Q$ satisfying $y*a = b$.

We often write the elements x and y above as $a\backslash b$ and b/a; these new operations are called *left division* and *right division* of b by a. These binary operations give new quasigroups on the set Q.

The *dual* of a binary system $(Q,*)$ is the binary system $(Q,\circ)$ whose operation is defined by $a \circ b = b*a$. It is also a quasigroup if $(Q,*)$ is.

An *operation table* or *Cayley table* of a set with a binary operation is the square array, having rows and columns indexed by Q in some order (the same order for rows as for columns), for which the entry in row a and column b is $a*b$. Now we have the following observation:

Proposition 2 *(a) The binary system $(Q,*)$ is a quasigroup if and only if some (and hence any) Cayley table for it is a Latin square.*

(b) If $(Q,*)$ is a quasigroup, then the conjugates of its Cayley table are the Cayley tables of $(Q,*)$, $(Q,\backslash)$ and $(Q,/)$ and their duals.

We note that, for some applications, the orders of the row and column labels are not required to be the same. This doesn't change the concept of "quasigroup" but the correspondence between quasigroups and Latin squares is rather different.)

For algebraic structures such as quasigroups, the appropriate notion of equivalence is *isomorphism*. An isomorphism from $(Q,*)$ to $(R,\circ)$ is a bijective function $f : Q \to R$ such that, for all $a,b \in Q$, we have

$$f(a) \circ f(b) = f(a*b).$$

An *automorphism* of a quasigroup $(Q,*)$ is an isomorphism from $(Q,*)$ to itself.

Two Cayley tables representing the same quasigroup differ only in the order of the elements labelling the rows and columns; thus, one is obtained from the other by applying simultaneously the same permutation to the rows and columns (including their labels). If it happens that the resulting square could alternatively be obtained by applying the given permutation to the row and column labels and to the entries of the square, then it is an automorphism of the quasigroup. For example, in the second quasigroup in the list below, the permutation $(a)(bc)$ is an automorphism.

We see that isomorphism of quasigroups is a much finer relation than isotopy of Latin squares; isomorphisms are isotopies (f,f,f) whose row, column and symbol permutations are equal. So, although there is only one isotopy class of Latin squares of order 3, there are five isomorphism classes of quasigroups, as shown below.

$*$	a	b	c
a	a	c	b
b	c	b	a
c	b	a	c

$*$	a	b	c
a	a	b	c
b	b	c	a
c	c	a	b

$*$	a	b	c
a	a	b	c
b	c	a	b
c	b	c	a

$*$	a	b	c
a	a	c	b
b	b	a	c
c	c	b	a

$*$	a	b	c
a	b	a	c
b	a	c	b
c	c	b	a

These five quasigroups can be distinguished by algebraic properties. An element a of a quasigroup $(Q,*)$ is an *idempotent* if $a*a=a$; it is a *left identity* if $a*x=x$ for all $x\in Q$; a *right identity* is defined analogously; and a is a *two-sided identity* if it is both a left and a right identity. Any isomorphism must preserve these properties of elements. Now

- in the first quasigroup, every element is an idempotent;
- the second quasigroup has one idempotent, which is a two-sided identity;
- the third quasigroup has one idempotent, which is a left but not a right identity;
- the fourth quasigroup has one idempotent, which is a right but not a left identity;
- the fifth quasigroup has no idempotents.

It is a simple exercise to show that the quasigroup defined by each of the twelve Latin squares with symbol set $\{a,b,c\}$ is isomorphic to one of these five.

A *loop* is a quasigroup which has a two-sided identity. This element is necessarily unique; for, if a is a left identity and b a right identity, then $a=a*b=b$. (More is true: a quasigroup cannot have two different left identities. For, if $a*x=x=b*x$, then $a=b$ by cancellation.)

If we write the Cayley table of a loop so that the first element is the identity, then the elements in the first row are the same as the row labels, and similarly for columns. In particular, if we use the labels $1,\ldots,n$, then the resulting Latin square is normalised. So a loop is a quasigroup which has a normalised Latin square as a Cayley table (when the labels occur in natural order). However, different

normalised Latin squares can correspond to isomorphic loops! However, since the identity is unique, any quasigroup-isomorphism of loops is a loop-isomorphism.

Of the five quasigroups of order 3 (up to isomorphism), just one is a loop (the second). It is even a group. (A group can be defined as a loop satisfying the *associative law* $a*(b*c) = (a*b)*c$ for all a, b, c.)

The sequences enumerating quasigroups and loops are numbers A057991 and A057771 in the in the *On-Line Encyclopedia of Integer Sequences* [4].

4 Transversal designs and nets

Let L be a Latin square. Associated with L is an incidence structure called a 3-*net*, defined as follows. The points are the n^2 cells of the square, and there are three types of lines: the n rows; the n columns; and, for each of the n symbols in the alphabet, the set of cells containing that symbol. Nets are also called *square lattice designs*.

The net has the following properties:

(a) There are n^2 points and $3n$ lines.

(b) Each line contains n points, and each point lies on 3 lines.

(c) Two points lie on at most one line.

(d) The design is *resolvable*: the lines can be partitioned into three families of n lines, each of which is a partition of the set of points. Moreover, two lines from different families intersect in a (unique) point.

The three families of lines in the resolution correspond to rows, columns, and symbols. The second sentence of (d) shows that there is a unique resolution: two lines belong to the same family if and only if they are disjoint.

Because of this uniqueness, it is possible to recover the Latin square from a structure satisfying (a)–(d). Label the three resolution classes R, C, and S, and number the lines in each class from 1 to n. Now the Latin square has (i, j) entry k if and only if the (unique) point on the ith line of R and the jth line of C is also on the kth line of S.

An isomorphism of nets is a bijection between their point sets which carries lines to lines. It is clear from the above reconstruction that two nets are isomorphic if and only if the Latin squares used to construct them are main-class equivalent.

The *dual* of an incidence structure is obtained by interchanging the roles of 'point' and 'line' while preserving the relation of incidence. Now the dual of a net is a special type of *transversal design*. The defining conditions are:

(a′) There are $3n$ points and n^2 lines.

(b′) Each line contains 3 points, and each point lies on n lines.

(c′) Two points lie on at most one line.

(d′) The points can be partitioned into three families of n points, such that each line contains one point of each family. Moreover, two points from different families lie on a (unique) line.

The families in (d′) are sometimes called *groups*, though the word does not carry its algebraic sense.

One advantage of this representation is that it translates subsquares, transversals and orthogonal mates of a Latin square into familiar notions of design theory: subdesigns, parallel classes, and resolutions (parallelisms) respectively.

Two such transversal designs are isomorphic if and only if the nets dual to them are isomorphic; so this isomorphism is the same as main-class equivalence of the Latin squares.

The *complete tripartite graph* $K_{n,n,n}$ has $3n$ vertices partitioned into three sets of size n, with any two vertices in different classes being joined by an edge. A collection of triangles in such a graph with the property that every edge is contained in exactly one triangle (a partition of the edge set into triangles) is obviously the same thing as a transversal design of the type just discussed, and the same considerations apply.

5 Strongly regular graphs

Given a Latin square L, we define a graph as follows: the vertices of the graph are the n^2 cells of the Latin square; two vertices are adjacent if they lie in the same row or column or contain the same symbol. In other words, it is the *collinearity graph* of the net associated with the Latin square: the vertices are the points of the net, two vertices adjacent if they are collinear.

Such a graph is called a *Latin square graph*. It is *strongly regular* with parameters $(n^2, 3(n-1), n, 6)$: this means that

- there are n^2 vertices;
- each vertex is joined to $3(n-1)$ others;
- two adjacent vertices have n common neighbours;
- two non-adjacent vertices have 6 common neighbours.

The following result is due to Bruck [1].

Proposition 3 *(a) If $n > 23$, then any strongly regular graph with parameters $(n^2, 3(n-1), n, 6)$ is a Latin square graph.*

(b) If $n > 4$, then any isomorphism of Latin square graphs is induced by a main-class equivalence of the Latin squares.

Here the a graph isomorphism is a bijection between the vertex sets which carries edges to edges and non-edges to non-edges. The proof involves recognising the lines of the net as cliques in the strongly regular graph. Bruck's result is actually more general (it extends to sets of mutually orthogonal Latin squares) and was further generalised by Bose to 'partial geometries'.

A strongly regular graph and its complement form an example of a two-class *association scheme*. The notion of isomorphism of association scheme is more general; in this case, an isomorphism from the graph to its complement is an automorphism of the association scheme. However, counting arguments show that such an isomorphism is possible only if $n = 5$.

6 Orthogonal arrays and codes

A different way to describe a Latin square is to list all n^2 triples (i, j, k), where i, j and k are the row, column and symbol numbers associated with a cell of the square. We can imagine these as written out in an $n^2 \times 3$ array. This array is

- an *orthogonal array* of strength 2 and index 1: given any pair of columns, and any choice of two symbols, there is a unique row where those symbols occur in those columns;
- a 1-error-detecting code: any two rows of the array differ in at least two positions.

It is clear that these two properties of an $n^2 \times 3$ array with entries from an alphabet of size n are equivalent, and an array with these properties arises from a Latin square as described.

Two $v \times k$ arrays over an alphabet A are said to be *equivalent* if one can be obtained from the other by a combination of the following operations:

- applying a permutation f_i of A to the symbols in the ith column, for $i = 1, \ldots, k$;
- applying a permutation to the columns;
- applying a permutation to the rows.

Warning: regarding a Latin square as an $n \times n$ array, the above definition is not the same as any standard equivalence of Latin squares! This notion is particularly appropriate for codes, since column permutations and permutations to the symbols in each column independently generate all the isometries of A^n (where the metric is *Hamming distance*, the distance between two n-tuples being the number of positions where they differ.) It is clear that equivalence in this sense of the orthogonal arrays (or codes) constructed from Latin squares L, L' arises from main-class equivalence of L and L', and only thus.

Finally, the rows of such an array are the positions of n^2 non-attacking rooks on an $n \times n \times n$ board, and conversely. (A rook is allowed to move along a 'line' of the board, keeping two coordinates constant.)

If we allow arbitrary permutations of the board which preserve the $3n$ 'lines', then equivalence of such sets of rooks is the same as main class equivalence of Latin squares. However, we may wish to consider a more restricted version of equivalence (if, say, we are considering other kinds of chess pieces at the same time), in which case the equivalence relation will be finer. The most extreme position is not to allow any non-trivial equivalences at all, in which case each configuration of rooks corresponds to a single Latin square. An intermediate position might, for example, allow Euclidean symmetries of the board: here the equivalence relation on Latin squares would be main class equivalence where each of the three permutations involved in the isotopy is either the identity or the reversal on $\{1, \ldots, n\}$.

7 Edge-colourings

An *edge-colouring* of a graph is an assignment of 'colours' to the edges in such a way that two edges sharing a vertex get different colours. It is clear that the number of colours required cannot be smaller than the maximum valency of a vertex. A consequence of Hall's Marriage Theorem is that, if a graph is bipartite, then this bound is attained. If the graph is regular with valency r, then an edge-colouring with r colours is the same as a 1-factorisation of the graph (provided that the names of the colours are not significant).

The *complete bipartite graph* $K_{n,n}$ has $2n$ vertices partitioned into two sets R and C each of size n, such that every vertex of R is joined to every vertex of C (and these are all the edges). Let $R = \{r_1, \ldots, r_n\}$ and $C = \{c_1, \ldots, c_n\}$. Suppose that the edges are coloured with the set $S = \{s_1, \ldots, s_n\}$ of colours. Then we may form an $n \times n$ array in which the (i, j) entry is k if and only if the colour of the edge $\{r_i, c_j\}$ is s_k. This array is a Latin square. Reversing the construction, any Latin square of order n gives rise to an edge-colouring of $K_{n,n}$ with n colours.

An *isomorphism* of edge-colourings of graphs G, G' is a graph isomorphism from G to G' which maps each colour class in G to a colour class in G'. Now two Latin squares L and L' give rise to isomorphic edge-coloured complete bipartite graphs if and only if L is isotopic to either L' or its transpose $(L')^{(r,c)}$. This is because, in the edge-colouring situation, exchanging rows and columns corresponds to a graph isomorphism, but symbols play a different role. So this relation is coarser than isotopy but finer than main-class equivalence.

8 Sharply transitive permutation sets

A set S of permutations of $\{1, \ldots, n\}$ is *sharply transitive* if, for any $i, j \in \{1, \ldots, n\}$, there is a unique $f \in S$ with $f(i) = j$.

If we identify a permutation f with its *passive form* $(f(1), \ldots, f(n))$, we see that a sharply transitive set is precisely the set of rows of a Latin square.

Two sets S, S' of permutations are isomorphic if S' can be obtained from S by re-labelling the domain: that is, there is a permutation g of $\{1, \ldots, n\}$ such that $S' = \{ghg^{-1} : h \in S\}$. The effect of g on the corresponding Latin square is to apply the permutation g simultaneously to the columns and the symbols: we have

$$h(j) = k \Leftrightarrow (ghg^{-1})(g(j)) = g(k).$$

Note that the order of the rows of the square is unspecified. Thus isomorphism

of permutation sets corresponds to a specialisation of isotopy of Latin squares: we are allowed only isotopies of the form (f,g,g) for permutations f and g. This relation is coarser than quasigroup isomorphism (which takes $g = f$) but finer than isotopy.

9 Complete Latin squares

A Latin square is said to be *row-complete* if each ordered pair of distinct symbols occurs exactly once in consecutive positions in the same row. A Latin square is said to be *row-quasi-complete* if each unordered pair of distinct symbols occurs exactly twice in adjacent positions in the same row. Such squares are used in experimental design where there is a spatial or temporal structure on the set of experimental units.

Column-completeness and *column-quasi-completeness* are defined analogously. A Latin square is *complete* if it is both row-complete and column-complete, and is *quasi-complete* if it is both row-quasi-complete and column quasi-complete.

For example, the first square below is complete, while the second is quasi-complete.

1	2	6	3	5	4
2	3	1	4	6	5
6	1	5	2	4	3
3	4	2	5	1	6
5	6	4	1	3	2
4	5	3	6	2	1

1	2	3	4	5
5	3	1	2	4
3	4	2	5	1
4	1	5	3	2
2	5	4	1	3

In a row-complete or row-quasi-complete Latin square, row and symbol permutations preserve the completeness property, but column permutations (except for the identity and the left-to-right reversal) do not, in general. So the appropriate concept of equivalence for these squares (regarding the completeness as part of the structure) allows row and symbol permutations but only reversal of columns. Similarly, for a complete or quasi-complete Latin square, we can permute the symbols arbitrarily, but at most reverse rows and/or columns (and we may allow transposition as well). This gives rise to several new notions of equivalence.

10 Conclusion

The most natural equivalence relations associated with Latin squares (equality, isotopy and main class equivalence) are not always the relevant ones for objects 'equivalent' to Latin squares. We have identified three others: isomorphism of quasigroups, of edge-coloured complete bipartite graphs, and of sharply transitive permutation sets (and potentially more, in configurations of non-attacking rooks and in Latin squares with various completeness properties).

We conclude by pointing out that the definition of 'isomorphism' of Latin squares in Chapter II.1 of the *Handbook of Combinatorial Design* [2] agrees with quasigroup isomorphism, but the enumeration of isomorphism classes immediately following is not consistent with this (giving only one class for $n = 3$). The moral is that care is required!

Finally, we remark that much of what is said above extends to sets of mutually orthogonal Latin squares.

Abstract

This talk presents a classification by rationality, algebraicity or transcendence of ECO-systems (Enumerating Combinatorial Objects) and of more general random walks. It is based on an article by Cyril Banderier, Mireille Bousquet-Mélou, Alain Denise, Philippe Flajolet, Danièle Gardy and Dominique Gouyou-Beauchamps [1].

1 Introduction

A *generating tree* is defined by a system (an axiom and a family of rewriting rules)

$$\left((s_0),\{(k)\to(e_1(k))(e_2(k))\ldots(e_k(k))\}_{k\geq 0}\right) \quad (1)$$

Here, the axiom (s_0) specifies the degree of the root, while the productions $e_i(k)$ (with $e_i(k)>0$) list the degrees of the k descendants of a node labelled k (note the constraint on the number of descendants of a node). Such a system constitutes an *ECO-System*.

Example 1 123-avoiding permutations. *Consider the set $S_n(123)$ of permutations of length n that* avoid the pattern *123: there exist no integers $i<j<k$ such that $\sigma(i)<\sigma(j)<\sigma(k)$. For instance, $\sigma=4213$ belongs to $S_4(123)$ but $\sigma=1324$ does not, since $\sigma(1)<\sigma(3)<\sigma(4)$.*

Observe that if $\tau\in S_{n+1}(123)$, then the permutation σ obtained by erasing the entry $n+1$ from τ belongs to S_n

(123). Conversely, for every $\sigma \in S_n(123)$*, insert the value n+1 in each place where this is compatible with the avoiding rule; this gives an element of* $S_{n+1}(123)$*. For example, the permutation* $\sigma=213$ *gives 4213, 2413 and 2143, by insertion of 4 in first, second and third place respectively. The permutation 2134, resulting of the insertion of 4 in the last place, does not belong to* $S_4(123)$*. This process can be described by a tree whose nodes are the permutations avoiding 123: the root is 1, and the children of any node* σ *are the permutations derived as above (see Figure 1(a)).*

Let us now label the nodes by their number of children: we obtain the tree of Figure 1(b). It can be proved that the k children of any node labelled k are labelled respectively k+1,2,3,...,k. Thus the tree we have constructed is the generating tree obtained from the following system:

$$\left((2),\{(k)\rightarrow(2)(3)\ldots(k-1)(k)(k+1)\}_{k\geq 2}\right) \quad (2)$$

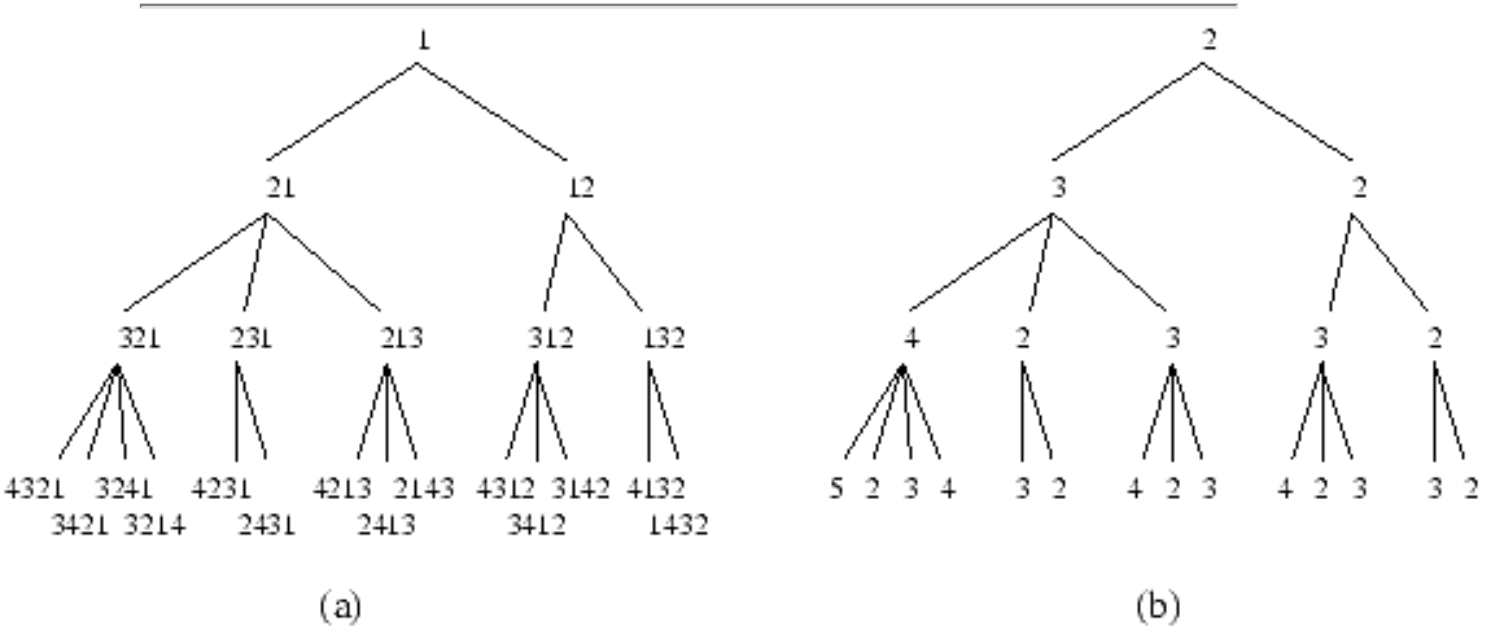

Figure 1: The generating tree of 123-avoiding permutations: (a) nodes labelled by the permutations; (b) nodes labelled by the numbers of children.

Notations. We assume that all the values appearing in the generating tree are positive.

In the generating tree, let f_n be the number of nodes at level n and s_n the sum of the labels of these nodes. By convention, the root is at level 0, so that $f_0=1$. In terms of walks, f_n is the number of walks of length n.

The generating function associated to the system is $F(z) = \sum_{n \geq 0} f_n z^n$.

Note that $s_n = f_{n+1}$, and that the sequence $(f_n)_n$ is nondecreasing.

Now let $f_{n,k}$ be the number of nodes at level n having label k (or the number of walks of length n ending at position k). The following generating functions will be of interest:

$$F_k(z) = \sum_{n \geq 0} f_{n,k} z^n \quad \text{and} \quad F(z,u) = \sum_{n,k \geq 0} f_{n,k} z^n u^k.$$

We have $F(z)=F(z,1)=\sum_{k \geq 1} F_k(z)$. Furthermore, the F_k's satisfy the relation

$$F_k(z) = [k=s_0] + z \sum_{j \geq 1} \pi_{j,k} F_j(z), \quad (3)$$

where $[k=s_0]$ is 1 if $k=s_0$ and 0 elsewhere and $\pi_{j,k}$ denotes the number $|\{ i \leq j \mid e_i(j)=k \}|$ of one-step transitions from j to k. This is equivalent to the recurrence $f_{n+1,k} = \sum_{j \geq 1} \pi_{j,k} f_{n,j}$ for the numbers $f_{n,k}$ (with $f_{0,s0} = 1$), that results from tracing all the paths that lead to k in n+1 steps.

We refer to [1] for random generation using counting and generating trees.

2 Rational Systems

ECO-systems satisfying strong regularity conditions lead to rational generating functions. This covers systems that have a finite number of allowed degrees, as well as systems where the sum of the labels at level k depends linearly on k.

Proposition 1 *If finitely many labels appear in the tree, then F(z)=F(z,1) is rational.*

Proof. Only a finite number of F_k's are nonzero; they are related by linear equations like Equation (3) above and therefore rational. $F(z)$ is a finite sum of these, and is also rational.

Example 2 *Fibonacci numbers are generated by the system ((1),{(k)→(k)$^{k-1}$((kmod2)+1)}) that can also be written as ((1),{(1)→(2),(2)→(1)(2)}).*

Proposition 2 *Let* $\sigma(k)=e_1(k)+e_2(k)+\ldots+e_k(k)$. *If* σ *is an affine function of* k, *say* $\sigma(k)=\alpha k+\beta$, *then the series* $F(z)$ *is rational. More precisely:*

$$F(z)=\frac{1+(s_0-\alpha)z}{1-\alpha z-\beta z^2}.$$

Proof. Let $n\geq 0$ and let $k_1, k_2,\ldots, k_{f_n}$ denote the labels of the f_n nodes at level n. Then

$$f_{n+2}=s_{n+1}=(\alpha k_1+\beta)+(\alpha k_2+\beta)+\ldots+(\alpha k_{f_n}+\beta)$$

$$=\alpha s_n+\beta f_n=\alpha f_{n+1}+\beta f_n.$$

We know that $f_0=1$ and $f_1=s_0$. The result follows.

Example 3 *The system* $((2),\{(k)\rightarrow(2)^{k-1}(k+1)\})$ *produces the Fibonacci numbers of even index.*

Proposition 2 can be adapted to apply to systems that ``almost" satisfy its criterion (see [1]).

3 Algebraic Systems

Systems where a finite modification of the set $\{1,\ldots,k\}$ is reachable from k lead to algebraic generating functions.

The possible moves from k are given by the rule:

$$(k)\rightarrow\{(0),\ldots,(k-1)\}\setminus\{(k-i)|\ i\in B\}\cup\{\{(k+j)|\ j\in A\}\},\quad (4)$$

where $A\subset\mathbf{N}$ and $B\subset\mathbf{N}^+$ are a finite multiset (denoted $\{\{\ldots\}\}$) and a finite set specifying respectively the *allowed forward jumps* (possibly coloured) and the *forbidden backwards jumps*.

Observe that these walk models are not necessarily ECO-systems, first because we allow labels to be zero---but a simple translation can take us back to a model with positive labels---, and second because we do not require (k) to have exactly k successors.

In this section $f_{n,k}$ is the number of walks of length n ending at point k and $f_n(u)=\sum_{k\geq 0}f_{n,k}u^k$ is the coefficient of z^n in $F(z,u)$.

We continue this section with the example $A=\{4,15\}$ and $B=\{2\}$, axiom (0) and the corresponding family of rules

$$\{(k)\rightarrow(0)(1)\ldots(k-3)(k-1)(k+4)(k+15)\}.$$

This corresponds in generating functions to substituting u^k in

$$u^0+\ldots+u^{k-1}-u^{k-2}+u^{k+4}+u^{k+15}=\frac{1-u^k}{1-u}-u^{k-2}+u^{k+4}+u^{k+15}$$

for $k\geq 2$. This gives the recurrence $f_{n+1}(u)=f_n(1)-f_n(u)/1-u+(u^4+u^{15}-u^{-2})f_n(u)$, and yields the functional equation

$$F(z,u)=1+z\left(\frac{F(z,1)-F(z,u)}{1-u}+P(u)F(z,u)-\{u^{<0}\}\sum_{n\leq 0} z^n L[f_n](u)\right), \quad (5)$$

Here $P(u)=\sum_{\alpha\in A} u^{\alpha}-\sum_{\beta\in B} u^{-\beta}$ and $L[g](u)=g(1)-g(u)/1-u+P(u)g(u)$. Equation (5) may be rewritten as

$$F(z,u)\left(1+\frac{z}{1-u}-zP(u)\right)=1+\frac{z}{1-u}F(z,1)-z\sum_{j=0}^{b-1} c_j(u)\partial_u^j F(z,0),$$

where the $c_j(u)$ are Laurent polynomials. The kernel $K(z,u)$ of Equation (5) is the coefficient of $F(z,u)$ in the left-hand side of this equation. $F(z,u)K(z,u)$ is a linear combination of $b+1$ unknown functions. Solving $K(z,u)=0$ in u gives $b+1$ convergent branches $u_i(z)$ which, in turn, give the $\partial_u^j F(z,0)$ through a $(b+1)\times(b+1)$ linear system, and from there $F(z,1)$, which is algebraic.

Proposition 3 *The generating function F(z,1) counting the number of walks, starting from zero and irrespective of their endpoint is algebraic and* $F(z,1)=-1/z\prod_{i=0}^{b}(1-u_i)$, *where* $b=\max B$ *and* $u_i(z)$ *are the finite solutions at z=0 of the equation K(z,u)=0.*

Examples of algebraic systems are the Catalan numbers $\{(k)\rightarrow(0)(1)\ldots(k)(k+1)\}$, the Motzkin numbers $\{(k)\rightarrow(0)\ldots(k-1)(k+1)\}$, the Schröder numbers $\{(k)\rightarrow(0)\ldots(k-1)(k)(k+1)\}$ or the m-ary trees $((m),\{(k)\rightarrow(m)\ldots(k)(k+1)(k+2)\ldots(k+m-1)\})$.

4 Transcendental Systems

4.1 Transcendence

If the coefficients of a series grow too fast, its radius of convergence is zero.

Proposition 4 *Let b be a nonnegative integer. For* $k\geq 1$, *let* $m_k=|\{\, i \mid e_i(k)\geq k-b \,\}|$. *Assume that:*

1. *for all k, there exists a forward jump from k (i.e.,* $e_i(k)>k$ *for some i),*

2. *the sequence* $(m_k)_k$ *is non-decreasing and tends to infinity.*

Then the generating function of the system has radius of convergence 0.

Proof. See [1].
However, there are ECO-systems or walks that are transcendental with positive radius of convergence such as $\{(k)\to(2)(4)...(2k)\}$ or $\{(k)\to(\lceil k/2\rceil)^{k-1}(k+1)\}$.

4.2 Holonomy

A subclass of transcendental functions is the class of holonomic functions. A series is said to be *holonomic* or *D-finite* if it satisfies a linear differential equation with polynomial coefficients in z. Equivalently, its coefficients f_n satisfy a linear recurrence relation with polynomial coefficients in n. Given a sequence f_n, the OGF (ordinary generating function) $\sum f_n z^n$ is holonomic if and only if the EGF (exponential generating function) $\sum f_n z^n/n!$ is holonomic.

The following table gives examples of holonomic and non-holonomic transcendental systems with references to the Encyclopedia of Integer Sequences (EIS) by Sloane and Plouffe [2, 3].

Axiom	Rewriting rules	Name	EIS Id.	Generating Function
	Holonomic OGF			**EGF**
(1)	$(k)\to(k+1)^k$	Permutations	M1675	$1/(1-z)$
(2)	$(k)\to(k)(k+1)^{k-1}$	Arrangements	M1497	$e^z/(1-z)$
(1)	$(k)\to(k-1)^{k-1}(k+1)$	Involutions	M1221	$e^{z+z2/2}$
(2)	$(k)\to(k+1)^{k-1}(k+2)$	Partial permutations	M1795	$e^{z/(1-z)}/(1-z)$
	Nonholonomic OGF			**EGF**
(1)	$(k)\to(k)^{k-1}(k+1)$	Bell numbers	M1484	e^{e^z-1}
(2)	$(k)\to(k-1)(k)^{k-2}(k+1)$	Bessel numbers	M1462	---

From Motzkin to Catalan permutations

Elena Barcucci, Alberto Del Lungo, Elisa Pergola *, Renzo Pinzani

Dipartimento di Sistemi e Informatica, Universita di Firenze, Via Lombroso 6/17, 50134 Firenze, Italy

Received 22 October 1997; revised 16 April 1999; accepted 11 June 1999

Abstract

For every integer $j \geqslant 1$, we define a class of permutations in terms of certain forbidden subsequences. For $j = 1$, the corresponding permutations are counted by the Motzkin numbers, and for $j = \infty$ (defined in the text), they are counted by the Catalan numbers. Each value of $j > 1$ gives rise to a counting sequence that lies between the Motzkin and the Catalan numbers. We compute the generating function associated to these permutations according to several parameters. For every $j \geqslant 1$, we show that only this generating function is algebraic according to the length of the permutations.

1. Introduction

Permutations with forbidden subsequences have been widely studied in the last few years. They are of interest in both Computer Science and Combinatorics because the permutations with forbidden subsequences are related to the characterization of words without any regularities or to the analysis of some regularities in words [7,19]. They are found in some sorting [21,24,25] and pattern matching [8] problems, and they codify a large number of nontrivial combinatorial objects [10,12,13,15–17]. Several classical sequences of numbers in Combinatorics arise in the problem of enumerating permutations with forbidden subsequences. For example, we refer to binomial coefficients and the Pell, Fibonacci, Motzkin and Schröder numbers [23]. Some of these results were obtained by West [22,24,26,27] and Gire [15]. Knuth studied the permutations sortable through a stack [18] and showed that they are the permutations with the forbidden subsequence 231. All the permutations with a forbidden subsequence of length three are enumerated by Catalan numbers. West [25] proved that the permutations sortable twice through a stack avoid the subsequences 2341 and $3\bar{5}241$. A permutation π avoids the barred pattern $3\bar{5}241$ if every subsequence of type 3241 is contained in a subsequence of type 35241 in π. West conjectured that the number of two-stack sortable

PII: S0012-365X(99)00254-X

permutations of length n is $2(3n)!/((2n+1)!(n+1)!)$. This conjecture was proved by Zeilberger [28]. Even though permutations with forbidden subsequences have been widely studied (see [16], for a survey), there are still many interesting problems to be solved on the subject. For instance, many efforts have been made to enumerate the permutations with the forbidden subsequence $12..(k+1)$ and which are related to pairs of standard Young tableaux having the same shape and length at most k. The results obtained refer to the number of permutations of length n avoiding the patterns 123 [22] and 1234 [14]. If k is larger than three, the enumeration problem is still open. In this case, Regev [20] obtained quite an interesting result, that is: the number of permutations of length n avoiding the pattern $1\ldots(k+1)$ is asymptotically equal to $c(k-1)^{2n}/n^{(k^2-2k)/2}$, where c is a constant.

In this paper, we characterize the permutations avoiding the patterns 321 and $(j+2)\bar{1}(j+3)2\ldots(j+1)$ and we denote this class by $\mathscr{M}(j)$. The enumeration of $\mathscr{M}(j)$ permutations produces sequences of numbers and provides a kind of 'discrete continuity' between the well-known Motzkin and Catalan number sequences. In Section 2 some definitions regarding permutations with forbidden subsequences are recalled. In Section 3, we describe the basic idea of the ECO method [6]. It is used for Enumerating Combinatorial Objects and allows us to obtain all the objects of size $(n+1)$ from the objects of size n by means of a 'local expansion'. In Section 4, we apply this method to the class $\mathscr{M}(j)$ and determine a recursive construction of the class which can be translated into a functional equation verified by the generating function of $\mathscr{M}(j)$ permutations according to their length, number of active sites, inversions and right minima. The definitions of these parameters are given in the following section (see Definitions 2.4 and 2.5). We also prove that this generating function is algebraic only according to the length of the permutations. The following well-known cases have algebraic generating functions of degree two:

- $\mathscr{M}(1)$ permutations enumerated by Motzkin numbers;
- $\mathscr{M}(2)$ permutations enumerated by the numbers of the left factors in Motzkin words;
- $\mathscr{M}(\infty)$ permutations enumerated by Catalan numbers.

Finally, in Section 5, we propose some perspectives for future research on this subject.

2. Notations and definitions

In this section, we recall the basic definitions used in this paper. A permutation $\pi=\pi(1)\pi(2)\ldots\pi(n)$ on $[n]=\{1,2,\ldots,n\}$ is a bijection between $[n]$ and $[n]$. Let $\mathscr{S}_n$ be the set of permutations on $[n]$.

Definition 2.1. A permutation $\pi\in\mathscr{S}_n$ contains a subsequence of type $\tau\in\mathscr{S}_k$ if a sequence of indexes $1\leqslant i_{\tau(1)}<i_{\tau(2)}<\cdots<i_{\tau(k)}\leqslant n$ exists such that $\pi(i_1)<\pi(i_2)<\cdots<\pi(i_k)$. We denote the set of permutations of $\mathscr{S}_n$ not containing any subsequences of type τ by $\mathscr{S}_n(\tau)$.

Example 2.1. The permutation $\pi = 5\ 1\ 6\ 2\ 7\ 3\ 8\ 4\ 9$ belongs to $\mathscr{S}_9(321)$ because all its subsequences of length 3 are not of type 321. This permutation does not belong to $\mathscr{S}_9(3412)$ because it contains subsequences of type 3412:

$$\pi(1)\pi(3)\pi(4)\pi(6) = 5623,$$

$$\pi(1)\pi(3)\pi(4)\pi(8) = 5624,$$

$$\pi(1)\pi(3)\pi(6)\pi(8) = 5634,$$

$$\pi(1)\pi(5)\pi(6)\pi(8) = 5734,$$

$$\pi(3)\pi(5)\pi(6)\pi(8) = 6734.$$

Definition 2.2. A *barred* permutation $\bar{\tau}$ of $[k]$ is a permutation of $\mathscr{S}_k$ having a bar over one of its elements. Let τ be a permutation on $[k]$ identical to $\bar{\tau}$ but unbarred: $\hat{\tau}$ is the permutation of $[k-1]$ made up of the $k-1$ unbarred elements of $\bar{\tau}$, rearranged as a permutation on $[k-1]$.

Definition 2.3. A permutation $\pi \in \mathscr{S}_n$ contains a type $\bar{\tau}$ subsequence if π contains a type $\hat{\tau}$ subsequence and which, in turn, is not a type τ subsequence. We denote the set of permutations in $\mathscr{S}_n$ not containing any type $\bar{\tau}$ subsequences by $\mathscr{S}_n(\bar{\tau})$.

Example 2.2. If $\bar{\tau} = 4\bar{1}523$, we have $\tau = 41523$ and $\hat{\tau} = 3412$. The permutation $\pi = 5\ 1\ 6\ 2\ 7\ 3\ 8\ 4\ 9$ belongs to $\mathscr{S}_9(\bar{\tau})$ because the subsequences of type $\hat{\tau}$ (see Example 2.1) are subsequences of:

$$\pi(1)\pi(2)\pi(3)\pi(4)\pi(6) = 51623,$$

$$\pi(1)\pi(2)\pi(3)\pi(4)\pi(8) = 51624,$$

$$\pi(1)\pi(2)\pi(3)\pi(6)\pi(8) = 51634,$$

$$\pi(1)\pi(2)\pi(5)\pi(6)\pi(8) = 51734,$$

$$\pi(3)\pi(4)\pi(5)\pi(6)\pi(8) = 62734,$$

which are of type τ.

If we have a set $\tau_1 \in \mathscr{S}_{k_1}, \ldots, \tau_p \in \mathscr{S}_{k_p}$ of barred or unbarred permutations, we denote the set $\mathscr{S}_n(\tau_1) \cap \cdots \cap \mathscr{S}_n(\tau_p)$ by $\mathscr{S}_n(\tau_1, \ldots, \tau_p)$. We call the family $F = \{\tau_1, \ldots, \tau_p\}$ a *family of forbidden subsequences* and the set $\mathscr{S}_n(F)$, a *family of permutations with forbidden subsequences.*

Example 2.3. Since the permutation $\pi = 5\ 1\ 6\ 2\ 7\ 3\ 8\ 4\ 9$ avoids the patterns 321 and $4\bar{1}523$, we have that π belongs to $\mathscr{S}_9(321, 4\bar{1}523)$.

Let us now define some permutation parameters. Let $\pi \in \mathscr{S}_n$: we denote the position lying to the left of $\pi(1)$ by s_0, the position between $\pi(i)$,$\pi(i+1)$, $1 \leqslant i \leqslant n-1$, by s_i

and the position to the right of $\pi(n)$ by s_n. The positions $s_0, s_1, \ldots, s_{n-1}, s_n$ are the *sites* of π.

Definition 2.4. Let $F = \{\tau_1, \ldots, \tau_p\}$: a site s_i, $0 \leqslant i \leqslant n$, of a permutation $\pi \in \mathscr{S}_n(F)$ is *active* if the insertion of $(n+1)$ into s_i produces a permutation belonging to the set $\mathscr{S}_{n+1}(F)$; otherwise, it is said to be *inactive*. We denote the set of active sites of π by $\mathscr{A}(\pi)$.

Definition 2.5. Let $\pi \in \mathscr{S}_n$. The pair (i,j), $i < j$ is an inversion if $\pi(i) > \pi(j)$. An element $\pi(i)$ is a *right minimum* if $\pi(i) < \pi(j)$, $\forall j \in [i+1, n]$.

Given a permutation π, we denote its length by $n(\pi)$, the number of its active sites by $a(\pi)$, the number of its right minima by $m(\pi)$ and the number of its inversions by $i(\pi)$.

Example 2.4. The permutation π=5 1 6 2 7 3 8 4 9 has 10 inversions: $(1,2)(1,4)(1,6)(1,8)(3,4)(3,6)(3,8)(5,6)(5,8)(7,8)$ and 4 right minima: $\pi(2)=1$, $\pi(4)=2$, $\pi(6)=3$ and $\pi(8)=4$.

In this paper, we study the $\mathscr{S}_n(321, (j+2)\bar{1}(j+3)2\ldots(j+1))$ family and denote it by $\mathscr{M}_n(j)$. Moreover, we indicate the $S_n(321)$ family by $\mathscr{M}_n(\infty)$ and $\bigcup_{n\geqslant 1}\mathscr{M}_n(j)$ by $\mathscr{M}(j)$.

3. The ECO method

In this section, we review the basic ideas of the ECO method [6] and refer to [1–4] for some further applications and examples of it. Let $\mathscr{O}$ be a class of combinatorial objects and p a parameter of enumeration on $\mathscr{O}$ taking values in $\mathbb{N}$: we denote $\mathscr{O}_n = \{s \in \mathscr{O}: p(s) = n\}$. An operator θ on $\mathscr{O}$ is a function from $\mathscr{O}_n$ to $2^{\mathscr{O}_{n+1}}$, where $2^{\mathscr{O}_{n+1}}$ is the power set of $\mathscr{O}_{n+1}$.

Proposition 3.1. *Let θ be an operator on $\mathscr{O}$. If θ satisfies the following conditions*:

(1) $\forall Y \in \mathscr{O}_{n+1}\ \exists X \in \mathscr{O}_n$ *such that* $Y \in \theta(X)$,
(2) *if* $X_1, X_2 \in \mathscr{O}_n$ *and* $X_1 \neq X_2$ *then* $\theta(X_1) \cap \theta(X_2) = \emptyset$,

then the family of sets $\mathscr{F}_{n+1} = \{\theta(X): \forall X \in \mathscr{O}_n\}$ *is a partition of* $\mathscr{O}_{n+1}$.

Given a class $\mathscr{O}$ of combinatorial objects, if we are able to define an operator θ satisfying conditions (1) and (2), then Proposition 3.1 allows us to construct each object $Y \in \mathscr{O}_{n+1}$ from another object $X \in \mathscr{O}_n$ and each $Y \in \mathscr{O}_{n+1}$ is given by only one $X \in \mathscr{O}_n$. If we have an operator on $\mathscr{O}$ which satisfies conditions (1) and (2), we obtain

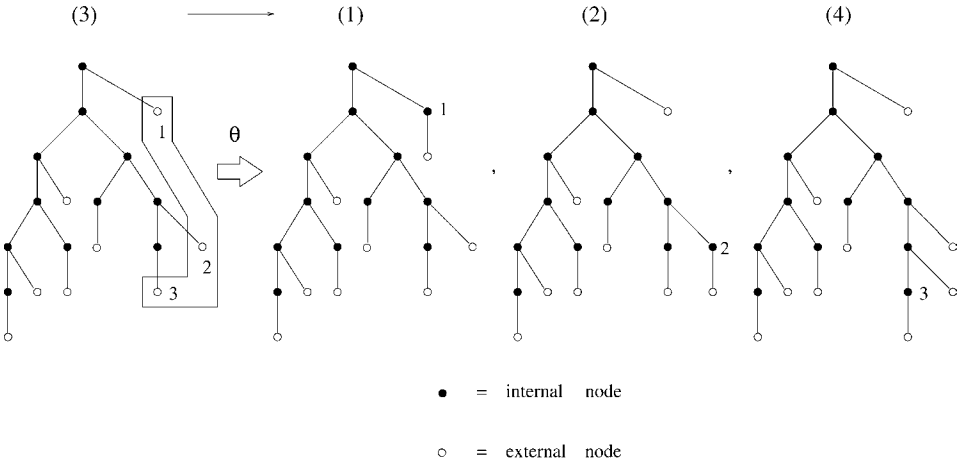

Fig. 1. The operator θ on a 1–2 tree.

a recursive description of the elements of $\mathcal{O}$. In some cases, this recursive description allows us to deduce a functional equation verified by the generating function of $\mathcal{O}$.

Example 3.1. A 1–2 tree is an ordered tree (in the sense used by Knuth [18, p. 305]) whose internal nodes all have degree 0, 1 or 2. Let $\mathcal{O}$ be the class of 1–2 trees and p the number of their internal nodes. Let $P \in \mathcal{O}$ and $\mathcal{A}(P)$ be the set of external nodes that follow the last internal node in the preorder traversal. The operator θ replaces each external node in $\mathcal{A}(P)$ by an internal one (see Fig. 1). It is easy to prove that θ satisfies Proposition 3.1. For some detailed definitions and proofs see [4].

4. Permutations with one forbidden subsequence of increasing length

In this section, we define an operator θ on the class $\mathcal{M}(j)$, $j \geqslant 1$, which satisfies Proposition 3.1. We obtain a recursive description of the objects in $\mathcal{M}(j)$ and deduce the set of functional equations verified by its generating function according to the permutations' length, number of right minima and inversions.

Proposition 4.1. *Let π be a permutation in $\mathcal{M}(j)$, $j \geqslant 1$. If s is an active site of π, each site to its right is also active.*

Proof. Let s be an active site of π and t be a site on its right. If we assume that t is not active, by inserting $(n+1)$ into t, we obtain a permutation containing 321 or $(j+2)\bar{1}(j+3)2\ldots(j+1)$.

If the insertion of $(n+1)$ into t produces a subsequence $(n+1)\pi(i_1)\pi(i_2)$ of type 321, the insertion of $(n+1)$ into s produces the same subsequence, and so s is not active.

$$\pi = \pi(1)\ldots.\pi(n-a(\pi)+1)-\pi(n-a(\pi)+2)-\ldots.-\pi(n-1)-\pi(n)-$$
$$\underset{s_{n-a(\pi)+1}}{\qquad}\quad\underset{s_{n-a(\pi)+2}\cdots s_{n-2}}{\qquad\qquad}\quad\underset{s_{n-1}}{\qquad}\quad\underset{s_n}{\qquad}$$

Fig. 2. A permutation $\pi \in \mathscr{M}_n(j)$ with $a(\pi)$ active sites.

If the insertion of $(n+1)$ into t gives us a permutation containing $(j+2)\bar{1}(j+3)2\ldots(j+1)$, we obtain a subsequence $\pi(i_1)(n+1)\pi(i_2)\ldots\pi(i_{j+1})$ of type $(j+2)(j+3)2\ldots(j+1)$, and there is no element in π between $\pi(i_1)$ and $(n+1)$ corresponding to the 1 of $(j+2)1(j+3)2\ldots(j+1)$. Moreover, $\pi(i_1)$ is on the left of s: as a matter of fact, if we assume that $\pi(i_1)$ is on the right of s, by inserting $(n+1)$ into s, we obtain the subsequence $(n+1)\pi(i_1)\pi(i_2)$ which is of type 321. Consequently, the insertion of $(n+1)$ into s produces a sequence of type $(j+2)\bar{1}(j+3)2\ldots(j+1)$. Therefore, s is not active and contradicts our hypothesis. □

Let π be a permutation in $\mathscr{M}_n(j)$, $j \geqslant 1$. From Proposition 4.1, it follows that the set $\mathscr{A}(\pi)$ of active sites of π is $\{s_{n-a(\pi)+1},\ldots,s_n\}$ (see Fig. 2). We define the operator θ on π as follows:

$$\theta(\pi) = \{\sigma \in \mathscr{M}_{n+1}(j) \mid \sigma = \pi(1)\cdots\pi(n-a(\pi)+i)(n+1)\cdots\pi(n),$$
$$\forall i = 1,\ldots,a(\pi)\}.$$

We can easily prove that the operator θ satisfies conditions (1) and (2) of Proposition 3.1.

The number of active sites in π is equal to the number of permutations obtained by performing the operator θ on π (i.e., $|\mathscr{A}(\pi)| = |\theta(\pi)|$). We number the sites in $\mathscr{A}(\pi)$ from right to left in increasing order (see Fig. 2). If θ inserts $(n+1)$ into the ith active site of $\pi \in \mathscr{M}_n(j)$, $1 \leqslant i \leqslant a(\pi)$, we obtain $\pi' \in \mathscr{M}_{n+1}(j)$, and its set of active sites is such that:

(a) if $i = 1$, then $\mathscr{A}(\pi') = \{s_{n(\pi)-(a(\pi)-1)},\ldots,s_{n(\pi)},s_{n(\pi)+1}\}$ and $|\mathscr{A}(\pi')| = a(\pi)+1$;
(b) if $2 \leqslant i \leqslant \min\{a(\pi), j\}$, then $\mathscr{A}(\pi') = \{s_{n(\pi)-(i-2)},\ldots,s_{n(\pi)},s_{n(\pi)+1}\}$ and $|\mathscr{A}(\pi')| = i$;
(c) if $\min\{a(\pi), j\} < i \leqslant a(\pi)$, then $\mathscr{A}(\pi') = \{s_{n(\pi)-(i-3)},\ldots,s_{n(\pi)},s_{n(\pi)+1}\}$ and $|\mathscr{A}(\pi')| = i-1$.

Therefore, if π has k active sites, then θ constructs k permutations $\sigma_1,\sigma_2,\ldots,\sigma_k$ whose number of active sites is:

- $k+1,2,\ldots,k$, for $a(\pi) \leqslant j$,
- $k+1,2,3,\ldots,j,j,\ldots,k-1$, for $a(\pi) > j$.

From this recursive description, we deduce a functional equation verified by the generating function of the $\mathscr{M}(j)$ permutations according to their length, number of active

sites, inversions and right minima:

$$M^{(j)}(x,y,s,q)=\sum_{\pi\in\mathscr{M}(j)} x^{n(\pi)}y^{m(\pi)}s^{a(\pi)}q^{i(\pi)}.$$

If θ inserts the subsequent element into the ith active site of π, $1\leqslant i\leqslant a(\pi)$, we obtain a permutation $\pi'\in\mathscr{M}(j)$ and the parameters change as follows:

(a) if $i=1$, then

$$n(\pi')=n(\pi)+1,\quad m(\pi')=m(\pi)+1,\quad a(\pi')=a(\pi)+1,\quad i(\pi')=i(\pi);$$

(b) if $2\leqslant i\leqslant\min\{a(\pi),j\}$, then

$$n(\pi')=n(\pi)+1,\quad m(\pi')=m(\pi),\quad a(\pi')=i,\quad i(\pi')=i(\pi)+i-1;$$

(c) if $\min\{a(\pi),j\}+1\leqslant i\leqslant a(\pi)$, then

$$n(\pi')=n(\pi)+1,\quad m(\pi')=m(\pi),\quad a(\pi')=i-1,\quad i(\pi')=i(\pi)+i-1.$$

At this point, we can translate this recursive construction into a functional equation verified by $M^{(j)}(x,y,s,q)$.

Let us note that:

- if $\boldsymbol{j=1}$ then point (b) does not hold. The permutation of length one has 2 active sites and is represented by xys^2. From the recursive construction, we obtain the following functional equation:

$$M^{(1)}(x,y,s,q)=\frac{xys^2}{(1-xys)}+\frac{xsq\,M^{(1)}(x,y,1,q)}{(1-xys)(1-sq)}-\frac{x\,M^{(1)}(x,y,sq,q)}{(1-xys)(1-sq)};\qquad(1)$$

- if $\boldsymbol{j=\infty}$ (i.e., $\mathscr{M}_n(\infty)=S_n(321)$), then point (c) does not hold and we obtain the following functional equation:

$$M^{(\infty)}(x,y,s,q)=\frac{xys^2}{(1-xys)}+\frac{xs^2q\,M^{(\infty)}(x,y,1,q)}{(1-xys)(1-sq)}-\frac{xs\,M^{(\infty)}(x,y,sq,q)}{(1-xys)(1-sq)}.\qquad(2)$$

We refer to [1] for the solution of these equations and only wish to point out that:

$$M^{(1)}(x,1,1,1)=\frac{1-x-2x^2-\sqrt{-3x^2-2x+1}}{2x^2},$$

$$M^{(\infty)}(x,1,1,1)=\frac{1-2x-\sqrt{1-4x}}{2x},$$

which means that, the number of n-length permutations in $\mathscr{M}(1)$ is equal to the nth Motzkin number while the nth Catalan number counts the n-length permutations in $\mathscr{M}(\infty)$. Therefore, the sequence of numbers enumerating the permutations in $\mathscr{M}(j)$, $j\geqslant 2$, according to their length, lies between the sequences of Motzkin and Catalan numbers.

Let us now take the case of $j\geqslant 2$ into consideration. By translating the construction into formulae, we obtain a set of functional equations. We partition the set $\mathscr{M}(j)$ into j subsets:

$$\mathscr{M}(j,2),\mathscr{M}(j,3),\ldots,\mathscr{M}(j,j),\mathscr{M}(j,>),$$

where

$$\mathscr{M}(j,i)=\{\pi\in\mathscr{M}(j)\,|\,a(\pi)=i\}\quad\text{and}\quad\mathscr{M}(j,>)=\{\pi\in\mathscr{M}(j)\,|\,a(\pi)>j\}.$$

We get the following proposition:

Proposition 4.2. *The generating function $M^{(j)}(x,y,s,q)$ of the $\mathscr{M}(j)$ permutations, $j\geqslant 2$, is such that*

$$M^{(j)}(x,y,s,q)=\sum_{i=2}^{j}M^{(j,i)}(x,y,1,q)s^i+M^{(j,>)}(x,y,s,q),\tag{3}$$

where the $M^{(j,i)}(x,y,s,q)$ satisfy:

$$M^{(j,2)}(x,y,s,q)=xs^2[y+qM^j(x,y,1,q)],\quad j>2,$$

$$M^{(j,i)}(x,y,s,q)=\frac{xys^i}{1-xq^{i-1}}M^{(j,i-1)}(x,y,1,q)+\frac{xq^{i-1}s^i}{1-xq^{i-1}}(M^{(j,i+1)}(x,y,1,q)+\cdots+M^{(j,>)}(x,y,1,q)),\quad 3\leqslant i\leqslant j-1,$$

$$M^{(j,j)}(x,y,s,q)=\frac{xys^j}{1-xq^{j-1}}M^{(j,j-1)}(x,y,1,q)+\frac{xq^{j-1}s^j}{1-xq^{j-1}}(1+q)M^{(j,>)}(x,y,1,q),$$

$$M^{(j,>)}(x,y,s,q)=\frac{xys}{1-xys}M^{(j,j)}(x,y,s,q)+\frac{x(sq)^{j+1}}{(1-xys)(1-sq)}M^{(j,>)}(x,y,1,q)-\frac{x}{(1-xys)(1-sq)}M^{(j,>)}(x,y,sq,q).$$

We set $M^{(j,1)}(x,y,1,q)=1$ in the case of $j=2$.

Proof. Eq. (3) immediately follows from the definition of $\mathscr{M}(j,i)$. Let $\pi\in\mathscr{M}(j)$ and $\mathscr{A}(\pi)=\{s_{n(\pi)-(a(\pi)-1)},\ldots,s_{n(\pi)-1},s_{n(\pi)}\}$: we obtain a permutation $\pi'\in\mathscr{M}(j)$ by performing the operator θ on π and obtain the following:

- $\pi'\in\mathscr{M}(j,2)$, $j>2$, is obtained from π by an insertion into $s_{n(\pi)-1}$;
- $\pi'\in\mathscr{M}(j,i)$, $3\leqslant i\leqslant j-1$, is obtained from:
  - $\pi\in\mathscr{M}(j,i-1)$ by an insertion into $s_{n(\pi)}$,
  - $\pi\in\mathscr{M}(j,i)\cup\cdots\cup\mathscr{M}(j,j)\cup\mathscr{M}(j,>)$ by an insertion into $s_{n(\pi)-(i-1)}$;
- $\pi'\in\mathscr{M}(j,j)$ is obtained from:
  - $\pi\in\mathscr{M}(j,j-1)$ by an insertion into $s_{n(\pi)}$,
  - $\pi\in\mathscr{M}(j,j)$ by an insertion into $s_{n(\pi)-(j-1)}$,
  - $\pi\in\mathscr{M}(j,>)$ by an insertion into both $s_{n(\pi)-(j-1)}$ and $s_{n(\pi)-j}$;
- $\pi'\in\mathscr{M}(j,>)$ is obtained from:
  - $\pi\in\mathscr{M}(j,j)\cup\mathscr{M}(j,>)$ by an insertion into $s_{n(\pi)}$,
  - $\pi\in\mathscr{M}(j,>)$ by an insertion into $s_{n(\pi)-(i-1)}$, $j+2\leqslant i\leqslant a(\pi)$.

The permutation of length one belongs to $\mathscr{M}(j,2)$ and is represented by xys^2. The set of equations:

$$M^{(j,2)}(x,y,s,q) = s^2[xy + xqM^{(j)}(x,y,1,q)], \quad j > 2,$$

$$M^{(j,i)}(x,y,s,q) = s^i[xyM^{(j,i-1)}(x,y,1,q) + xq^{i-1}(M^{(j,i)}(x,y,1,q) + \cdots + M^{(j,>)}(x,y,1,q))], \quad 3 \leqslant i \leqslant j-1,$$

$$M^{(j,j)}(x,y,s,q) = s^j[xyM^{(j,j-1)}(x,y,1,q) + xq^{j-1}M^{(j,j)}(x,y,1,q) + xq^{j-1}(1+q)M^{(j,>)}(x,y,1,q)]$$

$$M^{(j,>)}(x,y,s,q) = xysM^{(j,j)}(x,y,s,q) + \sum_{\pi \in M^{(j,>)}} x^{n(\pi)+1} y^{m(\pi)+1} s^{a(\pi)+1} q^{i(\pi)} + \sum_{\pi \in M^{(j,>)}} \sum_{i=j+2}^{a(\pi)} x^{n(\pi)+1} y^{m(\pi)} s^{i-1} q^{i(\pi)+i-1}$$

follows from the previous discussion and so the proposition is proved. □

The fourth equation in Proposition 4.2 can be solved by Bousquet-Mélou's lemma [9]:

Lemma 4.3. *Let $\mathscr{R} = \mathbb{R}[[x,y,s,q]]$ be the algebra of formal power series in variables x,y,s and q with real coefficients, and let $\mathscr{S}$ be a sub-algebra of $\mathscr{R}$ such that the series converge for $s=1$. Let $A(s) = A(x,y,s,q)$ be a formal power series in $\mathscr{S}$. We assume that*

$$A(s) = xe(s) + xf(s)A(1) + xg(s)A(sq),$$

where $e(s)$, $f(s)$ and $g(s)$ are some given power series in $\mathscr{A}$. Then

$$A(s) = \frac{J_1(s) + J_1(1)J_0(s) - J_1(s)J_0(1)}{1 - J_0(1)},$$

where $J_1(s) = \sum_{n \geqslant 0} x^{n+1} g(s)g(sq)\ldots g(sq^{n-1})e(sq^n)$ and $J_0(s) = \sum_{n \geqslant 0} x^{n+1} g(s)g(sq)\ldots g(sq^{n-1})f(sq^n)$.

By means of Lemma 4.3 and the fourth equation in Proposition 4.2, we get the following:

Proposition 4.4. *The generating function $M^{(j,>)}(x,y,s,q)$ is given by*

$$M^{(j,>)}(x,y,s,q) = \frac{J_1(s)J_0(1) - J_1(1)J_0(s) + J_1(1)}{J_0(1)},$$

where

$$J_1(x,y,s,q)=\sum_{n\geqslant 0}\frac{(-1)^n x^{n+1}ys^{j+1}q^{n(j+1)}}{(xys,q)_{n+1}(sq,q)_n}M^{(j,j)}(x,y,1,q),$$

$$J_0(x,y,s,q)=1+\sum_{n\geqslant 0}\frac{(-1)^{n+1}x^{n+1}s^{j+1}q^{(n+1)(j+1)}}{(xys,q)_{n+1}(sq,q)_{n+1}},$$

and

$$(a,q)_n=\prod_{k=0}^{n-1}(1-aq^k).$$

Let us now take the generating function $M^{(j,>)}(x,y,1,q)$ into consideration. We denote the functions $M^{(j,>)}(x,y,1,q)$, $M^{(j,j)}(x,y,1,q)$, $J_0(x,y,1,q)$ and $J_1(x,y,1,q)$ by $M^{(j,>)}(x,y,q)$, $M^{(j,j)}(x,y,q)$, $J_0(x,y,q)$ and $J_1(x,y,q)$, respectively. From Proposition 4.4, it follows that

$$M^{(j,>)}(x,y,q)=f(x,y,q)M^{(j,j)}(x,y,q), \tag{4}$$

where

$$f(x,y,q)=y\frac{\sum_{n\geqslant 0}\frac{(-1)^n x^{n+1}q^{n(j+1)}}{(xy,q)_{n+1}(q,q)_n}}{\sum_{n\geqslant 0}\frac{(-1)^n x^n q^{n(j+1)}}{(xy,q)_n(q,q)_n}}.$$

Theorem 4.5. *The generating function $M^{(j)}(x,y,q)$ of the $\mathcal{M}(j)$ permutations is such that*:

- $M^{(2)}(x,y,q)=\dfrac{xy(1+f(x,y,q))}{1-xq-xq(1+q)f(x,y,q)}$;
- $M^{(j)}(x,y,q)=\dfrac{xy(1-xq^2)\Delta_j(x,y,q)}{(1-xq)(1-xq^2)\Delta_j(x,y,q)+xy\Delta_{j-1}(x,y,q)}, \quad j\geqslant 3,$

  where $\Delta_j(x,y,q)=c_1(x,y,q)\lambda_1^j(x,y,q)+c_2(x,y,q)\lambda_2^j(x,y,q)$ *being*

$$\lambda_1(x,y,q)=\frac{1}{2}\left[-\left(1+\frac{xy}{1-xq^2}\right)+\sqrt{\left(1+\frac{xy}{1-xq^2}\right)^2-\frac{4xy}{(1-xq^2)(1-xq^3)}}\right]$$

  and

$$\lambda_2(x,y,q)=\frac{1}{2}\left[-\left(1+\frac{xy}{1-xq^2}\right)-\sqrt{\left(1+\frac{xy}{1-xq^2}\right)^2-\frac{4xy}{(1-xq^2)(1-xq^3)}}\right].$$

  The functions $c_1(x,y,q)$, $c_2(x,y,q)$ *satisfy*:

$$\begin{aligned}c_1(x,y,q)\lambda_1^2(x,y,q)+c_2(x,y,q)\lambda_2^2(x,y,q) &= 1+f(x,y,q),\\ c_1(x,y,q)\lambda_1^3(x,y,q)+c_2(x,y,q)\lambda_2^3(x,y,q) &= f(x,y,q)\frac{xq^{j-1}(1+q)-xy}{1-xq^{j-1}}\\ &\quad -\frac{1+xy-xq^{j-1}}{1-xq^{j-1}}.\end{aligned}$$

Proof.

- The generating function $M^{(2)}(x,y,s,q)$ satisfies the following equations:

$$\begin{aligned} M^{(2,2)}(x,y,s,q) &= \frac{xys^2}{1-xq} + \frac{xs^2q}{1-xq}(1+q)M^{(2,>)}(x,y,1,q), \\ M^{(2,>)}(x,y,s,q) &= \frac{xys}{1-xys}M^{(2,2)}(x,y,s,q) + \frac{x(sq)^3}{(1-xys)(1-sq)} \\ &\quad \times M^{(2,>)}(x,y,1,q) - \frac{x}{(1-xys)(1-sq)}M^{(2,>)}(x,y,sq,q), \\ M^{(2)}(x,y,s,q) &= M^{(2,2)}(x,y,s,q) + M^{(2,>)}(x,y,s,q). \end{aligned} \tag{5}$$

  The thesis is obtained by some easy substitutions involving the solution of this set of equations and Eq. (4).

- Let $A_{j-i}(x,y,q)$ be an array of dimension $(j-i)\times(j-i)$ defined by:

$$A_{j-i}(x,y,q) = \begin{pmatrix} 1 & 1 & 1 & \ldots.. & 1 & 1 & 1 & 1 \\ \frac{xy}{1-xq^{i+2}} & -1 & \frac{xq^{i+2}}{1-xq^{i+2}} & \cdots & \frac{xq^{i+2}}{1-xq^{i+2}} & \frac{xq^{i+2}}{1-xq^{i+2}} & \frac{xq^{i+2}}{1-xq^{i+2}} & \frac{xq^{i+2}}{1-xq^{i+2}} \\ & \ddots & & & \vdots & \vdots & \vdots & \vdots \\ & & \ddots & & \vdots & \vdots & \vdots & \vdots \\ & & & \ddots & \frac{xy}{1-xq^{j-2}} & -1 & \frac{xq^{j-2}}{1-xq^{j-2}} & \frac{xq^{j-2}}{1-xq^{j-2}} \\ & & & & & \frac{xy}{1-xq^{j-1}} & -1 & \frac{xq^{j-1}(1+q)}{1-xq^{j-1}} \\ & & & & & & -f(x,y,q) & 1 \end{pmatrix}, \quad i \geqslant 0. \tag{6}$$

Its first and last row always appear because they do not depend on $(j-i)$; on the contrary, the $((j-i)-k)$th row is in $A_{j-i}(x,y,q)$ if and only if $(j-i)-2 \geqslant k \geqslant 1$. This means that

$$A_2(x,y,q) = \begin{pmatrix} 1 & 1 \\ -f(x,y,q) & 1 \end{pmatrix}$$

and

$$A_3(x,y,q) = \begin{pmatrix} 1 & 1 & 1 \\ \frac{xy}{1-xq^{j-1}} & -1 & \frac{xq^{j-1}(1+q)}{1-xq^{j-1}} \\ 0 & -f(x,y,q) & 1 \end{pmatrix}.$$

The set of equations given by Proposition 4.2 and Eq. (4) is represented by the matrix expression

$$A_j(x,y,q)X_j(x,y,q) = Y_j(x,y,q), \tag{7}$$

where

$$X_j(x,y,q)=\begin{pmatrix} M^{(j,2)}(x,y,q)\\ M^{(j,3)}(x,y,q)\\ \vdots\\ M^{(j,j)}(x,y,q)\\ M^{(j,>)}(x,y,q)\end{pmatrix},\qquad Y_j(x,y,q)=\begin{pmatrix} M^{(j)}(x,y,q)\\ 0\\ \vdots\\ 0\\ 0\end{pmatrix}$$

and $A_j(x,y,q)$ is defined by (6) for $i=0$. It is easy to verify that the determinant $\Delta_{j-i}(x,y,q)$ of (6) satisfies the recursive relation:

$$\begin{aligned}&\Delta_{j-i}(x,y,q)+\left(1+\frac{xy}{1-xq^{i+2}}\right)\Delta_{j-(i+1)}(x,y,q)+\frac{xy}{(1-xq^{i+2})(1-xq^{i+3})}\\ &\quad\times\Delta_{j-(i+2)}(x,y,q)=0,\quad 0\leqslant i\leqslant j-4,\\ &\Delta_2(x,y,q)=1+f(x,y,q)\quad(i=j+2),\\ &\Delta_3(x,y,q)=f(x,y,q)\frac{xq^{j-1}(1+q)-xy}{1-xq^{j-1}}-\frac{1+xy-xq^{j-1}}{1-xq^{j-1}}\quad(i=j+3).\end{aligned}\tag{8}$$

By using standard solution techniques, we get

$$\Delta_j(x,y,q)=c_1(x,y,q)\lambda_1^j(x,y,q)+c_2(x,y,q)\lambda_2^j(x,y,q)$$

for $i=0$; where $\lambda_1(x,y,q)$ and $\lambda_2(x,y,q)$ are the solutions of the equation:

$$\lambda^2+\left(1+\frac{xy}{1-xq^2}\right)\lambda+\left(\frac{xy}{(1-xq^2)(1-xq^3)}\right)=0$$

and $c_1(x,y,q)$, $c_2(x,y,q)$ the terms given by the initial conditions of the recursive relation (8).

The solution of (7) gives

$$M^{(j,2)}(x,y,q)=M^{(j)}(x,y,q)\left(1+\frac{xy}{1-xq^2}\frac{\Delta_{j-1}(x,y,q)}{\Delta_j(x,y,q)}\right),\tag{9}$$

moreover, from Proposition 4.2, $M^{(j,2)}(x,y,q)$ yields

$$M^{(j,2)}(x,y,q)=x[y+qM^{(j)}(x,y,q)],$$

and so

$$M^{(j)}(x,y,q)=\frac{xy}{(1-xq)+\frac{xy}{q-xq^2}\frac{1}{\frac{\Delta_j(x,y,q)}{\Delta_{j-1}(x,y,q)}}},$$

and therefore our thesis is proved. □

Remark 4.1.

- Let us note that

$$\frac{\Delta_{j-i}(x,y,q)}{\Delta_{j-(i+1)}(x,y,q)} = -\frac{1+xy-xq^{i+2}}{1-xq^{i+2}} - \frac{xy}{(1-xq^{i+2})(1-xq^{i+3})\frac{\Delta_{j-(i+1)}(x,y,q)}{\Delta_{j-(i+2)}(x,y,q)}},$$

  thus we have

$$\lim_{j\to\infty} M^{(j)}(x,y,q) = \cfrac{xy}{1-xq-\cfrac{xy}{1+xy-xq^2-\cfrac{xy}{1+xy-xq^3-\cfrac{xy}{\vdots}}}}.$$

  If $y=q=1$, we obtain the continued fraction representing the generating function of Catalan numbers less 1, that is $(1-\sqrt{1-4x}/2x)-1=C(x)-1=\sum_{n\geqslant 1} S_n(321)x^n$.
- This continued fraction represents the generating function of Catalan permutations enumerated according to their length, number of right minima and inversions and is an alternative to the one obtained by developing the functional equation that appears in [1]. Consequently, we obtain the following identities:

$$\frac{\sum_{n\geqslant 0}\frac{(-1)^n x^{n+1} q^{\frac{n(n+3)}{2}}}{(q;q)_n (xy;q)_{n+1}}}{\sum_{n\geqslant 0}\frac{(-1)^n x^n q^{\frac{n(n+1)}{2}}}{(q;q)_n (xy;q)_n}} = \cfrac{xy}{1-xq-\cfrac{xy}{1+xy-xq^2-\cfrac{xy}{1+xy-xq^3-\cfrac{xy}{\vdots}}}}$$

$$= \cfrac{xy}{1-xq-xy-\cfrac{x^2yq^2}{1-xq^2-xyq-\cfrac{x^2yq^4}{1-xq^3-xyq^2-\cfrac{x^2yq^6}{\vdots}}}}.$$

Theorem 4.5 gives us the generating function for $\mathscr{M}(j)$ permutations according to various parameters. At the moment, we wish to treat the enumeration of $\mathscr{M}(j)$ permutations only according to their length. The generating function $M^{(j)}(x,1,1)$ is obtained from Theorem 4.5 by setting $y=q=1$ and by substituting $f(x,y,q)$ with $\tilde{f}(x)=(1-x-\sqrt{1-2x-3x^2})/2x$. The function $\tilde{f}(x)$ is obtained by the following steps:

(1) from Proposition 4.4, we obtain the following equalities by some computations:

$$\frac{J_1(x,y,q)}{M^{(j,j)}(x,y,q)} - xyJ_0(x,y,q) = \frac{x^2y^2}{1-xy}J_0(xq,y,q),$$

$$(x^2yq^{j+1}+xy-1)\frac{J_1(x,y,q)}{M^{(j,j)}(x,y,q)} + xyJ_0(x,y,q) = -\frac{x^3y^2q^{j+1}}{1-xy}\frac{J_1(xq,y,q)}{M^{(j,j)}(xq,y,q)};$$

(2) from Proposition 4.4, we deduce that

$$xq^{j+1}M^{(j,>)}(xq,y,q) = \frac{(1-xy-x^2yq^{j+1})\frac{M^{(j,>)}(x,y,q)}{M^{(j,j)}(x,y,q)} - xy}{\frac{M^{(j,>)}(x,y,q)}{M^{(j,j)}(x,y,q)} - xy} M^{(j,j)}(xq,y,q); \quad (10)$$

(3) by setting $y = q = 1$ in Eq. (10), we obtain

$$x(M^{(j,>)}(x,1,1))^2 - M^{(j,j)}(x,1,1)(1-x)M^{(j,>)}(x,1,1) + x(M^{(j,j)}(x,1,1))^2 = 0; \tag{11}$$

(4) by solving Eq. (11), we obtain

$$M^{(j,>)}(x,1,1) = \tilde{f}(x)M^{(j,j)}(x,1,1), \quad \text{with } \tilde{f}(x) = \frac{1-x-\sqrt{1-2x-3x^2}}{2x}.$$

In order to simplify the computations, we use the generating function $\bar{M}^{(j)}(x)$ of the $\mathscr{M}(j)$ permutations according to their length, including the empty permutation's length; consequently $M^{(j)}(x) = M^{(j)}(x,1,1) + 1$. The generating function $M^{(j)}(x,1,1)$ which can be deduced from Theorem 4.5 allows us to verify the equality:

$$\bar{M}^{(j)}(x) = \frac{1}{1 - x\bar{M}^{(j-1)}(x)}. \tag{12}$$

- If $j = \infty$, then (12) reduces to

$$\bar{M}^{(\infty)}(x) = \frac{1}{1 - x\bar{M}^{(\infty)}(x)},$$

  which is the functional equation verified by the generating function of Catalan numbers.
- Otherwise, we assume that $\bar{M}^{(j-1)}(x)$ satisfies the functional equation:

$$\bar{M}^{(j-1)}(x) = c_{j-1}(x) + b_{j-1}(x)\bar{M}^{(j-1)}(x) + a_{j-1}(x)(\bar{M}^{(j-1)}(x))^2 \tag{13}$$

  and we look for the expression of $c_j(x)$, $b_j(x)$ and $a_j(x)$ satisfying

$$\bar{M}^{(j)}(x) = c_j(x) + b_j(x)\bar{M}^{(j)}(x) + a_j(x)(\bar{M}^{(j)}(x))^2 \tag{14}$$

  in a recursive way.

  Let us note that $c_1(x) = 1$, $b_1(x) = x$ and $a_1(x) = x^2$ because $\bar{M}^{(1)}(x)$ verifies

$$\bar{M}^{(1)}(x) = 1 + x\bar{M}^{(1)}(x) + x^2(\bar{M}^{(1)}(x))^2.$$

If we substitute $\bar{M}^{(j-1)}(x) = (\bar{M}^{(j)}(x) - 1)/x\bar{M}^{(j)}(x)$ in (13), we obtain a functional equation satisfied by $\bar{M}^{(j)}(x)$. We want to make this equation exactly the same as (14) in order to obtain the recursive definition of the terms $c_j(x)$, $b_j(x)$ and $a_j(x)$. After some computations we get:

$$a_j(x) = \frac{x\left(-x^2(C(x))^2(1-C(x))(x^2(C(x))^4)^j - (1-3x-2x^2)(C(x))^2(x(C(x))^2)^j + x\right)}{(1-4x)(C(x))^2(1-C(x))^j}, \quad j > 2,$$

$$b_j(x) = \frac{-2x^3(C(x))^2(x^2(C(x))^4)^j + (1-3x-2x^2)C(x)(x(C(x))^2)^j - 2x^2}{(1-4x)C(x)(1-C(x))^j}, \quad j > 2,$$

$$c_j(x) = \frac{(x^2(x^2(C(x))^4)^j - (1-3x-2x^2)(x(C(x))^2)^j + x^2}{(1-4x)(1-C(x))^j}, \quad j > 2,$$

$$a_1(x) = x^2,$$

Class of Permutations	Forbidden Subsequences	Number Sequences
$\mathscr{M}(1)$	$321, 3\bar{1}42$	1 2 4 9 21 . . .
$\mathscr{M}(2)$	$321, 4\bar{1}523$	1 2 5 13 35 . . .
$\mathscr{M}(3)$	$321, 5\bar{1}6234$	1 2 5 14 41 . . .
$\mathscr{M}(4)$	$321, 6\bar{1}72345$	1 2 5 14 42 . . .
⋮	⋮	⋮
$\mathscr{M}(\infty)$	321	1 2 5 14 42 . . . $\frac{1}{n+1}\binom{2n}{n}$ . . .

Fig. 3. First numbers of the sequences enumerating the permutations in $\mathscr{M}(j)$.

$$b_1(x) = x,$$

$$c_1(x) = 1,$$

in which $C(x) = M^{(\infty)}(x) = (1 - \sqrt{1-4x})/2x$.

The final result follows from Eq. (14):

$$\bar{M}^{(j)}(x) = \frac{1 - b_j(x) + (-1)^j \sqrt{(1-b_j(x))^2 - 4a_j(x)c_j(x)}}{2a_j(x)}.$$

5. Conclusions

Our main aim in this work is to give an exhaustive description of some classes of permutations with a barred forbidden subsequence that orderly increases in length. The classes of permutations described in this paper are enumerated by numbers lying between the Motzkin and the Catalan numbers. We view the number sequences obtained as providing a 'discrete continuity' between the Motzkin and the Catalan sequences (see Fig. 3): we find the well-known numbers of the left factors in Motzkin words as a special case. We are presently working on the construction of some particular mesh lattices on which the n-area underdiagonal directed animals are in bijection with the $\mathscr{M}_n(j)$ family of permutations. This is suggested by the fact that the Motzkin permutations are in bijection with the underdiagonal directed animals on the square lattice and the Catalan permutations are in bijection with the underdiagonal directed animals on the triangular lattice [5]. A further step consists in translating the classical parameters of permutation enumeration into some parameters of directed animals and vice-versa. Since it is well known that the asymptotic values for $\mathscr{M}_n(1)$, $\mathscr{M}_n(2)$ and

$\mathscr{M}_n(\infty)$ are $(3^{n+1}/2n)\sqrt{3/\pi n}$, $3^{n+1}\sqrt{3/\pi(n+2)}$ and $[4^n/(n+1)]1/\sqrt{\pi n}$, respectively; it would be interesting to discover the asymptotic value for $|\mathscr{M}_n(j)|$, depending on the parameter j.

ECO Method and Hill-free Generalized Motzkin Paths

Abstract. In this paper we study the class of generalized Motzkin paths with no hills and prove some of their combinatorial properties in a bijective way; as a particular case we have the Fine numbers, enumerating Dyck paths with no hills. Using the ECO method, we define a recursive construction for Dyck paths such that the number of local expansions performed on each path depends on the number of its hills. We then extend this construction to the set of generalized Motzkin paths.

Random incidence matrices: Moments of the spectral density

Matrices d'incidence aléatoires : moments de la densité spectrale

J. Stat. Phys. 103, 301-307 (2001) [cond-mat/0007127]
Preprint cond-mat/0007127

We study numerically and analytically the spectrum of incidence matrices of random labeled graphs on N vertices : any pair of vertices is connected by an edge with probability p. We give two algorithms to compute the moments of the eigenvalue distribution as explicit polynomials in N and p. For large N and fixed p the spectrum contains a large eigenvalue at Np and a semi-circle of ``small" eigenvalues. For large N and fixed average connectivity pN (dilute or sparse random matrices limit) we show that the spectrum always contains a discrete component. An anomaly in the spectrum near eigenvalue 0 for connectivity close to e is observed. We develop recursion relations to compute the moments as explicit polynomials in pN. Their growth is slow enough so that they determine the spectrum. The extension of our methods to the Laplacian matrix is given in Appendix.

1 Introduction

In this paper we investigate sums of the form

$$a_n := \sum_{k \geq 1} \frac{k^n F_k}{2^{k+1}}. \tag{1}$$

For any given n, such a sum can be determined [3] by applying the $x\frac{d}{dx}$ operator n times to the generating function

$$G(x) := \sum_{k\geq 1} F_k x^k = \frac{x}{1-x-x^2},$$

then evaluating the resulting expression at $x = 1/2$. This leads to $a_0 = 1$, $a_1 = 5$, $a_2 = 47$, and so on. These sums may be used to determine the expected value and higher moments of the number of flips needed of a fair coin until two consecutive heads appear [3]. In this article, we pursue the reverse strategy of using probability to derive a_n and develop an exponential generating function for a_n in Section 3. In Section 4, we present a method for finding an exact, non-recursive, formula for a_n.

2 Probabilistic Interpretation

Consider an infinitely long binary sequence of independent random variables $b_1, b_2, b_3, \ldots$ where $P(b_i = 0) = P(b_i = 1) = 1/2$. Let Y denote the random variable denoting the beginning of the first 00 substring. That is, $b_Y = b_{Y+1} = 0$ and no 00 occurs before then. Thus $P(Y = 1) = 1/4$. For $k \geq 2$, we have $P(Y = k)$ is equal to the probability that our sequence begins $b_1, b_2, \ldots, b_{k-2}, 1, 0, 0$, where no 00 occurs among the first $k-2$ terms. Since the probability of occurence of each such string is $(1/2)^{k+1}$, and it is well known [1] that there are exactly F_k binary strings of length $k-2$ with no consecutive 0's, we have for $k \geq 1$,

$$P(Y = k) = \frac{F_k}{2^{k+1}}.$$

Since Y is finite with probability 1, it follows that

$$\sum_{k\geq 1} \frac{F_k}{2^{k+1}} = \sum_{k\geq 1} P(Y=k) = 1.$$

For $n \geq 0$, the expected value of Y^n is

$$a_n := E(Y^n) = \sum_{k\geq 1} \frac{k^n F_k}{2^{k+1}}. \tag{2}$$

Thus $a_0 = 1$. For $n \geq 1$, we use conditional expectation to find a recursive formula for a_n. We illustrate our argument with $n = 1$ and $n = 2$ before proceeding with the general case.

For a random sequence $b_1, b_2, \ldots$, we compute $E(Y)$ by conditioning on b_1 and b_2. If $b_1 = b_2 = 0$, then $Y = 1$. If $b_1 = 1$, then we have wasted a flip, and we are back to the drawing board; let Y' denote the number of remaining flips needed. If $b_1 = 0$ and $b_2 = 1$, then we have wasted two flips, and we are back to the drawing board; let Y'' denote the number of remaining flips needed in this case. Now by conditional expectation we have

$$\begin{aligned} E(Y) &= \frac{1}{4}(1) + \frac{1}{2}E(1+Y') + \frac{1}{4}E(2+Y'') \\ &= \frac{1}{4} + \frac{1}{2} + \frac{1}{2}E(Y') + \frac{1}{2} + \frac{1}{4}E(Y'') \\ &= \frac{5}{4} + \frac{3}{4}E(Y) \end{aligned}$$

since $E(Y') = E(Y'') = E(Y)$. Solving for $E(Y)$ gives us $E(Y) = 5$. Hence,

$$a_1 = \sum_{k\geq 1} \frac{kF_k}{2^{k+1}} = 5.$$

Conditioning on the first two outcomes again allows us to compute

$$\begin{aligned} E(Y^2) &= \frac{1}{4}(1^2) + \frac{1}{2}E\left[(1+Y')^2\right] + \frac{1}{4}E\left[(2+Y'')^2\right] \\ &= \frac{1}{4} + \frac{1}{2}E(1+2Y+Y^2) + \frac{1}{4}E(4+4Y+Y^2) \\ &= \frac{7}{4} + 2E(Y) + \frac{3}{4}E(Y^2). \end{aligned}$$

Since $E(Y) = 5$, it follows that $E(Y^2) = 47$. Thus,

$$a_2 = \sum_{k\geq 1} \frac{k^2 F_k}{2^{k+1}} = 47.$$

Following the same logic for higher moments, we derive for $n \geq 1$,

$$\begin{aligned} E(Y^n) &= \frac{1}{4}(1^n) + \frac{1}{2}E[(1+Y)^n] + \frac{1}{4}E[(2+Y)^n] \\ &= \frac{1}{4} + \frac{3}{4}E(Y^n) + \frac{1}{2}\sum_{k=0}^{n-1}\binom{n}{k}E(Y^k) + \frac{1}{4}\sum_{k=0}^{n-1}\binom{n}{k}2^{n-k}E(Y^k). \end{aligned}$$

Consequently, we have the following recursive equation:

$$E(Y^n) = 1 + \sum_{k=0}^{n-1}\binom{n}{k}[2+2^{n-k}]E(Y^k)$$

Thus for all $n \geq 1$,

$$a_n = 1 + \sum_{k=0}^{n-1}\binom{n}{k}[2+2^{n-k}]a_k. \tag{3}$$

Using equation (3), one can easily derive $a_3 = 665$, $a_4 = 12,551$, and so on.

3 Generating Function and Asymptotics

For $n \geq 0$, define the exponential generating function

$$a(x) = \sum_{n\geq 0} \frac{a_n}{n!}x^n.$$

It follows from equation (3) that

$$\begin{aligned} a(x) &= 1 + \sum_{n\geq 1} \frac{\left(1 + \sum_{k=0}^{n-1} \binom{n}{k}[2 + 2^{n-k}]a_k\right)}{n!} x^n \\ &= e^x + 2a(x)(e^x - 1) + a(x)(e^{2x} - 1). \end{aligned}$$

Consequently,

$$a(x) = \frac{e^x}{4 - 2e^x - e^{2x}}. \tag{4}$$

For the asymptotic growth of a_n, one need only look at the leading term of the Laurent series expansion [4] of $a(x)$. This leads to

$$a_n \approx \frac{\sqrt{5} - 1}{10 - 2\sqrt{5}} \left(\frac{1}{\ln(\sqrt{5} - 1)}\right)^{n+1} n!. \tag{5}$$

4 Closed Form

While the recurrence (3), generating function (4), and asymptotic result (5) are satisfying, a closed form for a_n might also be desired. For the sake of completeness, we demonstrate such a closed form here.

To calculate

$$a_n = \sum_{k\geq 1} \frac{k^n F_k}{2^{k+1}},$$

we first recall the Binet formula for F_k [3]:

$$F_k = \frac{1}{\sqrt{5}} \left(\left(\frac{1 + \sqrt{5}}{2}\right)^k - \left(\frac{1 - \sqrt{5}}{2}\right)^k\right) \tag{6}$$

Then (6) implies that (1) can be rewritten as

$$a_n = \frac{1}{2\sqrt{5}} \sum_{k\geq 1} k^n \left(\frac{1 + \sqrt{5}}{4}\right)^k - \frac{1}{2\sqrt{5}} \sum_{k\geq 1} k^n \left(\frac{1 - \sqrt{5}}{4}\right)^k. \tag{7}$$

Next, we remember the formula for the geometric series:

$$\sum_{k\geq 0} x^k = \frac{1}{1-x} \tag{8}$$

This holds for all real numbers x such that $|x| < 1$. We now apply the $x\frac{d}{dx}$ operator n times to (8). It is clear that the left-hand side of (8) will then become

$$\sum_{k\geq 1} k^n x^k.$$

The right-hand side of (8) is transformed into the rational function

$$\frac{1}{(1-x)^{n+1}} \times \sum_{j=1}^{n} e(n,j)x^j, \tag{9}$$

where the coefficients $e(n,j)$ are the Eulerian numbers [2, Sequence A008292], defined by

$$e(n,j) = j \cdot e(n-1,j) + (n-j+1) \cdot e(n-1,j-1) \text{ with } e(1,1) = 1.$$

(The fact that these are indeed the coefficients of the polynomial in the numerator of (9) can be proven quickly by induction.) From the information found in [2, Sequence A008292], we know

$$e(n,j) = \sum_{\ell=0}^{j} (-1)^\ell (j-\ell)^n \tbinom{n+1}{\ell}.$$

Therefore,

$$\sum_{k\geq 1} k^n x^k = \frac{1}{(1-x)^{n+1}} \times \sum_{j=1}^{n} \left[\sum_{\ell=0}^{j} (-1)^\ell (j-\ell)^n \tbinom{n+1}{\ell} \right] x^j. \tag{10}$$

Thus the two sums

$$\sum_{k\geq 1} k^n \left(\frac{1+\sqrt{5}}{4}\right)^k \quad \text{and} \quad \sum_{k\geq 1} k^n \left(\frac{1-\sqrt{5}}{4}\right)^k$$

that appear in (7) can be determined explicitly using (10) since

$$\left|\frac{1+\sqrt{5}}{4}\right| < 1 \quad \text{and} \quad \left|\frac{1-\sqrt{5}}{4}\right| < 1.$$

Hence, an exact, non-recursive, formula for a_n can be developed.

Computing the Generating Function of a Series Given Its First Few Terms

François Bergeron and Simon Plouffe

CONTENTS

We outline an approach for the computation of a good candidate for the generating function of a power series for which only the first few coefficients are known. More precisely, if the derivative, the logarithmic derivative, the reversion, or another transformation of a given power series (even with polynomial coefficients) appears to admit a rational generating function, we compute the generating function of the original series by applying the inverse of those transformations to the rational generating function found.

1. INTRODUCTION

We address the problem of finding the generating function $f(x)$ of a power series

$$\alpha(x) = a_0 + a_1 x + a_2 x^2 + \cdots + a_n x^n + \cdots,$$

of which we know only a limited number of initial terms. We say that $\alpha(x)$ has *precision* n if all coefficients up to x^n are known. Clearly, in the absence of additional information, the knowledge of $\alpha(x)$ to any finite precision is not sufficient to determine $f(x)$ uniquely.

One instance when the problem can be solved is when $f(x)$ is known a priori to be a rational function

$$\frac{p_0 + p_1 x + \cdots + p_j x^j}{q_0 + q_1 x + \cdots + q_k x^k} \quad \text{with } p_j, q_k \neq 0, \qquad (1.1)$$

and the precision of $\alpha(x)$ is at least $j + k$. Many good algorithms exist for computing $f(x)$ in this case. A naive one is to use the method of indeterminate coefficients in (1.1), with $j + k = n$. Better algorithms make use of (for example) Padé approximants. The function `convert/ratpoly` provided by the computer algebra system Maple [Char et al. 1985] includes the Padé approximants method.

Bergeron had support from NSERC-Canada and FCAR-Québec.

1058-6458/96 $0.50 per page

If we don't know that the generating function is rational, we can still apply a rational function approximation algorithm to $\alpha(x)$, to obtain an expression of the form (1.1) whose Taylor expansion coincides with $\alpha(x)$ throughout the known terms. If we find out that $k+j$ is much less than the precision n, we can consider the rational fraction obtained a good candidate for the generating function $f(x)$. The greater n is with respect to $j+k$, the more confident we can be in our guess.

Our purpose here is to show that one can easily extend the class of series for which a good candidate for a generating function can explicitly be computed from the knowledge of just enough terms of a series. The main idea is to try to transform the series into one that admits a rational generating function. If this transformation is successful, in the sense that the result appears to be rational, one need only apply the inverse transformation to the resulting rational function in order to produce an explicit candidate for the generating function of the original series. Thus, a measure of rationality for series is crucial to our scheme.

Using this idea, we wrote a Maple program that will find generating functions such as

$$\tan x, \qquad \exp(te^x - t), \qquad (1-4x)^{-3/2},$$
$$\exp\left(\frac{1-\sqrt{1-2\,xt}}{x} - t\right) \quad \text{and} \quad \frac{1}{1-xe^{A(x)}},$$

where $A(x)$ is the solution to the functional equation $A(x) = x\exp A(x)$—and even more complex ones. The program is described in Section 2, and examples are given in Section 3 that show it to be surprisingly successful. It typically gives results in a few seconds on a Mips/3000 or on a Macintosh IIfx. Moreover, it works with series whose coefficients are polynomials or rational functions, as well as numbers; the generating function in such cases involves a formal parameter, as in the case of $\exp(te^x - t)$ above, which arises in connection with Stirling polynomials of the second kind (see Example 8 in Section 3).

2. THE PROGRAM

The heart of the program is a test for the existence of a good rational function approximation (1.1) for a given series, where *good* is defined to mean that $k+j$ is less than the precision n of the series. This rationality test is implemented in the function `testrat`, which returns either the rational function that has been found, or the keyword `FAIL`.

The power of the program lies in the association of this rationality test with operations such as differentiation, logarithmic differentiation and reversion. (Recall that a series

$$\alpha(x) = a_0 + a_1x + a_2x^2 + \cdots + a_nx^n + \cdots$$

with $a_0 = 0$ and $a_1 \neq 0$ has a unique *reversion* $\alpha^{\langle -1\rangle}(x)$, that is, a series satisfying $\alpha^{\langle -1\rangle}(\alpha(x)) = x$. The generating function of $\alpha^{\langle -1\rangle}(x)$ is inverse to the generating function of $\alpha(x)$, and the first n terms of $\alpha^{\langle -1\rangle}(x)$ depend only on the first n terms of $\alpha(x)$. The *logarithmic derivative* of a series $\alpha(x)$ is $\alpha'(x)/\alpha(x)$.)

In general, the first step of a computation is to execute some transformation Γ on a given series $\alpha(x)$, then to test the resulting series for rationality. If $\Gamma(\alpha(x))$ admits a good rational generating function $f(x)$, the program computes $\Gamma^{-1}(f(x))$, where Γ^{-1} is the transformation inverse to Γ. Note that some operations Γ, such as differentiation, reduce the precision of the series.

This strategy is implemented by calling `testrat` with the functions `testdrat`, `testdlograt` and `testrevrat`. Each of these three functions takes three arguments: the series, the variable (which we have been calling x), and the type of test that should be performed on the transform. The last argument allows tests to be combined: for example, the call `testrevrat(series,x,testdlograt)` will test the logarithmic derivative of the reversion of the series for rationality. These tests, or compositions of them, are successively called by the main program (named `generating` in the examples that follow), which returns a generating function if possible.

Some renormalization of the series is included in `testdrat`, `testdlograt` and `testrevrat`, so that further operations can always be applied. For instance, a series should preferably be of the form

$$x + a_2x^2 + \cdots + a_nx^n + O(x^{n+1}).$$

for reversion.

3. EXAMPLES

The sidebars on this page and the next show a number of representative examples of use of the program `generating`. In some cases, the output has been simplified, using Maple. We use standard mathematical notation for ease of reading, but the Maple input and output is straightforward. The input for Example 1, for example, would be

```
> generating(x + x^2 + 2 x^3 + 3 x^4 +
>    5 x^5 + 8 x^6 + O(x^7));
```

where > is the Maple prompt. The program outputs either "`The generating function of this series appears to be ...`" or "`I can find no generating function for this series.`"

Some of the examples were selected from the forthcoming second edition of N. J. A. Sloane's *Handbook of Integer Sequences* [Sloane]. We applied the program to a great number of power series, both ordinary and exponential, corresponding to the sequences in that book (that is, the coefficients of the series were the terms of the sequences). We chose our examples either for their intrinsic elegance, or because they appear to be unknown, or to illustrate the power of the method. Some examples illustrate the use of the program on series with polynomial coefficients.

Example 1. This is the series coming from the Fibonacci sequence. Here `generating` uses directly Maple's function `convert/ratpoly`. The smallest precision for which the result comes out right is six, as shown. With a direct use of this `ratpoly` function (and a simple rejection test) we obtained generating functions for about 600 out of the 4568 sequences in [Sloane].

Example 2. Here the program took the derivative.

Example 3. This is a specialization at $t = -1$ of the next example.

Example 4. This is the exponential generating function for Hermite polynomials. Observe how the input series can have polynomial coefficients, and how the number of terms needed to yield a significant result is quite small.

Example 5. Here the program took the logarithmic derivative.

Example 6. Several generating functions with exponents such as $\frac{3}{2}$, $\frac{5}{2}$, $\frac{7}{2}$ and $\frac{11}{2}$ were obtained when we ran our program on the sequences appearing in [Sloane].

Example 7. This is the exponential generating function for Stirling polynomials of the first kind, which count permutations by number of cycles.

	Input	Output
1	$x + x^2 + 2x^3 + 3x^4 + 5x^5 + 8x^6 + O(x^7)$	$\dfrac{-x}{-1+x+x^2}$
2	$2 + 5x + \frac{11}{2}x^2 + \frac{19}{3}x^3 + \frac{29}{4}x^4 + \frac{41}{5}x^5 + \frac{55}{6}x^6 + \frac{71}{7}x^7 + \frac{89}{8}x^8 + \frac{109}{9}x^9 + O(x^{10})$	$\dfrac{2-x^2}{(1-x)^2} + \ln\dfrac{1}{1-x}$
3	$1 + x + x^2 + \frac{2}{3}x^3 + \frac{5}{12}x^4 + \frac{13}{60}x^5 + \frac{19}{180}x^6 + \frac{29}{630}x^7 + \frac{191}{10080}x^8 + \frac{131}{18144}x^9 + O(x^{10})$	$\exp\left(x + \frac{1}{2}x^2\right)$
4	$1 - xt + \left(\frac{1}{2} + \frac{1}{2}t^2\right)x^2 - \left(\frac{1}{2}t + \frac{1}{6}t^3\right)x^3 + \left(\frac{1}{8} + \frac{1}{4}t^2 + \frac{1}{24}t^4\right)x^4 - \left(\frac{1}{8}t + \frac{1}{12}t^3 + \frac{1}{120}t^5\right)x^5 + O(x^6)$	$\exp\left(\frac{1}{2}x(-2t+x)\right)$
5	$1 + x + x^2 + \frac{5}{6}x^3 + \frac{17}{24}x^4 + \frac{73}{120}x^5 + \frac{97}{180}x^6 + \frac{2461}{5040}x^7 + \frac{3631}{8064}x^8 + \frac{152531}{362880}x^9 + O(x^{10})$	$\dfrac{\exp\left(\frac{1}{4}x^2 + \frac{1}{2}x\right)}{\sqrt{1-x}}$
6	$1 + 24x + 270x^2 + 2240x^3 + 15750x^4 + 99792x^5 + 588588x^6 + 3294720x^7 + 17721990x^8 + 92378000x^9 + O(x^{10})$	$\dfrac{1+10x+4x^2}{(1-4x)^{7/2}}$
7	$1 + tx + \frac{1}{2}(t^2+t)x^2 + \frac{1}{6}(t^3+3t^2+2t)x^3 + \frac{1}{24}(t^4+6t^3+11t^2+6t)x^4 + \frac{1}{120}(t^5+10t^4+35t^3+50t^2+24t)x^5 + O(x^6)$	$\left(\dfrac{1}{1-x}\right)^t$

Example 8. This is the exponential generating function for Stirling polynomials of the second kind, which count partitions of a set by number of parts. This result was obtained through a double logarithmic derivative.

Example 9. This illustrates the use of a rationality test on the reversion of a series. The reversion of this generating function is $x/(1+x)^3$; therefore the generating function $f(x)$ is obtained as the real solution of the cubic equation

$$(1+f(x))^3\, x - f(x) = 0.$$

Example 10. This generating function has two parameters, and admits as one specialization the generating function for Laguerre polynomials. One can find a generating function for most of the classical orthogonal polynomials using our program on the first seven or so terms of their series.

Example 11. This generating function counts functions from a set into itself with weight t^k, where k is the number of recurrent points in the function. $\mathrm{Rev}(f(x), x)$ stands for the inverse for composition of $f(x)$. If we denote by $A(x)$ the solution to the functional equation $A(x) = x\exp(A(x))$, the generating function is equal to

$$\frac{1}{1 - txe^{A(x)}}.$$

$A(x)$ is the generating function for rooted trees.

Many other functions such as $\tan x$, $\arctan x$, or $\arcsin x$ also appeared as generating functions in our experiments.

4. CONCLUSIONS

The success of our approach, and also its limitations, depend on the set of transformations tried before a rationality test is made. Many transfor-

	Input	Output

11	$xt + \left(t+t^2\right)x^2 + \left(\frac{3}{2}t+2t^2+t^3\right)x^3 + \left(4t^2+3t^3+\frac{8}{3}t+t^4\right)x^4 + \left(\frac{25}{3}t^2+\frac{15}{2}t^3+\frac{125}{24}t+4t^4+t^5\right)x^5 + \left(18t^2+18t^3+\frac{54}{5}t+12t^4+5t^5+t^6\right)x^6 + \left(\frac{343}{8}t^3+\frac{98}{3}t^4+\frac{2401}{60}t^2+\frac{35}{2}t^5+\frac{16807}{720}t+6t^6+t^7\right)x^7 + \left(\frac{16384}{315}t+7t^7+t^8+24t^6+\frac{160}{3}t^5+\frac{256}{3}t^4+\frac{512}{5}t^3+\frac{4096}{45}t^2\right)x^8 + O(x^9)$	$t\,\mathrm{Rev}\left(\frac{x}{xt+1}\exp\left(-\frac{x}{xt+1}\right), x\right)$

mations beyond differentiation, logarithmic differentiation and reversion may be considered. For instance, one could choose any invertible function $f(x)$ and consider the following transformations on a series $\alpha(x) = a_0 + a_1x + a_2x^2 + \cdots + a_nx^n + O(x^{n+1})$:

$$\theta_f(\alpha(x)) = \text{taylor}(a_0 + a_1f(x) + \cdots + a_nf(x)^n),$$
$$\theta^f(\alpha(x)) = \text{taylor}(f(a_1x + a_2x^2 + \cdots + a_nx^n)).$$

Here taylor(g) stands for the operation of taking the Taylor expansion around 0 of a function g, and θ^f is defined when $a_0 = 0$. If $f^{\langle -1\rangle}$ denotes the reversion of $f(x)$, one easily checks that

$$(\theta_f)^{-1}(g(x)) = g(f^{\langle -1\rangle}(x)),$$
$$(\theta^f)^{-1}(g(x)) = f^{\langle -1\rangle}(g(x)).$$

One nice case is when $f(x) = \ln x$ in θ_f. This transformation allows the computation of generating functions that are rational functions of the exponential. For instance, one could obtain in this manner the generating function

$$\frac{e^x - 1}{2 - e^x}$$

for the series

$$x + \tfrac{3}{2}x^2 + \tfrac{13}{6}x^3 + \tfrac{25}{8}x^4 + \tfrac{541}{120}x^5 + \tfrac{1561}{240}x^6 + \tfrac{47293}{5040}x^7 + \tfrac{36389}{2688}x^8 + \tfrac{7087261}{362880}x^9 + O(x^{10}),$$

which is the exponential series for ordered partitions of a set. As it happens, our program found this generating function by other means, namely by taking the derivative of the reversion of the series, whose generating function is

$$\frac{1}{(1+2x)(1+x)}.$$

To describe other possible extensions of our approach, we recall some definitions. A series $y(x)$, with coefficients in $\mathbf{K}$, is said to be *differentiably finite* or *D-finite* [Stanley 1980] if it satisfies some nontrivial linear differential equation

$$p_0(x)y + p_1(x)y' + \cdots + p_k(x)y^{(k)} = 0 \qquad (4.1)$$

with coefficients $p_j(x) \in \mathbf{K}[x]$. A series $y = y(x)$ is said to be *constructible differentially finite* or *CDF* [Bergeron and Reutenauer 1990] if, for some $k \geq 1$, there exist k series $y_1, \ldots, y_k$, with $y_1 = y$, and polynomials $P_1, \ldots, P_k$ with coefficients in $\mathbf{K}$, satisfying

$$y_i' = P_i(y_1, \ldots, y_k) \quad \text{for } i = 1, \ldots, k. \qquad (4.2)$$

Both of these classes of series contain polynomials, algebraic series, and the Taylor expansion around 0 of usual functions such as e^x, $\log(1+x)$, or the trigonometric functions. They are also closed under addition and multiplication, and under composition with algebraic series. However, the CDF class is not closed under Hadamard (termwise) product, whereas the D-finite class is. On the other hand, CDF is closed under differentiation, integration, inversion $(1/y(x))$, composition and reversion.

Neither class is contained in the other. All CDF series are analytic around 0, so $\sum_n n!\,x^n$ is not CDF, though it is D-finite. On the other hand, the series expansion around 0 of $1/\cos x$ is not D-finite, but is CDF.

Both classes allow for the characterization of a wide range of generating functions. If one knows the form of the liner differential equation (4.1) or the system (4.2)—that is, the number of equations and the degrees of the polynomials—the exact equation or system characterizing a given series or a set of series can then be found from the series' first terms. In the case of D-finite series, this technique has already been proposed and implemented by Guttmann [Brak and Guttmann 1990]. For CDF series, we have an experimental program that has been used to obtain nice new generating functions such as

$$F(u, v, x) = \frac{\alpha^2}{e^x((1+u)\sin(\frac{1}{2}\alpha x) - \cos(\frac{1}{2}\alpha x))^2}, \qquad (4.3)$$

where $\alpha = \sqrt{2v - (1+u)^2}$. This is a generating function (with parameters) for the number of maximal up-going paths in the composition poset (ongoing research in collaboration with S. Dulucq and M. Bousquet-Mélou). Function (4.3) is not D-finite but is CDF. To obtain it, we used the first few terms of the series

$$1 + ux + \tfrac{1}{2}(v+u^2)x^2 + \tfrac{1}{6}(v + 4vu + u^3)x^3 + \tfrac{1}{24}(v + 4v^2 + 6vu + 11vu^2 + u^4)x^4 + \tfrac{1}{120}(v + 14v^2 + 34uv^2 + 8vu + 23u^2v + 26vu^3 + u^5)x^5 + \cdots,$$

obtained by explicit enumeration of the objects considered, in order to find the system

$$F' = F(1+G), \qquad F(u,v,0) = 1,$$
$$G' = v + (1+u)G + G^2/2, \qquad G(u,v,0) = 0.$$

Expression (4.3) is easily computed from this.

Our first implementation of `generating` computed a generating function for either the ordinary or the exponential series of about 1000 out of the 4568 sequences appearing in [Sloane]. Since the first version of this article was written, a Maple package implementing some ideas presented here, as well as others such as the D-finite approach, has been written by Bruno Salvy and Paul Zimmermann of INRIA [Salvy and Zimmermann]. It is now available as a shared package under the name "`gfun`". (To learn more about obtaining shared packages, type `?share` to Maple.) The analogue of our function `generating` in `gfun` is the function `guessgf`. Giving `guessgf` the right set of options results in its using the set of transformations described in Section 2 of this paper.

Shifted Quasi-Symmetric Functions and the Hopf algebra of peak functions

Nantel Bergeron, S. Mykytiuk, Frank Sottile, and S. J. van Willigenburg

In his work on P-partitions, Stembridge defined the algebra of peak functions *Pi* which is both a subalgebra and a retraction of the algebra of quasi-symmetric functions. We show that *Pi* is closed under coproduct, and therefore a Hopf algebra, and describe the kernel of the retraction. Billey and Haiman, in their work on Schubert polynomials, also defined a new class of quasi-symmetric functions --- shifted quasi-symmetric functions --- and we show that *Pi* is strictly contained in the linear span *Xi* of shifted quasi-symmetric functions. We show that *Xi* is a coalgebra, and compute the rank of the n-th graded component.

Two-point Spectral Correlations for Star Graphs

Berkolaiko, G.; Keating, J.P.

HPL-BRIMS-1999-10
19991028
External

Keyword(s): spectral statistics; graph theory; combinatorics

Abstract: Please Note. This abstract contains mathematical formulae which cannot be represented here. The eigenvalues of the Schrodinger operator on a graph G are related via an exact trace formula to periodic orbits on G. This connection is used to calculate two- point spectral statistics for a particular family of graphs, called star graphs, in the limit as the number of edges tend to infinity. Combinatorial techniques are used to evaluate both the diagonal (same orbit) and off-diagonal (different orbit) contributions to the sum over pairs of orbits involved. In this way, a general formula is derived for terms in the (short- time) expansion of the form factor K ( ) in powers of , and the first few are computed explicitly. The result demonstrates that K ( ) is neither Poissonian nor random-matrix, but intermediate between the two. Off-diagonal pairs of orbits are shown to make a significant contribution to all but the first few coefficients.

Abstract

Extending earlier work of R. Donaghey and P. J. Cameron, we investigate
some canonical "eigen-sequences" associated with transformations of integer sequences.
Several known sequences appear in a new setting:
for instance the sequences (such as 1, 3, 11, 49, 257, 1531, ...) studied by
T. Tsuzuku, H. O. Foulkes and A. Kerber in connection with
multiply transitive groups are eigen-sequences for the binomial transform.
Many interesting new sequences also arise, such as 1, 1, 2, 26, 152, 1144, ...,
which shifts one place left when transformed by the Stirling numbers of the second kind,
and whose exponential generating function satisfies A'(x) = A(e^x -1) + 1.

Abstract

How many sublattices of index N are there in the planar hexagonal lattice? Which of them are the best from the point of view of packing density, signal-to-noise ratio, or energy? We answer the first question completely and give partial answers to the other questions.

Linear Spaces with at Most 12 Points

Journal of Combinatorial Designs 7 (1999), 119-145.

We maintain two versions of this page, one at the Journal's home page in the USA, the other one at the author's home page in Germany. Here are the links:

- JCD version in the USA
- author's version in Germany

Note that the two versions of this page differ slightly, the authors page giving also incidence matrices for the linear spaces.

Abstract:
The 28,872,973 linear spaces on 12 points are constructed. The parameters of the geometries play an important role. In order to make generation easy, we construct possible parameter sets for geometries first (purely algebraically). Afterwards, the corresponding geometries are tried to construct. We define line types, point types, point cases and also refined line types. These are the first three steps of a general decomposition according to the parameters which we call TDO. The depth of parameter precalculation can be varied, thereby obtaining a handy tool to react in a flexible way to different grades of difficulty of the problem.

Structured numbers

Properties of a hierarchy of operations on binary trees

Vincent D. Blondel⋆

Institute of Mathematics, University of Liège, B-4000 Liège, Belgium (e-mail: vblondel@ulg.ac.be)

Received: 11 December 1995 / 30 December 1996

Abstract. We introduce a hierarchy of operations on (finite and infinite) binary trees. The operations are obtained by successive repetition of one initial operation. The first three operations are generalizations of the operations of addition, multiplication and exponentiation for positive integers.

1 Introduction

The product of two positive integers a and b is equal to the sum of b factors each equal to a. The bth exponent of a, denoted by $a \uparrow b$, can similarly be defined as the product of b factors each equal to a. The process of getting new operations by repeating old ones ends with exponentiation because this last operation is not associative. The definition

$$a \uparrow\uparrow b = \underbrace{a \uparrow a \uparrow a \uparrow \ldots \uparrow a}_{b \text{ factors}} \tag{1}$$

is ambiguous since for example $(4 \uparrow 4) \uparrow 4 \neq 4 \uparrow (4 \uparrow 4)$. For the the right hand side of (1) to be well defined both the number of factors and the order in which the operations $\uparrow$ are performed have to be specified.

A way of doing this is to ask the second operand to carry not only a quantitative information, the number of times a is repeated, but also a structured information, the order in which the operations $\uparrow$ are performed. Binary trees are naturally designated object to convey such a structured information. The number of external nodes (leaves) of a binary tree can be used to specify the number of factors, and the structure of the tree can then be used to specify the order in which the operations are performed.

⋆ Parts of this work were completed while the author was at OCIAM Oxford, at KTH Stockholm and at INRIA Paris.

In this paper, we define countably many internal operations on binary trees. The first operation, which we denote by $\overset{1}{\cdot}$, is obtained by forming the binary tree whose left and right subtrees are equal to the operands. This operation is not associative. The second operation $\overset{2}{\cdot}$ is defined as follows: From the binary trees a and b we construct the binary tree $a \overset{2}{\cdot} b$ by repeating the operation $\overset{1}{\cdot}$ on the tree a with the structure dictated by b. In the same way, we define an operation $\overset{3}{\cdot}$ by repeating $\overset{2}{\cdot}$, an operation $\overset{4}{\cdot}$ by repeating $\overset{3}{\cdot}$, etc. We eventually obtain countably many internal operations ($\overset{k}{\cdot}$ for $k \geq 1$) with the definition

$$a \overset{k}{\cdot} b = \underbrace{a \overset{k-1}{\cdot} a \overset{k-1}{\cdot} a \overset{k-1}{\cdot} \ldots \overset{k-1}{\cdot} a}_{b \text{ factors}}$$

The number of external nodes of the binary tree resulting from the operation $\overset{1}{\cdot}$, $\overset{2}{\cdot}$ and $\overset{3}{\cdot}$ are equal to the sum, product and exponentiation of the number of external nodes of the operands. These three operations are thought of as binary trees counterparts of the usual operations of addition, multiplication and exponentiation. The operations $\overset{k}{\cdot}$ for $k \geq 4$ have no natural number counterparts since for these cases the structure of the trees have to be taken into account to compute the number of external nodes of a $\overset{k}{\cdot}$-product.

The object of this paper is to study some of the properties of the operations $\overset{k}{\cdot}$ described above and formalized in the second section of the paper. In Sect. 3 the operations are shown to satisfy algebraic properties that generalize elementary properties for integers. In Sect. 4 we show that binary trees can be decomposed in a unique way as products of prime binary trees. In Sect. 5 we analyse the operations $\overset{k}{\cdot}$ for $k \geq 4$. In Sect. 6 we describe various integer valued functions associated to trees and show how these functions behave with respect to $\overset{k}{\cdot}$-products of binary trees. In a final section we argue that the notions introduced for finite binary trees can be generalized for infinite trees. This is achieved by formalizing binary trees by means of factorial languages.

Different authors have proposed to continue the hierarchy $+, \times, \uparrow$ on natural numbers by introducing operations of "super-exponentiation". D. Knuth's recursive definition [18] is

$$\begin{aligned}
a \uparrow\uparrow b &= \underbrace{a \uparrow (a \uparrow (a \uparrow (a \ldots \uparrow a) \ldots))}_{b} \\
a \uparrow\uparrow\uparrow b &= \underbrace{a \uparrow\uparrow (a \uparrow\uparrow (a \uparrow\uparrow (a \ldots \uparrow\uparrow a) \ldots))}_{b} \\
a \underbrace{\uparrow \ldots \uparrow}_{k} b &= \underbrace{a \underbrace{\uparrow \ldots \uparrow}_{k-1} (a \underbrace{\uparrow \ldots \uparrow}_{k-1} a \ldots \underbrace{\uparrow \ldots \uparrow}_{k-1} a) \ldots))}_{b}
\end{aligned}$$

This definition coincide, modulo elementary notational modifications, with the definition originally given by Ackermann of a recursive function that is not primitive recursive (see [13]). The definition has the disadvantage of making an arbitrary choice on how the non-associative operations are performed and, as a result, these operations exhibit poor algebraic properties (see, however, [1]).

Operations on graphs, trees and binary trees constitute a classical object of study in theoretical computer science (see [20], [21], [19], [17, Vol. 1 Section 2.3]) but we have found no reference that uses the particular structure of binary trees as a mean for defining repeated operations. The contribution that is probably closest to ours is the "arithmetic of shapes" developed by I.M. Etherington half a century ago in the context of genetics. The transmission of a probability distribution of genes by mating is an operation that is commutative but not associative. In order to describe this operation, Etherington has introduced in [6] operations on trees that are similar to $\overset{1}{\cdot}$, $\overset{2}{\cdot}$ and $\overset{3}{\cdot}$ and that have given rise to the widely studied genetic algebras (see [6], [15] and [5]). The operations $\overset{k}{\cdot}$ for $k \geq 4$ are not defined in the context of genetic algebras because the trees considered there are not ordered and there is no natural definition of $\overset{k}{\cdot}$ for $k \geq 4$ for unordered trees.

Motivated by the remarks made in this introduction, binary trees are introduced in [2], [3] and [4] as one possible representation of the concept of "structured number". A motivation for this terminology is justified by the following observation: Free groups with a simple generator are isomorphic to $(\mathbf{Z}, +)$, free monoids with a single generator are isomorphic to $(\mathbf{N}, +)$ and free groupoids with a single generator are isomorphic to $(BT, \overset{1}{\cdot})$ where BT denotes the set of binary trees and $\overset{1}{\cdot}$ is the first operation in our hierarchy. This analogy motivates the notation **SN** used in [2] for denoting the set of binary trees which can be seen as one possible representation of the notion of structured number.

2 The operations

Let BT be the set of binary trees [17, Vol. 1 Sect. 2.3] defined by the symbolic equation [9]:

$$BT = \bullet + \underset{BT\ BT}{\overset{\cdot}{/\ \backslash}} .$$

A tree $a \in BT$ different from the one node tree $\bullet$ is ordered in such a way that we can make a distinction between the left subtree $a_L \in BT$ and the right subtree $a_R \in BT$. For notational convenience we represent a binary tree $a \in BT$ by its horizontal paranthesed expression $\phi(a) \in \{\bullet, (,)\}^*$, where $\phi : BT \to \{\bullet, (,)\}^*$ is recursively defined by

$$\phi(\bullet) = \bullet$$

$$\phi\left(\underset{a_L\ a_R}{\overset{\cdot}{/\ \backslash}}\right) = (\phi(a_L)\ \phi(a_R))$$

In the sequel we identify $a \in BT$ with $\phi(a)$. A binary tree $a \in BT$ is represented by $\bullet$ if it is the one node tree, and by $(a_L a_R)$ if it has the left

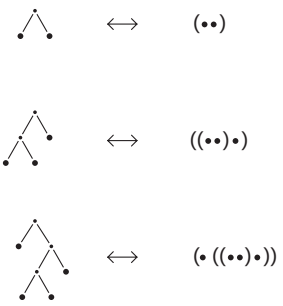

Fig. 1. Binary trees and their corresponding paranthesed expressions

and right subtree a_L and a_R, respectively. Some binary trees together with their paranthesed expressions are drawn in Fig. 1.

The number of external nodes (leaves) of a binary tree $a \in BT$ is called the weight of a.

Definition 1. *The* $weight$ *function* $weight : BT \to \mathbf{N}$ *is defined inductively by*

$$weight(a) = \begin{cases} 1 & \text{if } a = \bullet \\ weight(a_L) + weight(a_R) & \text{if } a = (a_L a_R) \end{cases}$$

Binary trees that are distinct but that have identical weight are said to differ by their shape.

We define countably many operations on binary trees.

Definition 2. *The operation* $\overset{1}{\cdot}$ $: BT \times BT \to BT$ *is defined by* $a \overset{1}{\cdot} b = (ab)$. *For* $k \geq 2$, *the operations* $\overset{k}{\cdot}$ $: BT \times BT \to BT$ *are defined by*

$$a \overset{k}{\cdot} b = \begin{cases} a & \text{if } b = \bullet \\ (a \overset{k}{\cdot} b_L) \overset{k-1}{\cdot} (a \overset{k}{\cdot} b_R) & \text{if } b = (b_L b_R) \end{cases}$$

The integer k *is called the index of the operation* $\overset{k}{\cdot}$.

The operation $\overset{k+1}{\cdot}$ has a simple expression in terms of $\overset{k}{\cdot}$. Suppose a, b are binary trees and $n \geq 1$ is the weight of b. The binary tree $c = a \overset{k+1}{\cdot} b$ is then equal to the tree resulting from the $\overset{k}{\cdot}$-product of n trees a, in an order prescribed by the shape of b. For example

$$a \overset{k+1}{\cdot} (\bullet\bullet) = (a \overset{k}{\cdot} a)$$

and

$$a \overset{k+1}{\cdot} ((\bullet(\bullet\bullet))(\bullet\bullet)) = ((a \overset{k}{\cdot} (a \overset{k}{\cdot} a)) \overset{k}{\cdot} (a \overset{k}{\cdot} a))$$

Elementary examples of binary trees resulting from the operations $\overset{1}{\cdot}$, $\overset{2}{\cdot}$ and $\overset{3}{\cdot}$ are given in Fig. 2. The tree $a \overset{1}{\cdot} b$ is obtained by constructing the tree whose left and right subtrees are a and b respectively. The tree $a \overset{2}{\cdot} b$ is obtained by grafting

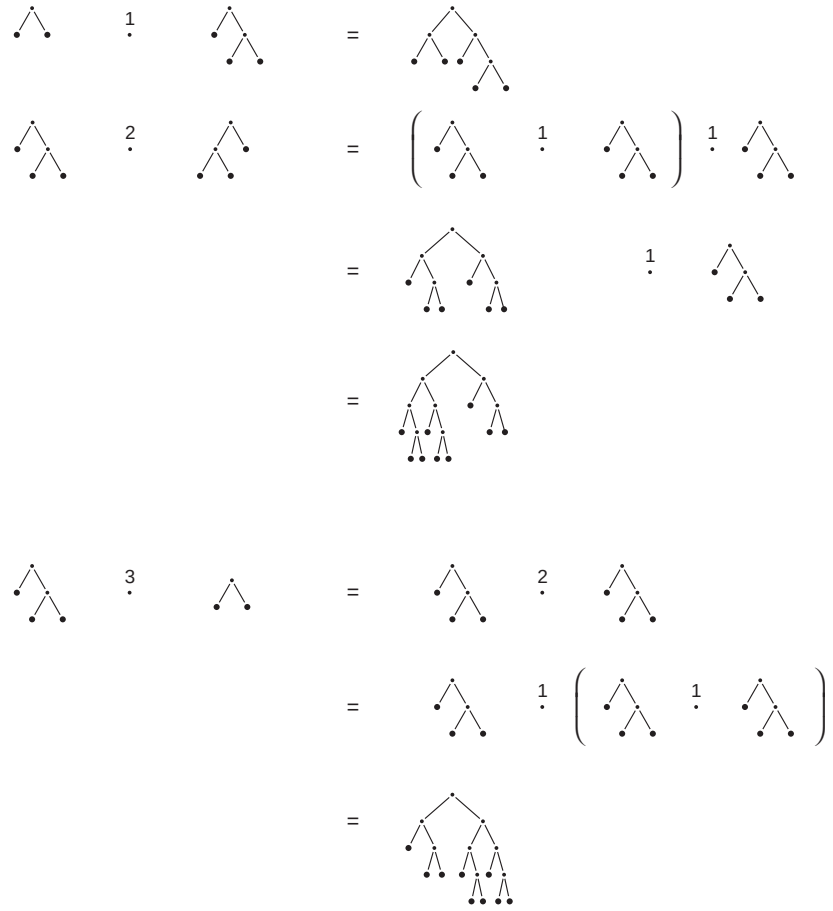

Fig. 2. Binary trees resulting from the operations of addition, multiplication and exponentiation

a copy of the tree a at the leaves of the tree b. No such simple geometrical description is available for $a \overset{3}{\cdot} b$.

From the definition of the function $weight$ and of the operation $\overset{1}{\cdot}$ we deduce that $weight(a \overset{1}{\cdot} b) = weight(a) + weight(b)$. Since the operations of higher index are defined by successive repetition of $\overset{1}{\cdot}$ the next result is easely obtained.

Proposition 1. *Let a, b be binary trees.*

1. $weight(a \overset{1}{\cdot} b) = weight(a) + weight(b)$
2. $weight(a \overset{2}{\cdot} b) = weight(a).weight(b)$
3. $weight(a \overset{3}{\cdot} b) = weight(a)^{weight(b)}$

In the sequel the three first operations $\overset{1}{\cdot}$, $\overset{2}{\cdot}$ and $\overset{3}{\cdot}$ on binary trees will be called addition, multiplication and exponentiation. There exist no natural number counterpart to $\overset{k}{\cdot}$ for $k \geq 4$ because in this case the weight of $a \overset{k}{\cdot} b$ depends on the weight of a and b but also on their respective shape.

3 Algebraic properties

The properties of the operations $\overset{1}{\cdot}$, $\overset{2}{\cdot}$, $\overset{3}{\cdot}$ for binary trees are similar to those of $+, ., \uparrow$ for natural numbers.

Theorem 1. *1. Let a be a binary tree and $k \geq 3$.*

1. $a \overset{2}{\cdot} \bullet = a = \bullet \overset{2}{\cdot} a$
2. $a \overset{k}{\cdot} \bullet = a$ *and* $\bullet \overset{k}{\cdot} a = \bullet$

2. Let a, b, c be binary trees and $k \geq 2$.

1. $a \overset{k}{\cdot} (b \overset{1}{\cdot} c) = (a \overset{k}{\cdot} b) \overset{k-1}{\cdot} (a \overset{k}{\cdot} c)$
2. $a \overset{k}{\cdot} (b \overset{2}{\cdot} c) = (a \overset{k}{\cdot} b) \overset{k}{\cdot} c$

3. Let a, b, c, d be binary trees.

1. *Left cancellation: If $a \overset{2}{\cdot} b = a \overset{2}{\cdot} c$ then $b = c$.*
2. *Right cancellation: If $a \overset{2}{\cdot} b = c \overset{2}{\cdot} b$ then $a = c$.*

Proof. 1. The equalities $a \overset{k}{\cdot} \bullet = a$ for $k \geq 2$ follow from the definition of $\overset{k}{\cdot}$. We prove $\bullet \overset{2}{\cdot} a = a$ by induction on a. The result is clearly true for $a = \bullet$ so let $a = (a_L a_R)$ and assume that $\bullet \overset{2}{\cdot} a_L = a_L$ and $\bullet \overset{2}{\cdot} a_R = a_R$. Then $a = a_L \overset{1}{\cdot} a_R = (\bullet \overset{2}{\cdot} a_L) \overset{1}{\cdot} (\bullet \overset{2}{\cdot} a_R) = \bullet \overset{2}{\cdot} (a_L \overset{1}{\cdot} a_R) = \bullet \overset{2}{\cdot} a$ and the theorem is proved. The equalities $\bullet \overset{k}{\cdot} a = a$ are proved by induction on a.

2. The first property is a rephrasement of the definition of $\overset{k}{\cdot}$. We prove the second property by induction on c. When $c = \bullet$ we have $a \overset{k}{\cdot} (b \overset{2}{\cdot} c) = a \overset{k}{\cdot} (b \overset{2}{\cdot} \bullet) = a \overset{k}{\cdot} b = (a \overset{k}{\cdot} b) \overset{k}{\cdot} \bullet = (a \overset{k}{\cdot} b) \overset{k}{\cdot} c$ so let $c = (c_L c_R)$ and assume that $a \overset{k}{\cdot} (b \overset{2}{\cdot} c_L) = (a \overset{k}{\cdot} b) \overset{k}{\cdot} c_L$ and $a \overset{k}{\cdot} (b \overset{2}{\cdot} c_R) = (a \overset{k}{\cdot} b) \overset{k}{\cdot} c_R$. Then by successive applications of the first property we obtain

$$\begin{aligned} (a \overset{k}{\cdot} (b \overset{2}{\cdot} c_L)) \overset{k-1}{\cdot} (a \overset{k}{\cdot} (b \overset{2}{\cdot} c_R)) &= ((a \overset{k}{\cdot} b) \overset{k}{\cdot} c_L) \overset{k-1}{\cdot} ((a \overset{k}{\cdot} b) \overset{k}{\cdot} c_R) \\ a \overset{k}{\cdot} ((b \overset{2}{\cdot} c_L) \overset{1}{\cdot} (b \overset{2}{\cdot} c_R)) &= (a \overset{k}{\cdot} b) \overset{k}{\cdot} (c_L \overset{1}{\cdot} c_R) \\ a \overset{k}{\cdot} (b \overset{2}{\cdot} (c_L \overset{1}{\cdot} c_R)) &= (a \overset{k}{\cdot} b) \overset{k}{\cdot} (c_L \overset{1}{\cdot} c_R) \end{aligned}$$

and thus

$$a \overset{k}{\cdot} (b \overset{2}{\cdot} c) = (a \overset{k}{\cdot} b) \overset{k}{\cdot} c.$$

3. We prove the right cancellation rule only, the proof of the left cancellation rule is similar. We proceed by induction on b. The result is clearly true for $b = \bullet$ so let $b = (b_L b_R)$ and assume that the result holds for b_L and b_R. If $a \overset{2}{\cdot} b = c \overset{2}{\cdot} b$, then $(a \overset{2}{\cdot} b_L) \overset{1}{\cdot} (a \overset{2}{\cdot} b_R) = (c \overset{2}{\cdot} b_L) \overset{1}{\cdot} (c \overset{2}{\cdot} b_R)$ and $a \overset{2}{\cdot} b_L = c \overset{2}{\cdot} b_L$. By the induction hypothesis we are lead to the conclusion. □

When evaluated with $k = 2$ the Properties 2.1 and 2.2 give

1. $a.(b + c) = a.b + a.c$
2. $a.(b.c) = (a.b).c$

whereas an evaluation with $k = 3$ gives

1. $a^{(b+c)} = a^b.a^c$

2. $a^{(b.c)} = (a^b)^c$

These four usual identities in **Z** have thus counterparts for binary trees. Central in the sequel is the fact that multiplication is associative.

Counterexamples

Commutativity. The operations $\overset{k}{\cdot}$ are non commutative. For $k = 1$ and $k = 2$ this can be seen from the examples $(\bullet\bullet)\overset{1}{\cdot}\bullet \neq \bullet\overset{1}{\cdot}(\bullet\bullet)$ and $(\bullet\bullet)\overset{2}{\cdot}(\bullet(\bullet\bullet)) \neq (\bullet(\bullet\bullet))\overset{2}{\cdot}(\bullet\bullet)$ whereas for the operations of higher index it suffices to notice that $a\overset{k}{\cdot}\bullet \neq \bullet\overset{k}{\cdot}a$ for any binary tree a different from $\bullet$.

Associativity. The operation $\overset{1}{\cdot}$ is not associative as is easily seen from the example $\bullet\overset{1}{\cdot}(\bullet\overset{1}{\cdot}\bullet) \neq (\bullet\overset{1}{\cdot}\bullet)\overset{1}{\cdot}\bullet$. The operations $\overset{k}{\cdot}$ for $k \geq 3$ are not associative either. For example, $(a\overset{k}{\cdot}\bullet)\overset{k}{\cdot}a \neq a\overset{k}{\cdot}(\bullet\overset{k}{\cdot}a)$ when $a \neq \bullet$. Thus, by Theorem 1, the only associative operation is $\overset{2}{\cdot}$.

Cancellation rule. The left cancellation rule does not hold for the operations $\overset{k}{\cdot}$ when $k \geq 3$. Indeed, for any binary tree a and $k \geq 3$ we have $\bullet\overset{k}{\cdot}a = \bullet$. Thus $\bullet\overset{k}{\cdot}a = \bullet\overset{k}{\cdot}b$ for all binary trees a and b which clearly shows that the left cancellation rule does not hold. In Sect. 5 we give necessary and sufficient conditions for the equality $a\overset{k}{\cdot}b = a\overset{k}{\cdot}d$.

The right cancellation rule is harder to analyse. It is known to hold for $k = 1$, $k = 2$, $k = 3$ and $k = 4$ but the general case is yet unsettled. We conjecture here that it holds for all $\overset{k}{\cdot}$ when $k \geq 1$.

4 Prime trees and prime decomposition

Definition 3. *A binary tree a is prime if it is different from the one node tree $\bullet$ and if $a = b\overset{2}{\cdot}c$ implies that $b = \bullet$ or $c = \bullet$. Trees that are not prime are composite.*

The weight of a product of binary trees is equal to the product of the weights. It is therefore clear that any binary tree whose weight is a prime number is automatically prime. The converse of this statement is not true. The binary tree $(\bullet(\bullet(\bullet\bullet)))$ has weight 4 and is a prime binary tree. It is easy to see that four of the five binary trees of weight four are prime and that, in general, a natural number n is prime if and only if all binary trees of weight n are prime.

In Table 1 we give, for the first values of $n \geq 1$, the number C_n of binary trees of weight n, the number I_n of composite trees of weight n, and the number P_n of prime trees of weight n. It is well-known that the number of binary trees of weigth n is equal to the nth Catalan number $C_n = (2n-2)!/(n!(n-1)!)$ (see [14], [12], [11] or [21]). No simple expression for I_n or P_n seems available. The sequence P_n does not appear in the recent encyclopedic list of integer sequences [22]. Ph. Flajolet has shown [9] that $T_n - I_n$ is equal to 0 if n is prime, is equal to $(C_p)^2$ if $n = p^2$ is the square of a prime, and is otherwise asymptotic to $2C_pC_{n/p}$ where p is the smallest prime factor of n.

Binary trees different from the one node tree can be decomposed into products of prime binary trees. The decomposition is unique up to, and including, the sequence in which the factors appear. We first need a lemma for proving this.

Lemma 1. *Let a_1, a_2, b_1, b_2 be binary trees such that $a_1 \overset{2}{\cdot} a_2 = b_1 \overset{2}{\cdot} b_2$. If a_1 and b_1 (or a_2 and b_2) are prime, then $a_1 = b_1$ and $a_2 = b_2$.*

Proof. If $a_1 = b_1$, then the left cancellation rule for multiplication shows that $a_2 = b_2$. We proceed by induction on a_2 to prove that $a_1 = b_1$. If $a_2 = \bullet$ then $a_1 = b_1 \overset{2}{\cdot} b_2$. Since a_1 is prime and b_1 is different from $\bullet$ we must have $b_2 = \bullet$ and thus $a_1 = b_1$. Assume now that $a_1 \overset{2}{\cdot} a_2 = b_1 \overset{2}{\cdot} b_2$ and $a_2 = (a_{2L} a_{2R})$. If $b_2 = \bullet$, then $a_1 \overset{2}{\cdot} a_2 = b_1$ and the theorem is proved, so assume $b_2 = (b_{2L} b_{2R})$. We have $(a_1 \overset{2}{\cdot} a_{2L}) \overset{1}{\cdot} (a_1 \overset{2}{\cdot} a_{2R}) = (b_1 \overset{2}{\cdot} b_{2L}) \overset{1}{\cdot} (b_1 \overset{2}{\cdot} b_{2R})$. By the cancellation rule for addition and the induction hypothesis we then conclude $a_1 = b_1$ as requested. □

It is now easy to show:

Theorem 2 (Existence and uniqueness of prime decomposition). *Let a be a binary tree different from $\bullet$. Then $a = a_1 \overset{2}{\cdot} a_2 \overset{2}{\cdot} \cdots \overset{2}{\cdot} a_n$ for some $n \geq 1$ and some prime binary trees a_i. If $a = b_1 \overset{2}{\cdot} b_2 \overset{2}{\cdot} \cdots \overset{2}{\cdot} b_m$ is another such decomposition. Then $n = m$ and $a_i = b_i$ for $i = 1, ..., n$.*

Proof. Let a be a binary tree different from $\bullet$. If a is prime, then $n = 1$ and $a_1 = a$ is the decomposition sought. If a is composite, there exists a_1 and a_2 different from $\bullet$ and such that $a = a_1 \overset{2}{\cdot} a_2$. The factors can then be further decomposed until prime factors are reached. Since the weight of the factors are positive and strictly decreasing, the procedure must end after a finite number of steps. Thus $a = a_1 \overset{2}{\cdot} a_2 \overset{2}{\cdot} \cdots \overset{2}{\cdot} a_n$ for some $n \geq 1$ and a_i prime binary trees.

Assume now that $a = b_1 \overset{2}{\cdot} b_2 \overset{2}{\cdot} \cdots \overset{2}{\cdot} b_m$ is another such decomposition. By the lemma we must have $a_1 = b_1$ and $a_2 \overset{2}{\cdot} a_3 \overset{2}{\cdot} \cdots a_n = b_2 \overset{2}{\cdot} b_3 \overset{2}{\cdot} \cdots b_m$. But then by successive repetition of the same argument we are lead to the conclusion. □

The decomposition given in the theorem is called a prime decomposition. The ith factor in the decomposition is uniquely determined and is the ith factor of a. We can characterise the binary trees whose sum is prime.

Theorem 3. *Let a, b be binary trees different from the one node tree $\bullet$. Then $a \overset{1}{\cdot} b$ is prime if and only if the first factors of a and b are distinct.*

Proof. (Necessity) Let the first factors of a and b be distinct and assume by contradiction that $a \overset{1}{\cdot} b$ is not prime. Then $a = c_1 \overset{2}{\cdot} c_2$ for some c_1 and c_2 different from $\bullet$. Since c_2 is different from $\bullet$ we may write $c_2 = c_{2L} \overset{1}{\cdot} c_{2R}$. Hence $a \overset{1}{\cdot} b = (c_1 \overset{2}{\cdot} c_{2L}) \overset{1}{\cdot} (c_1 \overset{2}{\cdot} c_{2R})$. By the cancellation rule this leads to $a = c_1 \overset{2}{\cdot} c_{2L}$ and $b = c_1 \overset{2}{\cdot} c_{2R}$. But since c_1 is different from $\bullet$ these last identies show that the first factors of a and b are identical and a contradiction is thus attained.
(Sufficiency) Let a, b be distinct from $\bullet$ and assume by contradiction that $a = c \overset{2}{\cdot} a'$ and $b = c \overset{2}{\cdot} b'$ for some c different from $\bullet$. Then $a \overset{1}{\cdot} b = (c \overset{2}{\cdot} a') \overset{1}{\cdot} (c \overset{2}{\cdot} b') = c \overset{2}{\cdot} (a' \overset{1}{\cdot} b') = c \overset{2}{\cdot} c'$ with c and c' different from $\bullet$. A contradiction is achieved and the theorem is proved. □

5 The operations $\overset{k}{\cdot}$ for $k \geq 3$

Multiplication of binary trees is associative. The result of $a \overset{3}{\cdot} b$ therefore depends on a and on the weight of b but not otherwise on the shape of b.

Table 1. Number of binary trees, composite trees and prime binary trees of given weight

Proposition 2. *Let a, b_1, b_2 be binary trees and assume that $weight(b_1) = weight(b_2)$. Then $a \stackrel{3}{\cdot} b_1 = a \stackrel{3}{\cdot} b_2$.*

We use this result for introducing a new notation. Let $n \geq 1$ and $a \in BT$. By $a \stackrel{3}{\cdot} n$ we mean the binary tree $a \stackrel{3}{\cdot} b$ where b is any binary tree of weight n. A similar construction is possible for operations of higher index.

Definition 4. *Let $k \geq 3$. The operations $\diamondsuit_k : BT \times BT \to \mathbf{N}$ are defined inductively by*

1. $a \diamondsuit_3 b = weight(b)$
2. $$a \diamondsuit_k b = \begin{cases} 1 & \text{if } b = \bullet \\ (a \diamondsuit_k b_L).((a \stackrel{k}{\cdot} b_L) \diamondsuit_{k-1} (a \stackrel{k}{\cdot} b_R)) & \text{if } b = (b_L b_R) \end{cases}$$

With this purpose-built definition we have:

Theorem 4. *Let a, b be binary trees and $k \geq 3$. Then $a \stackrel{k}{\cdot} b = a \stackrel{3}{\cdot} (a \diamondsuit_k b)$.*

Proof. We proceed by induction on k. For $k = 3$ the result is contained in Proposition 2. We assume that the result holds for $\stackrel{k-1}{\cdot}$ and show, by induction on b, that it also holds for $\stackrel{k}{\cdot}$. If $b = \bullet$, then $a \stackrel{k}{\cdot} \bullet = a = a \stackrel{3}{\cdot} \bullet = a \stackrel{3}{\cdot} 1 = a \stackrel{3}{\cdot} (a \diamondsuit_k \bullet)$ so let $b = (b_L b_R)$ and assume that $a \stackrel{k}{\cdot} b_L = a \stackrel{3}{\cdot} (a \diamondsuit_k b_L)$ and $a \stackrel{k}{\cdot} b_R = a \stackrel{3}{\cdot} (a \diamondsuit_k b_R)$. We have

$$\begin{aligned} a \stackrel{k}{\cdot} b &= a \stackrel{k}{\cdot} (b_L b_R) \\ &= (a \stackrel{k}{\cdot} b_L) \stackrel{k-1}{\cdot} (a \stackrel{k}{\cdot} b_R) \\ &= (a \stackrel{k}{\cdot} b_L) \stackrel{3}{\cdot} ((a \stackrel{k}{\cdot} b_L) \diamondsuit_{k-1} (a \stackrel{k}{\cdot} b_R)) \\ &= (a \stackrel{3}{\cdot} (a \diamondsuit_k b_L)) \stackrel{3}{\cdot} ((a \stackrel{k}{\cdot} b_L) \diamondsuit_{k-1} (a \stackrel{k}{\cdot} b_R)) \\ &= a \stackrel{3}{\cdot} ((a \diamondsuit_k b_L)((a \stackrel{k}{\cdot} b_L) \diamondsuit_{k-1} (a \stackrel{k}{\cdot} b_R))) \\ &= a \stackrel{3}{\cdot} (a \diamondsuit_k b) \end{aligned}$$

and the theorem is proved. □

Cancellation rules for $\overset{1}{\cdot}$ and $\overset{2}{\cdot}$ were analysed in Sect. 3. We have shown that the left cancellation rule does not hold for $k \geq 3$ since, for example, $\bullet \overset{k}{\cdot} a = \bullet \overset{k}{\cdot} b$ for any binary trees a and b. With the help of Theorem 4 this observation can now be made more precise.

Theorem 5. *Let a, b, d be binary trees different from $\bullet$ and $k \geq 3$. Then $a \overset{k}{\cdot} b = a \overset{k}{\cdot} d$ if and only if $a \diamondsuit_k b = a \diamondsuit_k d$.*

Proof. (Necessity) By Theorem 4 we know that $a \overset{k}{\cdot} b = a \overset{3}{\cdot} (a \diamondsuit_k b)$ and $a \overset{k}{\cdot} d = a \overset{3}{\cdot} (a \diamondsuit_k d)$. Hence $a \overset{3}{\cdot} (a \diamondsuit_k b) = a \overset{3}{\cdot} (a \diamondsuit_k d)$. But then the prime decomposition theorem leads to $a \diamondsuit_k b = a \diamondsuit_k d$ as requested.
(Sufficiency) This part is trivial. If $a \diamondsuit_k b = a \diamondsuit_k d$, then $a \overset{k}{\cdot} b = a \overset{3}{\cdot} (a \diamondsuit_k b) = a \overset{3}{\cdot} (a \diamondsuit_k d) = a \overset{k}{\cdot} d$. □

Corollary 1. *Let a, b, d be binary trees different from $\bullet$. Then $a \overset{3}{\cdot} b = a \overset{3}{\cdot} d$ if and only if $weight(b) = weight(d)$.*

Some of the algebraic properties of the operations $\overset{k}{\cdot}$ are summarized in Table 2

Table 2. Algebraic properties of the operations $\overset{k}{\cdot}$

	Commutativity	Associativity	neutral	cancellation rules
$\overset{1}{\cdot}$	no	no	no	$a \overset{1}{\cdot} b = c \overset{1}{\cdot} d \Leftrightarrow a = c$ and $b = d$
$\overset{2}{\cdot}$	no	yes	$a \overset{2}{\cdot} \bullet = a$ $\bullet \overset{2}{\cdot} a = a$	$a \overset{2}{\cdot} b = c \overset{2}{\cdot} b \Leftrightarrow a = c$ $a \overset{2}{\cdot} b = a \overset{2}{\cdot} d \Leftrightarrow b = d$
$\overset{3}{\cdot}$	no	no	$a \overset{3}{\cdot} \bullet = a$ $\bullet \overset{3}{\cdot} a = \bullet$	$a \overset{3}{\cdot} b = c \overset{3}{\cdot} b \Leftrightarrow a = c$ $a \overset{3}{\cdot} b = a \overset{3}{\cdot} d \Leftrightarrow weight(b) = weight(d)$
$\overset{4}{\cdot}$	no	no	$a \overset{4}{\cdot} \bullet = a$ $\bullet \overset{4}{\cdot} a = \bullet$	$a \overset{4}{\cdot} b = c \overset{4}{\cdot} b \Leftrightarrow a = c$ $a \overset{4}{\cdot} b = a \overset{4}{\cdot} d \Leftrightarrow a \diamondsuit_4 b = a \diamondsuit_4 d$
$\overset{k}{\cdot}$ ($k \geq 5$)	no	no	$a \overset{k}{\cdot} \bullet = a$ $\bullet \overset{k}{\cdot} a = \bullet$	Conjecture: $a \overset{k}{\cdot} b = c \overset{k}{\cdot} b \Leftrightarrow a = c$ $a \overset{k}{\cdot} b = a \overset{k}{\cdot} d \Leftrightarrow a \diamondsuit_k b = a \diamondsuit_k d$

6 Valuations

A valuation μ is a function defined on binary trees and taking values in $\mathbf{Z}$. Operations on integers can be used in a natural way to define valuations.

Definition 5. *Associated to $\Delta : \mathbf{Z} \times \mathbf{Z} \to \mathbf{Z}$ and $e \in \mathbf{Z}$ is a valuation $\mu : BT \to \mathbf{Z}$ defined inductively by*

$$\mu(a) = \begin{cases} e & \text{if } a = \bullet \\ \mu(a_L) \Delta \mu(a_R) & \text{if } a = (a_L a_R) \end{cases}$$

Valuations that can be obtained in this way are called inductive.

We immediatly recognise that the weight function is an inductive valuation obtained by setting $a \Delta b = a + b$ and $e = 1$. Other inductive valuations are given next.

Maximal height. If we set $a\Delta b = 1 + \max(a, b)$ and $e = 0$ the valuation obtained gives the maximal height of all external nodes. This quantity is referred to as the height of the tree and the corresponding valuation is denoted by $height$.

Minimal height. The valuation obtained with $a\Delta b = 1 + \min(a, b)$ and $e = 0$ gives the minimal height of all external nodes and is denoted *minheight*.

Strahler number. The valuation obtained with $a\Delta b = [a = b] + \max(a, b)$ and $e = 0$ appear in various contexts (the expression $[a = b]$ outputs 1 when $a = b$ and outputs 0 otherwise). In [8] it is called the "register function" and is used to calculate the minimal number of registers needed to evaluate an arithmetic expression (see also [16]). The same function is known in hydrology as the Horton-Strahler function and is used to describe characteristics of river flows (see [23], [24] and references cited therein). The Strahler number of a tree is equal to the height of the maximal complete tree that can be embedded in the tree [8]. We denote this valuation by *Strahler*.

2-*bud.* The valuation obtained with $a\Delta b = [a = b] + \min(a, b)$ and $e = 0$ (note the similarity with the definition of the Strahler number) has, to our knowledge, never been analysed. We denote this function by $2 - bud$. The 2-bud of a binary tree a can be shown equal the largest $n \geq 0$ for which the nth first factors of a are equal to $(\bullet\bullet)$. The $2 - bud$ of a binary tree a is thus equal to the largest n for which $a = ((\bullet\bullet)^{3}\!\cdot n)^{2}\!\cdot b$ for some tree b. Because of the grafting interpretation of the operation $^{2}_{\cdot}$ this number corresponds also to the height n of the largest complete binary tree $(\bullet\bullet)^{3}\!\cdot n$ that appear everywhere on the boundary of a.

Boolean valuation. The valuation obtained with $a\Delta b = [a = b]$ and $e = 0$ outputs 1 if the weight of the tree is even and outputs 0 if it is odd.

In Table 3 we list some possible choices of operation Δ and their resulting valuations. Several of these inductive valuations have remarkable properties with respect to $^{k}_{\cdot}$.

Theorem 6. *Assume $\Delta : \mathbf{Z} \times \mathbf{Z} \to \mathbf{Z}$, $e = 0$, and let μ be the inductive valuation associated to Δ and e. If $a + (b\Delta c) = (a + b)\Delta(a + c)$ for all $a, b, c \in \mathbf{Z}$, then*

1. $\mu(a\,^{2}_{\cdot}\,b) = \mu(a) + \mu(b)$
2. $\mu(a\,^{3}_{\cdot}\,b) = \mu(a).\mu(b)$
3. $\mu(a\,^{4}_{\cdot}\,b) = \mu(a)^{\mu(b)}$

Proof. We prove the first identity by induction on b. For $b = \bullet$ we have $\mu(a\,^{2}_{\cdot}\,\bullet) = \mu(a) = \mu(a) + \mu(\bullet)$ so let $b = (b_L b_R)$ and assume that $\mu(a\,^{2}_{\cdot}\,b_L) = \mu(a) + \mu(b_L)$ and $\mu(a\,^{2}_{\cdot}\,b_R) = \mu(a) + \mu(b_R)$. We have then

$$\begin{aligned}
\mu(a\,^{2}_{\cdot}\,b) &= \mu(a\,^{2}_{\cdot}\,(b_L\,^{1}_{\cdot}\,b_R)) \\
&= \mu((a\,^{2}_{\cdot}\,b_L)\,^{1}_{\cdot}\,(a\,^{2}_{\cdot}\,b_R)) \\
&= \mu(a\,^{2}_{\cdot}\,b_L)\Delta\mu(a\,^{2}_{\cdot}\,b_R) \\
&= (\mu(a) + \mu(b_L))\Delta(\mu(a) + \mu(b_R)) \\
&= \mu(a) + (\mu(b_L)\Delta\mu(b_R)) \\
&= \mu(a) + \mu(b)
\end{aligned}$$

The other identities are similarly proved. □

Corollary 2. *Let μ be one of the valuations height, minheight, Strahler or $2-bud$. Then*

1. $\mu(a \overset{2}{\cdot} b) = \mu(a) + \mu(b)$
2. $\mu(a \overset{3}{\cdot} b) = \mu(a).\mu(b)$
3. $\mu(a \overset{4}{\cdot} b) = \mu(a)^{\mu(b)}$

Proof. The corresponding pairs (Δ, e) satisfy the conditions of Theorem 6. □

Table 3. Some inductive valuations

$a \Delta b$	e	resulting valuation
$a + b$	1	*weight*
$1 + \max(a, b)$	0	*height*
$1 + \min(a, b)$	0	*minheight*
$[a = b] + \max(a, b)$	0	*strahler*
$[a = b] + \min(a, b)$	0	$2 - bud$
$[a = b]$	0	1 if *weight* is even 0 if *weight* is odd

7 Infinite trees

The operations $\overset{k}{\cdot}$ introduced for finite binary trees can be extended to infinite binary trees. For convenience we shall look at infinite trees as languages over 2-letter alphabets.

Let Σ be a finite alphabet and $L_1, L_2 \subseteq \Sigma^*$ be two languages over Σ (for definitions see [19]). The product of L_1 and L_2 is the language $L_1 \cdot L_2 = \{x_1 \cdot x_2 : x_1 \in L_1, x_2 \in L_2\}$. Given $x \in \Sigma^*$, the language $x \cdot L$ and the residual $x^{-1} \cdot L$ of L by x are defined by $x \cdot L = \{x\} \cdot L$ and $x^{-1} \cdot L = \{y \in \Sigma^* : x \cdot y \in L\}$, respectively. If $n \geq 0$, the truncation of L at size n is the language $\lceil L \rceil_n = \{x \in L : |x| \leq n\}$ where $|x|$ is the length of x. For a language L and $n \geq 0$ we define $L^0 = \{\omega\}$ (ω denotes the empty word), $L^{n+1} = L^n \cdot L$ and $L^* = \bigcup_{i=0}^{\infty} L^i$. Finally, a language L over Σ is factorial if $x, v \in \Sigma^*$ and $x \cdot v \in L$ implies that $x \in L$. Factorial languages always contain ω unless they are empty.

Proposition 3. *Let $L, L_1, L_2, \ldots$ be factorial languages over Σ, $x \in \Sigma^*$ and $n \geq 0$. The languages $x^{-1} \cdot L, \lceil L \rceil_n, L = \bigcup_{i=0}^{\infty} L_i, L = \bigcap_{i=0}^{\infty} L_i, L_1 \cdot L_2$ and L^* are factorial.*

A binary tree is entirely specified by its set of internal nodes. Any internal node can be reached by starting from the root and specifying the finite sequence of left and right movements needed to reach it. Let us denote these movements by a and b respectively. A node can thus be seen as a word over the alphabet $\Sigma = \{a, b\}$. A finite (infinite) tree will therefore have a representation as a finite (infinite) language over Σ. To the one node binary tree $\bullet$ corresponds the empty language $L = \emptyset$, the tree $(\bullet\bullet)$ is represented by $L = \{\omega\}$ and the two binary trees

of weight 3 have $\{\omega, a\}$ and $\{\omega, b\}$ as corresponding languages. It is easy to see that languages generated by binary trees are factorial. The converse is also true: Any factorial language over a 2-letter alphabet can be seen as a representation of a particular binary tree, the corresponding binary tree is infinite when the language is. We denote by *FL* the set of factorial languages and by *FFL* the set of finite factorial languages over the two letter alphabet $\{a, b\}$. There is an obvious bijection between *FFL* and *BT*.

Definition 6. *The operation* $\overset{1}{\cdot}$: $FFL \times FFL \to FFL$ *is defined by* $L_1 \overset{1}{\cdot} L_2 = \{\omega\} \cup a \cdot L_1 \cup b \cdot L_2$. *For* $k \geq 2$, *the operations* $\overset{k}{\cdot}$: $FFL \times FFL \to FFL$ *are defined inductively by*

$$L_1 \overset{k}{\cdot} L_2 = \begin{cases} L_1 & \text{if } L_2 = \emptyset \\ (L_1 \overset{k}{\cdot} a^{-1}L_2)^{k-1}\overset{\cdot}{}(L_1 \overset{k}{\cdot} b^{-1}L_2) & \text{if } L_2 \neq \emptyset \end{cases}$$

We now remove the finiteness condition on the languages L_1 *and* L_2 *and define, for finite or infinite languages, the operations* $\overset{k}{\cdot}$ *(*$k \geq 0$*) by*

$$L_1 \overset{k}{\cdot} L_2 = \cup_{i=0}^{\infty}(\lceil L_1 \rceil_i \overset{k}{\cdot} \lceil L_2 \rceil_i)$$

Proposition 4. *The operations* $\overset{k}{\cdot}$ *are operations from* $FL \times FL$ *to FL.*

Proof. The statement is clearly true for finite languages because any $\overset{k}{\cdot}$ product of two finite languages can be expressed in terms of finitely many operations of the form given in Proposition 3. We complete the proof by observing that the result of a $\overset{k}{\cdot}$ product of infinite languages is defined by a countable union of finite factorial languages. □

Most properties of the operations $\overset{k}{\cdot}$ for finite binary trees were proved by induction. This principle does not anymore hold for infinite binary trees and many of the properties shown for finite binary trees do therefore not hold for infinite binary trees. It is nevertheless possible to show that the Properties 2.1 and 2.2 of Theorem 1 remain satisfied for infinite binary trees. On the other hand the Properties 3.1 and 3.2 in the same theorem may be violated by infinite binary trees. Assume for example that $L_1 = \Sigma^*$, $L_2 = \{\omega\}$ and $L_3 = \{\omega, a, b\}$. Then $L_1 \overset{2}{\cdot} L_2 = L_1 \overset{2}{\cdot} L_3$ but $L_2 \neq L_3$.

The result of operations of index greater or equal to 3 can be expressed as $\overset{2}{\cdot}$ products of identical factors. Infinitely many factors are multiplied when the second operand is infinite. The operation $\overset{2}{\cdot}$ correspond to the usual multiplication of languages of computer science and the operation $\overset{3}{\cdot}$ therefore degenerates into the Kleene star operation when the second operand is infinite.

Theorem 7. *Let* L_1, L_2 *be two factorial languages. Then*

1. $L_1 \overset{2}{\cdot} L_2 = L_2 \cdot L_1$
2. $$L_1 \overset{3}{\cdot} L_2 = \begin{cases} L_1^n & \text{some } n \geq 1 \text{ if } L_2 \text{ is finite} \\ L_1^* & \text{if } L_2 \text{ is infinite} \end{cases}$$

Proof. We prove the result for L_2 finite by induction on L_1. The result is clearly true for $L_1 = \emptyset$; so let $L_2 = L_2' \overset{1}{\cdot} L_2''$ and assume that $L_1 \overset{3}{\cdot} L_2' = L_1^{n'}$ and $L_1 \overset{3}{\cdot} L_2'' = L_1^{n''}$ for some $n', n'' \geq 0$. We have then

$$\begin{aligned} L_1 \overset{3}{\cdot} L_2 &= L_1 \overset{3}{\cdot} (L_2' \overset{1}{\cdot} L_2'') \\ &= (L_1 \overset{3}{\cdot} L_2') \overset{2}{\cdot} (L_1 \overset{3}{\cdot} L_2'') \\ &= L_1^{n'} \cdot L_1^{n''} \\ &= L_1^{n'+n''} \end{aligned}$$

as requested. Assume now that L_2 is infinite. We show that the languages L_1^* and $L_1 \overset{3}{\cdot} L_2$ coincide. Indeed, if $x \in \Sigma^*$ and $x \in L_1 \overset{3}{\cdot} L_2$, then $x \in (\lceil L_1 \rceil_i \overset{3}{\cdot} \lceil L_2 \rceil_i)$ for some i. But then by the finite case there exist some n for which $x \in (\lceil L_1 \rceil_i)^n \subseteq L_1^n \subseteq L_1^*$. Assume now that $x \in L_1^*$. Then $x \in L_1^n$ for some n. But then $x \in L_1 \overset{3}{\cdot} \lceil L_2 \rceil_i$ for some i and thus $x \in L_1 \overset{3}{\cdot} L_2$ as requested. □

Remark. The condition in Definition 6 that the languages be factorial is not essential. The operations $\overset{k}{\cdot}$ can equally be defined for arbitrary language defined over 2-letter alphabets.

Notes added in proof

1. The right cancellation rule conjectured at the end of Sect. 3 has recently been proved by Philippe Duchon ("Some new results on a family of operations for binary trees", submitted, 1997).
2. The results contained in this article have been presented at a seminar at INRIA-Paris in October 1995. An abstract of the seminar appears in "Algorithms Seminars 1994–1995", INRIA Technical Report 2669, Bruno Salvy (ed.), 1995.

Autor: Bode, Jens-Peter
Titel: Strategien für Aufbauspiele mit Mosaik-Polyominos

Deutsch:
Bei einem Aufbauspiel setzen zwei Spieler abwechselnd Spielsteine ihrer Farbe auf ein noch unbesetztes Feld eines Spielbrettes. Derjenige Spieler, der den ersten Zug macht, gewinnt das Spiel, falls er ein vorher ausgewähltes Polyomino mit seinen Steinen besetzt. Ein Polyomino ist dabei eine endliche nichtleere Teilmenge der Felder, wobei die Teilmenge selbst und ihr Komplement jeweils durch gemeinsame Kanten zusammenhängen. Ein Polyomino wird Gewinner genannt, falls der erste Spieler unabhängig von den Zügen des zweiten Spielers immer gewinnen kann. Andernfalls heißt es Verlierer. Als Spielbretter werden hier die planaren Darstellungen der Mosaik-Graphen betrachtet. Mosaik-Graphen sind diejenigen planaren Graphen, die die Eigenschaft besitzen, daß es für je zwei ihrer Knoten einen Automorphismus gibt, der den einen Knoten auf den anderen abbildet. Zu den Mosaik-Graphen gehören die platonischen und archimedischen Körper sowie die euklidischen und archimedischen Parkettierungen der Ebene. Die Polyominos der Mosaik-Graphen wurden so weit wie möglich gezählt und mit Hilfe von Aufbau- und Verhinderungsstrategien in Gewinner und Verlierer eingeteilt.

Englisch:
In an achievement game two players alternately mark the cells of a game board. The first player wins the game if he achieves a copy of a polyomino with his marks. A polyomino is a finite nonempty set of cells where the set and its complement both are connected by common edges. A polyomino is called a winner if the first player can win regardless of the moves made by the second player. Otherwise it is called a loser. Here, the planar drawings of mosaic graphs are considered as game boards. Mosaic graphs are planar graphs, having the property that for every two vertices there is an automorphism that maps one vertex onto the other. Platonic and archimedian solids and euclidean and archimedian tessellations of the plane are mosaik graphs. The polyominos of the mosaic graphs are counted as far as possible and are divided into winners and losers using achievement and defensive strategies.

Generating Labeled Planar Graphs Uniformly at Random

2003

Manuel Bodirsky, Clemens Gröpl and Mihyun Kang.

In Proceedings of the Thirtieth International Colloquium on Automata, Languages and Programming (ICALP 2003), LNCS 2719, 1095 - 1107.

Abstract

We present an expected polynomial time algorithm to generate a labeled
planar graph uniformly at random. To generate the planar graphs, we
derive recurrence formulas that count all such graphs with
n vertices and m edges, based on a decomposition into 1-, 2-, and
3-connected components. For 3-connected graphs we apply a recent
random generation algorithm by Schaeffer and a counting formula by
Mullin and Schellenberg.

BLAKE

- Songs of Innocence and Experience (1825)

ABSTRACT.

"If my teachers had begun by telling me that mathematics was pure play with presuppositions, and wholly in the air, I might have become a good mathematician. But they were overworked drudges, and I was largely inattentive, and inclined lazily to attribute to incapacity in myself or to a literary temperament that dullness which perhaps was due simply to lack of initiation."
(George Santayana)

"Persons and Places", 1945, pp. 238-9

• Most research mathematicians neither think deeply about nor are terribly concerned about either pedagogy or the philosophy of mathematics. Nonetheless, as I hope to indicate, aesthetic notions have always permeated (pure and applied) mathematics.

• I shall argue for aesthetics before utility.

• Through examples, I aim to illustrate how and what that means at the research mine face. I also will argue that the opportunities to tie research and teaching to aesthetics are almost boundless — at all levels of the curriculum. This is in part due to the increasing power and sophistication of visualization, geometry, algebra and other mathematical software.

"The mathematician does not study pure mathematics because it is useful; he studies it because he delights in it and he delights in it because it is beautiful." (Henri Poincaré)

GAUSS

Gauss once confessed,

> *"I have the result, but I do not yet know how to get it."*

("Asimov's Book of ... Quotations," p. 115)

• One of Gauss's greatest discoveries, in 1799, was the relationship between the lemniscate sine function and the arithmetic-geometric mean iteration. This was based on a purely computational observation. The young Gauss wrote in his diary that the result

> *"will surely open up a whole new field of analysis."*

◇ He was right, as it pried open the whole vista of nineteenth century elliptic and modular function theory.

• Gauss's specific discovery, based on tables of integrals provided by Stirling (1692-1770), was that the reciprocal of the integral

$$\frac{2}{\pi}\int_0^1 \frac{dt}{\sqrt{1-t^4}}$$

agreed numerically with the limit of the rapidly convergent iteration given by $a_0 := 1$, $b_0 := \sqrt{2}$ and computing

$$a_{n+1} := \frac{a_n + b_n}{2}, \qquad b_{n+1} := \sqrt{a_n b_n}$$

◇ The sequences a_n, b_n have a common limit
1.198140234735592207 4 . . . .

• Which is familiar, which is elegant — then and now?

◇ Aesthetic criteria change: 'closed forms' versus 'recursion'. 'Biology envy' replaces 'the blind watchmaker'.

GAUSS and HADAMARD

> *The object of mathematical rigor is to sanction and legitimize the conquests of intuition, and there was never any other object for it.* (J. Hadamard, 1865-1963)

In Borel, "Lecons sur la theorie des fonctions," 1928.

• Perhaps the greatest mathematician to think deeply and seriously about cognition in mathematics (*"... in arithmetic, until the seventh grade, I was last or nearly last."*).

◇ Author of "The psychology of invention in the mathematical field" (1945) and co-prover of the Prime Number Theorem (1896):

> *"The number of primes less than n tends to ∞ as does $\frac{n}{\log n}$."*

AESTHETIC(s) in WEBSTER

aesthetic, adj 1. pertaining to a sense of the beautiful or to the science of aesthetics.

2. having a sense of the beautiful; characterized by a love of beauty.

3. pertaining to, involving, or concerned with pure emotion and sensation as opposed to pure intellectuality.

4. a philosophical *theory or idea of what is aesthetically valid at a given time and place*: the clean lines, bare surfaces, and sense of space that bespeak the machine-age aesthetic.

5. aesthetics.

6. Archaic. the study of the nature of sensation.

Also, esthetic. Syn 2. discriminating, cultivated, refined.

aesthetics, noun 1. the branch of philosophy dealing with such notions as the beautiful, the ugly, the sublime, the comic, etc., as applicable to the fine arts, with a view to establishing the meaning and validity of critical judgments concerning works of art, and the principles underlying or justifying such judgments.

2. *the study of the mind and emotions in relation to the sense of beauty*.

• **JMB**: (unexpected) simplicity or organization in apparent complexity or chaos.

† We need to integrate this into mathematics education — to capture minds not only for utilitarian reasons. Detachment is important, — curtains, stages and picture frames.

RESEARCH MOTIVATIONS

INSIGHT – demands speed $\equiv$ parallelism

- For rapid verification.

- For validation; proofs *and* refutations. For 'monster barring'.

† What is 'easy' changes — merging disciplines, levels and collaborators.

- Marry theory & practice, history & philosophy, proofs & experiments.

- Match elegance and balance to utility and economy.

- In analysis, algebra, geometry & topology.

AND GOALS

- Towards an Experimental M*a*thodology — philosophy and practice.

- Intuition is acquired — mesh computation and mathematics.

- Visualization — three is a lot of dimensions (pictures and sounds).

- 'Caging' and 'Monster-barring' (Lakatos).

  - graphic checks: compare $2\sqrt{y} - y$ and $\sqrt{y}\ln(y)$, $0 < y < 1$

  - randomized checks: equations, linear algebra, primality

PART of OUR 'METHODOLOGY'

1. (*High Precision*) computation of object(s).

2. *Pattern Recognition* of *Real Numbers* (Inverse Calculator and 'RevEng')*, or *Sequences* (Salvy & Zimmermann's 'gfun', Sloane and Plouffe's Encyclopedia).

3. Extensive use of 'Integer Relation Methods': *PSLQ & LLL* and FFT.†

   - Exclusion bounds are especially useful.
   - Great test bed for "Experimental Math" .

4. Some automated theorem proving (Wilf-Zeilberger etc).

*ISC space limits: from 10Mb in 1985 to 10Gb today.

†Top Ten "Algorithm's for the Ages," Random Samples, Science, Feb. 4, 2000.

FOUR EXPERIMENTS

• 1. **Kantian** example: generating "the classical non-Euclidean geometries (hyperbolic, elliptic) by replacing Euclid's axiom of parallels (or something equivalent to it) with alternative forms."

• 2. The **Baconian** experiment is a contrived as opposed to a natural happening, it "is the consequence of 'trying things out' or even of merely messing about."

• 3. **Aristotelian** demonstrations: "apply electrodes to a frog's sciatic nerve, and lo, the leg kicks; always precede the presentation of the dog's dinner with the ringing of a bell, and lo, the bell alone will soon make the dog dribble."

• 4. The most important is **Galilean**: "a critical experiment – one that discriminates between possibilities and, in doing so, either gives us confidence in the view we are taking or makes us think it in need of correction."

◇ It is also the only one of the four forms which will make Experimental Mathematics a serious enterprise.

• From Peter Medawar's *Advice to a Young Scientist*, Harper (1979).

MILNOR

"If I can give an abstract proof of something, I'm reasonably happy. But if I can get a concrete, computational proof and actually produce numbers I'm much happier. I'm rather an addict of doing things on the computer, because that gives you an explicit criterion of what's going on. I have a visual way of thinking, and I'm happy if I can see a picture of what I'm working with."

...

• Consider the following images of zeroes of 0/1 polynomials: `www.cecm.sfu.ca/interfaces/`

◇ But symbols are often more reliable than pictures.

A MISLEADING PICTURE

◇ Challenging students honestly? (Life)
◇ Making things tangible (Platonic solids)

De MORGAN & SYLVESTER

"Considerable obstacles generally present themselves to the beginner, in studying the elements of Solid Geometry, from the practice which has hitherto uniformly prevailed in this country, of never submitting to the eye of the student, the figures on whose properties he is reasoning, but of drawing perspective representations of them upon a plane. ... I hope that I shall never be obliged to have recourse to a perspective drawing of any figure whose parts are not in the same plane."

(Augustus De Morgan, 1806-71, First LMS President.)

• Adrian Rice, "What Makes a Great Mathematics Teacher?" MAA Monthly, June 1999, p. 540.

SYLVESTER'S THEOREM

† JavaViewLib : `www.cecm.sfu.ca/interfaces/` is Polthier's modern version of Felix Klein's (1840-1928) models.
† A modern version of Euclid: Cinderella.de : `personal/jborwein/circle.html` & Sketchpad.

> *"The early study of Euclid made me a hater of geometry."*
>
> (James Joseph Sylvester, 1814-97, Second LMS President)

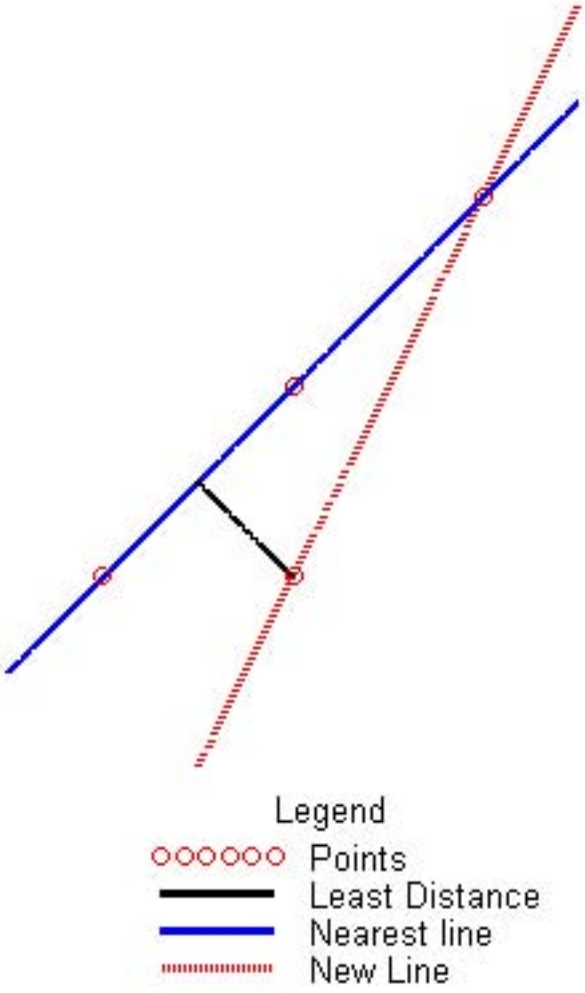
• In D. MacHale, "Comic Sections" (1993)

But discrete (now 'computational') geometry was different:

THEOREM. Given N non-collinear points in the plane there is a *proper* line through only two points.*

*Posed in *The Educational Times* **59** (1893).

KELLY'S "PROOF FROM 'THE BOOK' "



◇ It was forgotten for 50 years?

• First solved ("badly") by Gallai (1943). Also by Erdos who named 'the book'.

◇ Kelly's proof was published by Coxeter (1948)!

- Two more examples from the book:
  - Niven's 1947 proof that π is irrational (`personal/jborwein/pi.pdf`); and
  - Snell's law — travelling between Physics and the Calculus. (To or from?)

GEORGE LAKOFF & RAFAEL E. NUNEZ

"Recent Discoveries about the Nature of Mind.

In recent years, there have been revolutionary advances in cognitive science — advances that have a profound bearing on our understanding of mathematics.* Perhaps the most profound of these new insights are the following:

1. The embodiment of mind. The detailed nature of our bodies, our brains and our everyday functioning in the world structures human concepts and human reason. This includes mathematical concepts and mathematical reason.

*More serious curricular insights should come from neuro-biology (Dehaene et al., "Sources of Mathematical Thinking: Behavioral and Brain-Imaging Evidence," *Science*, May 7, 1999).

2. The cognitive unconscious. Most thought is unconscious — not repressed in the Freudian sense but simply inaccessible to direct conscious introspection. We cannot look directly at our conceptual systems and at our low-level thought processes. This includes most mathematical thought.

3. Metaphorical thought. For the most part, human beings conceptualize abstract concepts in concrete terms, using ideas and modes of reasoning grounded in sensory-motor systems. The mechanism by which the abstract is comprehended in terms of the concept is called *conceptual metaphor*. Mathematical thought also makes use of conceptual metaphor, as when we conceptualize numbers as points on a line."

- "Where Mathematics Comes From," Basic Books, 2000. (p. 5)

- They later observe:

> *"What is particularly ironic about this is that it follows from the empirical study of numbers as a product of mind that it is natural for people to believe that numbers are not a product of mind!"* (Lakoff and Nunez, p. 81)

...

- Compare a more traditional view:

> *"The price of metaphor is eternal vigalence."* (Arturo Rosenblueth and Norbert Wiener)

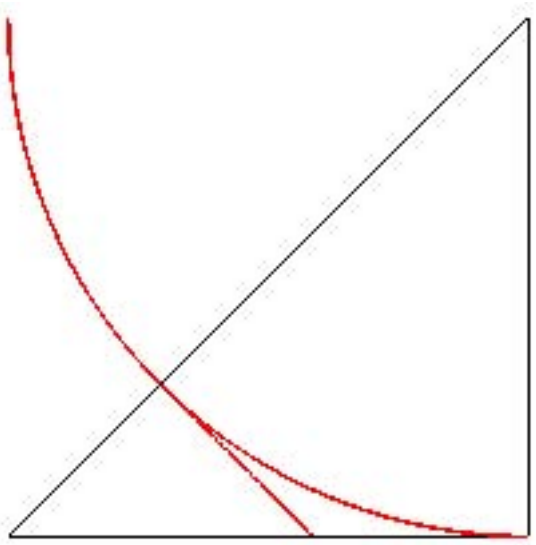
Quoted by R. C. Leowontin
in *Science* p. 1264, Feb 16, 2001
(The *Human Genome* Issue)

TWO THINGS ABOUT $\sqrt{2}$

• *A. Irrationality*.

• Tom Apostol's new geometric proof* of the irrationality of $\sqrt{2}$.

PROOF. Consider the *smallest* right-angled isoceles integral with integer sides:



◇ the smaller triangle is integral ···

*MAA, November 2000, pp. 241-242

• *B. Rationality.*

◇ $\sqrt{2}$ also makes things rational:

$$\left(\sqrt{2}^{\sqrt{2}}\right)^{\sqrt{2}} =$$
$$\sqrt{2}^{(\sqrt{2}\cdot\sqrt{2})} = \sqrt{2}^{2} = 2.$$

• Hence there are irrational numbers α and β with α^{β} rational. But which ones?

† Compare: $\alpha := \sqrt{2}$, $\beta := 2\ln_2(3)$, which Maples says yields $\alpha^{\beta} = 3$.

† There are eight possible (ir)rational triples:

$$\alpha^{\beta} = \gamma.$$

TWO INTEGRALS

Even Maple knows

- A. $\pi \neq \frac{22}{7}$.

$$\int_0^1 \frac{(1-x)^4 x^4}{1+x^2}\,dx = \frac{22}{7} - \pi,$$

...

but struggles with

- *B. The sophomore's dream.*

$$\int_0^1 \frac{1}{x^x}\,dx = \sum_{n=1}^{\infty} \frac{1}{n^n}.$$

PARTIAL FRACTIONS & CONVEXITY

• We consider a network *objective function* p_N given by

$$p_N(\vec{q}) = \sum_{\sigma \in S_N} \left(\prod_{i=1}^{N} \frac{q_{\sigma(i)}}{\sum_{j=i}^{N} q_{\sigma(j)}}\right)\left(\sum_{i=1}^{N} \frac{1}{\sum_{j=i}^{N} q_{\sigma(j)}}\right)$$

summed over *all* $N!$ permutations; so a typical term is

$$\left(\prod_{i=1}^{N} \frac{q_i}{\sum_{j=i}^{N} q_j}\right)\left(\sum_{i=1}^{N} \frac{1}{\sum_{j=i}^{n} q_j}\right) \ .$$

◇ For $N = 3$ this is

$$q_1 q_2 q_3 \left(\frac{1}{q_1+q_2+q_3}\right)\left(\frac{1}{q_2+q_3}\right)\left(\frac{1}{q_3}\right)$$

$$\times \left(\frac{1}{q_1+q_2+q_3} + \frac{1}{q_2+q_3} + \frac{1}{q_3}\right) \ .$$

• We wish to show p_N is *convex* on the positive orthant. First we try to simplify the expression for p_N.

- The *partial fraction decomposition* gives:

$$\begin{aligned} p_1(x_1) &= \frac{1}{x_1}, \\ p_2(x_1,x_2) &= \frac{1}{x_1}+\frac{1}{x_2}-\frac{1}{x_1+x_2}, \\ p_3(x_1,x_2,x_3) &= \frac{1}{x_1}+\frac{1}{x_2}+\frac{1}{x_3} \\ &- \frac{1}{x_1+x_2}-\frac{1}{x_2+x_3}-\frac{1}{x_1+x_3} \\ &+ \frac{1}{x_1+x_2+x_3}. \end{aligned}$$

So we predict the 'same' for $N = 4$ and are rewarded with:

CONJECTURE. For each $N \in \mathbb{N}$

$$p_N(x_1,\ldots,x_N) := \int_0^1 \left(1-\prod_{i=1}^{N}(1-t^{x_i})\right)\frac{dt}{t}$$

is convex, indeed 1/concave.

• One can check $N < 5$ via a large symbolic Hessian computation. But not $N = 5$!

PROOF. A year later, analysis of *joint expectations* gave a convex integrand:

$$p_N(\vec{x}) = \int_{\mathbb{R}^n_+} e^{-(y_1+\cdots+y_n)} \max\left(\frac{y_1}{x_1}, \ldots, \frac{y_n}{x_n}\right) dy$$

◇ See *SIAM Electronic Problems and Solutions.*

• Computing adds reality, making concrete the abstract, and some hard things simple.

† Pascal's Triangle : `www.cecm.sfu.ca/interfaces/`

BERLINSKI

"The computer has in turn changed the very nature of mathematical experience, suggesting for the first time that mathematics, like physics, may yet become an empirical discipline, a place where things are discovered because they are seen."

. . .

"The body of mathematics to which the calculus gives rise embodies a certain swashbuckling style of thinking, at once bold and dramatic, given over to large intellectual gestures and indifferent, in large measure, to any very detailed description. But the era in thought that the calculus made possible is coming to an end. *Everyone feels this is so and everyone is right."*

π and FRIENDS

A: (*A quartic algorithm* (1984).) Set $a_0 = 6 - 4\sqrt{2}$ and $y_0 = \sqrt{2} - 1$. Iterate

$$(1) \qquad y_{k+1} = \frac{1 - (1 - y_k^4)^{1/4}}{1 + (1 - y_k^4)^{1/4}}$$

$$\begin{aligned} a_{k+1} &= a_k(1 + y_{k+1})^4 \\ (2) \qquad &- 2^{2k+3} y_{k+1}(1 + y_{k+1} + y_{k+1}^2) \end{aligned}$$

Then a_k converges *quartically* to $1/\pi$.

$\diamond$ 19 pairs of simple algebraic equations (1, 2) that *fit on one page* differ from π only after 700 billion digits. After 17 years, this still gives me an aesthetic buzz!

• Used since 1986, with Salamin-Brent scheme, by Bailey (LBL) and Kanada (Tokyo).

• In 1997, Kanada computed over 51 billion digits on a Hitachi supercomputer (18 iterations, 25 hrs on 2^{10} cpu's). His present world record is 2^{36} digits in April 1999.

◇ A billion (2^{30}) digit computation has been performed on a single Pentium II PC in under 9 days.

◇ The 50 billionth decimal digit of π *or* of $\frac{1}{\pi}$ is 04$\underline{2}$!

• And after 18 billion digits, 0123456789 has finally appeared (Brouwer's famous intuitionist example *now* converges!).

Details at: www.cecm.sfu.ca/personal/jborwein/pi_cover.html.

B: (*'Pentium farming' for binary digits.*) Bailey, P. Borwein and Plouffe (1996) discovered a series for π (and some other *polylogarithmic constants*) which a startlingly allows one to compute hex–digits of π *without* computing prior digits.

• The algorithm needs very little memory and no multiple precision. The running time grows only slightly faster than linearly in the order of the digit being computed.

• The key, found by 'PSLQ' (below) is:

$$\pi = \sum_{k=0}^{\infty} \left(\frac{1}{16}\right)^k \left(\frac{4}{8k+1} - \frac{2}{8k+4} - \frac{1}{8k+5} - \frac{1}{8k+6}\right)$$

• Knowing an algorithm would follow they spent several months hunting for such a formula (PSLQ).

⋄ Once found, easy to prove in Mathematica, Maple or by hand.

◇ A most successful case of

REVERSE MATHEMATICAL ENGINEERING

...

This is entirely practicable, God reaches her hand deep into π:

...

• (Sept 97) Fabrice Bellard (INRIA) used a variant of this formula to compute 152 binary digits of π, starting at the *trillionth position* (10^{12}). This took 12 days on 20 work-stations working in parallel over the Internet.

PERCIVAL ON THE WEB

• (August 98) Colin Percival (SFU, age 17) finished a similar "embarrassingly parallel" computation of *five trillionth bit* (using 25 machines at about 10 times the speed). In *Hex*:

$$\underline{0}7E45733CC790B5B5979$$

The binary digits of π starting at the 40 trillionth place are

$$\underline{0}000011111100111111.$$

• (September 00) The quadrillionth bit is '0' (using 250 cpu years on 1734 machines from 56 countries).

Starting at the $999,999,999,999,997$th bit of π one has:

$$1110001100010000101101011000001 10$$

FORM FOLLOWS FUNCTION

• A century after biology started to think physically:

> *"The waves of the sea, the little ripples on the shore, the sweeping curve of the sandy bay between the headlands, the outline of the hills, the shape of the clouds, all these are so many riddles of form, so many problems of morphology, and all of them the physicist can more or less easily read and adequately solve."*
>
> (D'Arcy Thompson, "On Growth and Form" 1917)

• In Philip Ball's "The Self-Made Tapestry: Pattern Formation in Nature,"

`http://scoop.crosswinds.net/books/tapestry.html`

- How will mathematics follow?

  "The idea that we could make biology mathematical, I think, perhaps is not working, but what is happening, strangely enough, is that maybe mathematics will become biological!"

  (Greg Chaitin, Interview, 2000)

  - Consider
    - simulated annealing ('folding')
    - genetic algorithms ('scheduling')
    - neural networks ('training')
    - DNA computation ('traveling')
    - quantum computing ('sorting').

PARTITIONS and PATTERNS

• The number of *additive partitions* of n, $p(n)$, is generated by

$$P(q) := \prod_{n \geq 1} (1 - q^n)^{-1}.$$

◇ Thus $p(5) = 7$ since

$$5 = 4 + 1 = 3 + 2 = 3 + 1 + 1 = 2 + 2 + 1$$

$$= 2 + 1 + 1 + 1 = 1 + 1 + 1 + 1 + 1.$$

QUESTION. How hard is $p(n)$ to compute — in 1900 (for MacMahon) and in 2000 (for Maple)?

...

• Algorithmic analysis uncovers *Euler's pentagonal number theorem*:

$$\boxed{\prod_{n \geq 1} (1 - q^n) = \sum_{n=-\infty}^{\infty} (-1)^n q^{(3n+1)n/2}.}$$

◇ Ramanujan used MacMahon's table to find remarkable and deep congruences such as

$$p(5n+4) \equiv 0 \mod 5, \quad p(7n+5) \equiv 0 \mod 7$$

and

$$p(11n+6) \equiv 0 \mod 11,$$

from data like

$$\begin{aligned} P(q) \quad &= 1 + q + 2\,q^2 + 3\,q^3 + 5\,q^4 + 7\,q^5 + 11\,q^6 \\ &+15\,q^7 + 22\,q^8 + 30\,q^9 + 42\,q^{10} + 56\,q^{11} \\ &+77\,q^{12} + 101\,q^{13} + 135\,q^{14} + 176\,q^{15} \\ &+231\,q^{16} + 297\,q^{17} + 385\,q^{18} + 490\,q^{19} \\ &+627\,q^{20} + 792\,q^{21} + 1002\,q^{22} + 1255\,q^{23} \\ &+ \cdots \end{aligned}$$

◇ We can recognize the *pentagonal numbers* in *Sloane's* on-line 'Encyclopedia of Integer Sequences'. And much more: `www.research.att.com/personal/njas/sequences/eisonline.html`.

• Keith Devlin: *Mathematics: he Science of Patterns* (1997).

A TASTE of RAMANUJAN

• G. N. Watson, discussing his response to such formulae of the wonderful Indian mathematical genius Ramanujan (1887-1920), describes:

> *"a thrill which is indistinguishable from the thrill I feel when I enter the Sagrestia Nuovo of the Capella Medici and see before me the austere beauty of the four statues representing 'Day,' 'Night,' 'Evening,' and 'Dawn' which Michelangelo has set over the tomb of Guiliano de'Medici and Lorenzo de'Medici."*
>
> (G. N. Watson, 1886-1965)

One of these is his remarkable formula

$$\frac{1}{\pi} = \frac{2\sqrt{2}}{9801} \sum_{k=0}^{\infty} \frac{(4k)!(1103 + 26390k)}{(k!)^4 396^{4k}}$$

Each term of this series produces an additional *eight* correct digits in the result. Gosper used this formula to compute 17 million terms of the continued fraction for π in 1985.

• That said, Ramanujan prefers explicit forms such as

$$\frac{\log(640320^3)}{\sqrt{163}} = 3.14159265358979\underline{30164} \approx \pi.$$

◇ The number e^{π} is the easiest transcendental to fast compute (by elliptic methods). One 'differentiates' $e^{-t\pi}$ to obtain π (the AGM).

HARDY'S APOLOGY

"All physicists and a good many quite respectable mathematicians are contemptuous about proof." (G.H. Hardy, 1877-1947)

◇ Hardy's "A Mathematician's Apology" is a spirited defense of beauty over utility: *"Beauty is the first test. There is no permanent place in the world for ugly mathematics."*
His *"Real mathematics ... is almost wholly 'useless'"* has been overplayed and is dated: *"If the theory of numbers could be employed for any practical and obviously honourable purpose ..."*

◇ The Apology is one of Amazon's best sellers.

• "Hardy asked *'What's your father doing these days. How about that esthetic measure of his?'* I replied that my father's book was out. He said, *'Good, now he can get back to real mathematics'*." (Garret Birkhoff).

• Hardy, in "Ramanujan, Twelve Lectures . . . ," page 15, gives 'Skewes number' as a *"striking example of a false conjecture"*. The integral

$$\operatorname{li} x = \int_0^x \frac{dt}{\log t}$$

is a very good approximation to $\pi(x)$, the number of primes not exceeding x. Thus,
$\operatorname{li} 10^8 = 5,761,455$ while $\pi(10^8) = 5,762,209$.

• It was conjectured that

$$\operatorname{li} x > \pi(x)$$

and indeed it so for many x. Skewes (1933) showed the first explicit crossing $10^{10^{10^{34}}}$ — now reduced merely to 10^{1167}.

INTEGER RELATION DETECTION

The USES of LLL and PSLQ

• A vector $(x_1, x_2, \cdots, x_n)$ of reals *possesses an integer relation* if there are integers a_i not all zero with

$$0 = a_1 x_1 + a_2 x_2 + \cdots + a_n x_n.$$

PROBLEM: Find a_i if such exist. If not, obtain lower bounds on the size of possible a_i.

- ($n = 2$) *Euclid's algorithm* gives solution.

- ($n \geq 3$) Euler, Jacobi, Poincaré, Minkowski, Perron, others sought method.

- *First general algorithm* in 1977 by Ferguson & Forcade. Since '77: **LLL** (in Maple), HJLS, PSOS, **PSLQ** ('91, *parallel* '99).

• Integer Relation Detection was recently ranked among "the 10 algorithms with the greatest influence on the development and practice of science and engineering in the 20th century." J. Dongarra, F. Sullivan, *Computing in Science & Engineering* **2** (2000), 22–23.

Also: Monte Carlo, Simplex, Krylov Subspace, QR Decomposition, Quicksort, ..., FFT, Fast Multipole Method.

ALGEBRAIC NUMBERS

Compute α to sufficiently high precision ($O(n^2)$) and apply LLL to the vector

$$(1, \alpha, \alpha^2, \cdots, \alpha^{n-1}).$$

- Solution integers a_i are coefficients of a polynomial likely satisfied by α.

- If no relation is found, exclusion bounds are obtained.

FINALIZING FORMULAE

◇ If we know or suspect an identity exists integer relations are very powerful.

- (*Machin's Formula*) We try `lin_dep` on

  $$[\arctan(1), \arctan(1/5), \arctan(1/239)]$$

  and recover `[1, -4, 1]`. That is,

  $$\frac{\pi}{4} = 4\arctan(\frac{1}{5}) - \arctan(\frac{1}{239}).$$

  (Used on all serious computations of π from 1706 (100 digits) to 1973 (1 million).)

- (*Dase's Formula*). We try `lin_dep` on

  $$[\pi/4, \arctan(1/2), \arctan(1/5), \arctan(1/8)]$$

  and recover `[-1, 1, 1, 1]`. That is,

  $$\frac{\pi}{4} = \arctan(\frac{1}{2}) + \arctan(\frac{1}{5}) + \arctan(\frac{1}{8}).$$

  (Used by Dase to compute 200 digits of π in his head.$\cdots$)

JOHANN MARTIN ZACHARIAS DASE

• History at: www-history.mcs.st-andrews.ac.uk

"Zacharias Dase (1824-1861) had incredible calculating skills but little mathematical ability. He gave exhibitions of his calculating powers in Germany, Austria and England. While in Vienna in 1840 he was urged to use his powers for scientific purposes and he discussed projects with Gauss and others.

Dase used his calculating ability to calculate to 200 places in 1844. This was published in Crelle's Journal for 1844. Dase also constructed 7 figure log tables and produced a table of factors of all numbers between 7 000 000 and 10 000 000.

Gauss requested that the Hamburg Academy of Sciences allow Dase to devote himself full-time to his mathematical work but, although they agreed to this, Dase died before he was able to do much more work."

KUHN

"The issue of paradigm choice can never be unequivocally settled by logic and experiment alone.

...

in these matters neither proof nor error is at issue. The transfer of allegiance from paradigm to paradigm is a conversion experience that cannot be forced."

(Thomas Kuhn)

• In *Who got Einstein's Office?* by Ed Regis. A 1986 history of the Institute for Advanced Study.

And PLANCK

"... a new scientific truth does not triumph by convincing its opponents and making them see the light, but rather because its opponents die and a new generation grows up that's familiar with it."

(Albert Einstein quoting Max Planck)

• From "The Quantum Beat," by F.G. Major, Springer (1998)

HERSH

• Whatever the outcome of these discourses, mathematics is and will remain a uniquely human undertaking. Indeed Reuben Hersh's arguments for a humanist philosophy of mathematics, as paraphrased below, become more convincing in our setting:

> *1. Mathematics is human*. It is part of and fits into human culture. It does not match Frege's concept of an abstract, timeless, tenseless, objective reality.
>
> *2. Mathematical knowledge is fallible*. As in science, mathematics can advance by making mistakes and then correcting or even re-correcting them. The "fallibilism" of mathematics is brilliantly argued in Lakatos' *Proofs and Refutations*.

3. There are different versions of proof or rigor. Standards of rigor can vary depending on time, place, and other things. The use of computers in formal proofs, exemplified by the computer-assisted proof of the four color theorem in 1977, is just one example of an emerging nontraditional standard of rigor.

4. Empirical evidence, numerical experimentation and probabilistic proof all can help us decide what to believe in mathematics. Aristotelian logic isn't necessarily always the best way of deciding.

5. Mathematical objects are a special variety of a social-cultural-historical object. Contrary to the assertions of certain post-modern detractors, mathematics cannot be dismissed as merely a new form of literature or religion. Nevertheless, many mathematical objects can be seen as shared ideas, like Moby Dick in literature, or the Immaculate Conception in religion.

◇ From "Fresh Breezes in the Philosophy of Mathematics", *American Mathematical Monthly*, August-Sept 1995, 589–594.

• The recognition that "quasi-intuitive" analogies may be used to gain insight in mathematics can assist in the learning of mathematics. And honest mathematicians will acknowledge their role in discovery as well.

We should look forward to what the future will bring.

SANTAYANA

"When we have before us a fine map, in which the line of the coast, now rocky, now sandy, is clearly indicated, together with the winding of the rivers, the elevations of the land, and the distribution of the population, we have the simultaneous suggestion of so many facts, the sense of mastery over so much reality, that we gaze at it with delight, and need no practical motive to keep us studying it, perhaps for hours altogether. A map is not naturally thought of as an aesthetic object...

† My earliest, and still favourite, encounter with aesthetics.*

*Jerry Fodor: "... it is no doubt important to attend to the eternally beautiful and true. But it is more important not to be eaten." In Kieran Egan's, *Getting it Wrong from the Beginning*).

And yet, let the tints of it be a little subtle, let the lines be a little delicate, and the masses of the land and sea somewhat balanced, and we really have a beautiful thing; a thing the charm of which consists almost entirely in its meaning, but which nevertheless pleases us in the same way as a picture or a graphic symbol might please. Give the symbol a little intrinsic worth of form, line and color, and it attracts like a magnet all the values of things it is known to symbolize. It becomes beautiful in its expressiveness." (George Santayana)

- From "The Sense of Beauty," 1896.

A FEW CONCLUSIONS

- Draw your own! – perhaps ···
- Proofs are often out of reach – understanding, even certainty, is not.
- Packages can make concepts accessible (Maple, Cinderella).
- Progress is made 'one funeral at a time' (Niels Bohr (?)).
- 'We are Pleistocene People' (Kieran Egan).
- 'You can't go home again' (Thomas Wolfe).

MY INTENTIONS

- Part I: TALK a bit
- Part II: SHOW some things
- Part III: and TELL some more

ABSTRACT

Technology has repeatedly promised to transform mathematics pedagogically. More recently it has made similar promises to the research community. That said, mathematics in 1999 looked a lot more like mathematics in 1939 than was the case with any of its sister sciences.

That this is changing is inarguable. The confluence of ubiquitous compute power with new networking and collaborative environments will push the teaching and discovering of mathematics in conflicting directions often beyond our control. The burgeoning role of corporate edu-packages is hardly likely to diminish. Nor are battles over curriculum and its delivery about to stop.

PART I:

I intend to survey and illustrate some of the ways in which twenty-first century mathematics will be changed by these new technologies. I will try to distinguish issues of ownership of technology from those of control over content. I also intend to discuss how as mathematical educators we might best prepare for the coming storms. Finally, as a partner in a small educational technology firm, I will offer some modest prescriptions for living on both sides of the fence.

- Intellectual issues
- Technological issues
- Commercial issues

all bang up against each other.

A CHANGING WORLD

"The world will change. It will probably change for the better. It won't seem better to me."

• J.B. Priestley

.....

"It's generally the way with progress that it looks much greater than it really is."

• From *The Wittgenstein Controversy*, by Evelyn Toynton in the *Atlantic Monthly*, June 1997, pp. 28-41.

◇ The epigraph that Ludwig Wittgenstein (1889-1951) ("whereof one cannot speak, thereof one must be silent") had wished for a never realized joint publication of *Tractatus Logico-Philosophicus* (1922) and *Philosophical Investigations* (1953): suggesting the two volumes are not irreconcilable.

INNOVATION

• Academics mean *new ideas*. Decision makers usually don't:

"Innovation. The process of bringing new goods and services to market. or the result of that process." ('Hard Economic Definition')

PI

• Modern Computer Algebra Systems *know*

$$\boxed{\pi \neq \frac{22}{7}}$$

...

Indeed

$$\int_0^1 \frac{(1-x)^4 x^4}{1+x^2}\, dx = \frac{22}{7} - \pi.$$

and the integrand is positive on $(0, 1)$.

◇ Who knows why Maple (open) or Mathematica (closed) knows what they know?

• Is symbolic computation a sustaining or disruptive technology in the classroom?

THE KEPT UNIVERSITY

"Thorstein Veblen [...] comment[ed] acerbically in 1908 that "business principles" were transforming higher education into "a merchantable commodity, to be produced on a piece-rate plan, rated, bought, and sold by standard units, measured, counted and reduced to staple equivalence by impersonal, mechanical tests."

.....

"New products and new processes do not appear full-grown," Vannevar Bush, President Franklin Roosevelt's chief science adviser, declared in 1944. "They are founded on new principles and new conceptions, which in turn are painstakingly developed by research in the purest realms of science."

• Eyal Press and Jennifer Washburn in *The Kept University*, Atlantic Monthly, March 2000
`www.theatlantic.com/issues/2000/03/press.htm`

◇ Which quote more accurately reflects 2001?

INTELLECTUAL PROMISES ···

- Lively and realistic examples: learning by doing (Papert)
  - 'we are all constructivists now'
- Math goes into colour: sliding down surfaces/virtual reality
- Background pattern-checkers and *inverse calculation*
- Speed & space $\equiv$ insight (demands rapid reinforcement via *micro-parallelism*)
- Individually tailored learning: varied pathways for quick/slow and for distinct modes of thinking
  - *algebraic, analytic, topological*

··· INTELLECTUAL PROMISES

- Promises students richer means to represent and present the fruits of their mathematical imagination

- Increased need to teach how to judge the results of computation (visual candy everywhere)

- Unifying research and teaching, theory and practice (jobs)

- Serious curricular insights from neurobiology ("Sources of Mathematical Thinking: Behavioral and Brain Imaging Evidence," S. Dehaene et al, in *Science*, May 7, **284** (1999)).

INTELLECTUAL PITFALLS

- Wasted or wonderful add-ons ("Newton & Euclid meet Java". The "Idiot pivoter")
- Loss of focus
- Loss of control: student centred learning of hierarchical subjects
- Degradation of long-lived robust mathematical knowledge (unique to our discipline)
- Growing reliance on effectively closed architecture software ('total solutions')
- 'Haves and havenots': class, race, gender
- Degeneration to machine-based rote learning ('buzzword compliant shovelware')

IN THE LONG TERM ···

"Keynes distrusted intellectual rigour of the Ricardian type as likely to get in the way of original thinking and saw that it was not uncommon to hit on a valid conclusion before finding a logical path to it.

.....

'I don't really start', he said, 'until I get my proofs back from the printer. Then I can begin serious writing.' "

• From *Keynes the man* written on the 50th Anniversary of Keynes' death. (Sir Alec Cairncross, in the *Economist*, April 20, 1996)

TECHNICAL PROMISES

- Teachers abilities vs students demands
- Access to global data bases (*free access to information* not *access to free information*)
- Doing what is easy: machines don't think like us.
  - cognitive vs descriptive models
- What we learned earlier is not always easier
- Expert systems & belief revision
- Seamless work-spaces: marriage of text and computation

TECHNICAL PITFALLS

- Legacy software
- Legacy hardware
- The weakest link determines the value
- Over promising payoffs and underestimating effort (reform calculus)
- Infinite time-sinks – especially in higher level courses
- Growing (unavoidable) reliance on commercial software

PART II: SOME DEMONSTRATIONS

- MathSciNet: `e-math.ams.org/mathscinet/`
- Sloane's Encyclopedia of Integer Sequences: `www.research.att.com/~njas/sequences/`
- Let's Do Math (Math Resources): `www.mathresources.ca`
- Math On the Web (Tele-Learning): `www.cecm.sfu.ca/TLRN/`
- Cinderella (Geometry): `www.cinderella.de` (not 'net' (music) or 'com' (porn))
- JavaView: `www-sfb288.math.tu-berlin.de/vgp/javaview/demo/PaPlatonic.html`

PART III: INFORMATION RULES

- Economic laws have not been suspended

◇ Carl Shapiro & Hal Varian, *Information Rules*, 1999.

- Some of the topics they discuss and terms worth reflecting on:
  - branding
  - value networks
  - switching costs
  - lock in
  - vicious and virtuous cycles
  - tipping

THE INFORMATION REVOLUTION

"What the new industries and institutions will be, no one can say yet. No one in the 1520s anticipated secular literature, let alone the secular theater. No one in the 1820s anticipated the electric telegraph, or public health, or photography.

"The one thing (to say it again) that is highly probable, if not nearly certain, is that the next twenty years will see the emergence of a number of new industries. At the same time, it is nearly certain that few of them will come out of information technology, the computer, data processing, or the Internet."

• Peter Drucker, *Beyond the Information Revolution*, Atlantic Monthly, Oct 1999.
`www.theatlantic.com/issues/99oct/9910drucker.htm`

INTELLECTUAL PROPERTY ISSUES

- Different stake-holders often have wildly different views
  - Supervisors and teachers
  - Students (and parents)
  - Professional societies (big and small)
  - Publishing houses (big and small)
  - Software companies (big and small)
- As job security disappears more students see *IP* as their future: (Ma vs Phong &Stein, non-disclosure, insider-trading, interleukin).
- The researcher as CEO: conflicts of interest are inevitable. They must be declared. They are rarely resolved.

OPEN PUBLISHING

- So many issues: access, cost, reliability, inter-operability, charging mechanisms, etc.

- Every day another initiative:
  - Los Alamos server and ArXiv (Math) `http://xxx.lanl.gov/archive/math`
  - Santa Fe Initiative (metadata, MathML)
  - International Math Union's *Math-Net* `www.ceic.math.ca`
  - National Institutes of Health (grey literature)
  - DOE, AAAS and Fathom Web Sites (validation?)

COMMERCIAL ISSUES

- Can't make what you can't sell
- Can't sell what you can't make (market discipline?)
- Conservatism in the edu-software business: no R&D model
- Commoditization (*macro-media everywhere*)
- Machine closets versus kitchen cabinets
- Weaning from software: overloading the senses (HCI issues)
- Corporate asset stripping: 'dot-com fever'

RIGO(U)R

"I have no satisfaction in formulas unless I feel their numerical magnitude."

• The scientist and entrepreneur, Lord Kelvin (William Thomson, 1824-1907)

.....

"The object of mathematical rigor is to sanction and legitimize the conquests of intuition, and there was never any other object for it."

• J. Hadamard, in E. Borel, Lecons sur la theorie des fonctions, 3rd ed. 1928, quoted in G. Polya, *Mathematical discovery: On understanding, learning, and teaching problem solving (Combined Edition)*, Wiley, (1981).

REALITY

"If you have a great idea, solid science, and earth shaking discoveries, you are still only 10% of the way there."

• David Tomei, LXR Biotechnology Inc, on the vicissitudes of startup companies.

◇ Quoted in *Science* page 1039, Nov. 7, 1997.

.....

"A truly popular lecture cannot teach, and a lecture that truly teaches cannot be popular."

• Michael Faraday: 'When Gladstone was British Prime Minister he visited Faraday's laboratory and asked if some esoteric substance called 'Electricity' would ever have practical significance. *"One day, sir, you will tax it."* was the answer.' (Science, 1994)

SUGGESTIONS AND ···

- Clearly identify expectations of technology
- Be realistic about the learning curve for advanced software (such as *Mathematica* or *Maple*)
- Commit to use of open architecture software (Linux) and open publishing
- Form (not for profit and 'pre-competitive') consortia
  - to share expertise
  - access to markets
  - ability to compete with the big guys

··· CONCLUSIONS

- Opportunity to recapture computing from our sister sciences

- Realistic now to benefit from:
  - advances in cognitive neuroscience
  - advances in software design, and testing, interfaces, expert systems

- Good technology will never be cheap (*Malthusian principle* that 'expectations outstrip performance')

FREEDOM AND DISCIPLINE

"... so long as we conceive intellectual education as merely consisting in the acquirement of mechanical mental aptitudes, and of formulated statements of useful truths, there can be no progress; although there will be much activity, amid aimless rearrangement of syllabuses, in the fruitless endeavour to dodge the inevitable lack of time. "

• A.N. Whitehead, "The Rythmic Claims of Freedom and Discipline" in *The Aims of Education and Other Essays* (1929).

Contents **Next:** Preamble:

Challenges in Mathematical Computing

Jonathan M. Borwein and Peter B. Borwein*

February 19, 2001

ABSTRACT. Almost all interesting mathematical algorithmic questions relate to NP-hard questions and such computation is prone to explode exponentially. More space, more speed and processors, and even say massive parallelism will have an impact but it will be largely at a 'micro not macro' level. We anticipate the greatest benefit accruing from mathematical platforms that allow for highly computer assisted insight generation (more 'aha's' per cycle), not from solution of grand challenge problems.

1 Mathematics Embraces Computing

It is often said that pure mathematicians invented digital computers and then proceeded to ignore them for the better part of half a century. In the past two decades this situation has started to change with a vengeance.

Major *symbolic mathematics* or *computer algebra* packages, most notably Maple and Mathematica, have over the last fifteen years reached a remarkable degree of sophistication. We should also allude to counterparts such as Axiom, Macsyma, Reduce, MuPad and Derive and to many other more specialized packages such as GAP, Magma or Cayley (for group theoretic computation), Pari (for number theory), KnotPlot (for knot theory) SnapPea

*Centre for Experimental & Constructive Mathematics, Simon Fraser University, Burnaby, British Columbia V5A 1S6, Canada. Email: jborwein@cecm.sfu.ca,pborwein@cecm.sfu.ca. Research supported by NSERC and by the Network of Centres of Excellence Program.

(for hyperbolic 3-manifolds) and SPlus (for statistics), and many more. This sophistication has relied on a confluence of algorithmic breakthroughs, dramatically increased processor power, almost limitless storage capacity, and most recently network communication, excellent online data bases and web-distributed (often Java-based) computational tools. We mention: the mathematics front end to the Los Alamos Preprint ArXiv (`front.math.ucdavis.edu/`), Mathematical Reviews on the Web (`e-math.ams.org/mathscinet`), Neil Sloane's Encyclopedia of Integer Sequences (`www.research.att.com/personal /njas/sequences/eisonline.html`), our own Inverse Symbolic Calculator (`www.cecm.sfu.ca/projects/ISC/ISCmain.html`) which infers symbolic structure from numerical input, and an Integer Relation Finder (`www.cecm.sfu.ca/projects/IntegerRelations/`).

The relatively seamless *integration* of all these components arguably represents *the* challenge for 21st Century computational mathematics. By contrast, it is hard to think of mathematical problems where a dramatic increase in speed and scale of computation would make possible a presently intractable line of research. It is easy to give examples where it would not. Thus, consider Lam's 1991 proof (`www.cecm.sfu.ca/organics/papers/lam/index.html`) of the nonexistence of a finite projective plane of order 10.[1] It involved thousands of hours of CRAY and other computation. Lam's estimate is that the next case ($n = 18$) susceptible to his methods would take millions of years on any conceivable architecture. While a certain class of mathematical enquiries is susceptible to massively parallel, even web based 'embarrassingly parallel', computation[2] these tend, however interesting, not to to be problems central to mathematics.

2 Computational Excursions in Contemporary Mathematics

Rather difficult problems, previously viewed as intractable, such as exact integration of elementary functions have been significantly attacked. A number of the most important mathematical algorithms of the twentieth century are (i) the Fast Fourier Transform, (ii) Lattice Basis Reduction methods and

[1] A hunt for a configuration of $n^2 + n^1 + 1$ points and lines.

[2] For example, discovering Mersenne primes: those of the form $2^n - 1$.

related Integer Relation algorithms, (iii) the Risch algorithm for indefinite integration, (iv) Gröbner basis computation for solving algebraic equations, and (v) the Wilf/Zeilberger Algorithms for 'hypergeometric' summation and integration that rigorously prove very large classes of identities. All these are, or soon will be, centrally incorporated in such packages.[3]

Such packages, and powerful more numerical relatives such as MatLab, can now substantially deal with large parts of the standard mathematics curriculum – and can out-perform most of our undergraduates to boot. They provide extraordinary opportunities for research that most mathematicians are only beginning to appreciate and digest. They also allow access to sophisticated mathematics to a very broad cross-section of scientists and engineers.

There is a coherent argument that the emergence of such packages, and their integration into mathematical parole, represents the most significant part in a paradigm shift in how mathematics is done; and certainly they have already become a central research tool in many subareas of mathematics both from an exploratory and from a formal point of view. (It is acceptable now to see a line in a proof that begins "by a large calculation in Maple we see ...".) The first objective of symbolic algebra packages was to do as much exact mathematics as possible. A second increasingly important objective is to do it very fast and to deal in an arbitrary precision environment with the more standard algorithms of mathematical analysis. Roughly, one would like to be able to incorporate the usual methods of numerical analysis into an exact environment or at least into an arbitrary precision environment.

The problems are obvious and hard. For example, how does one do arbitrary precision numerical quadrature? When does one switch methods with precision required or with different analytic properties of the integrand? How does one deal with branch cuts of analytic functions? How does one deal consistently with log? (Even this isn't completely worked out.) More ambitiously how does one do a similar analysis for differential equations? The goal is to marry the algorithms of analysis with symbolic and exact computation and to do this with as little loss of speed as possible. Sometimes this means we must first go back and speed up the core algebraic calculations. And ultimately, can we provide any 'certificates' that a given numeric or

[3]The first two were among the ten algorithms with "the greatest influence on the development and practice of science and engineering in the 20th century" described in the previous volume of this journal. Of course many of the others, such as sorting algorithms, are fundamental to the needs of contemporary mathematics.

symbolic computation is indeed a proof or even just correct?

Within this context a number of very interesting problems concerning the visualization of mathematics arise. How does one actually "see" what one is doing. It has been argued that Cartesian graphing was the most important invention of the last millennium. Certainly it changed how we thought about mathematics – the subsequent development of differential calculus rested on it. More subtle and complicated graphics, like those of fractals, allow for a kind of exploration that was previously impossible. There are many issues to be worked out here that live at the interface of mathematics, pedagogy and even psychology but are very timely to get right. (Think of how one visualizes the human genome and its patterns – which is after all just a particular several billion digit number base four.) An instructive example is afforded by the growing reliance of numerical analysts on graphic representation of large sparse matrices – the pictures show structure, numerical measurements very little.[4]

The great success of the symbolic algebra packages has been their mathematical generality and ease of use. These packages deal most successfully with algebraic problems while many (perhaps most) serious applications require analytic objects such as definite integrals, series and differential equations. All the elementary notions of analysis, like continuity and differentiability have to be given precise computational meaning. The first challenge involves mathematical algorithmic developments to allow the handling of a variety of these only partially handled problems – including the analysis of functions given by programs. Many of these relate to the difficult mathematical problems involved in automatic simplification of complicated analytic formulae and recognition of when two very different such expressions represent the same object. There is also an intrinsic need to mix numeric and symbolic (exact and inexact) methods. Human mathematicians often criticize programs for making dumb errors but often these errors (such as over simplifying expressions, leaving out hypotheses or 'dividing by zero') are precisely how one begins oneself. As Hadamard noted almost a century ago:

> "The object of mathematical rigor is to sanction and legitimize the conquests of intuition, and there was never any other object for it."

[4] A nice example is JavaView (`www-sfb288.math.tu-berlin.de/vgp/javaview/index.html`) for doing 3D Geometry on the web.

3 Challenge Problems for Computational Pure Mathematics

1. The question that a pure mathematician might trade his soul with the devil to solve is most likely the so called "Riemann–Hypothesis" of 1859. The bounty on its solution now exceeds $\$1,000,000$ – the amount offered by the *Millennium Prize* of the Clay Mathematics Institute (`www.claymath.org/prize_problems/rules.htm`).

At the Clay Institute website the problem is described in the following form:

> "Some numbers have the special property that they cannot be expressed as the product of two smaller numbers, e.g., $2, 3, 5, 7$, etc. Such numbers are called prime numbers, and they play an important role, both in pure mathematics and its applications. The distribution of such prime numbers among all natural numbers does not follow any regular pattern, however the German mathematician G.F.B. Riemann (1826–1866) observed that the frequency of prime numbers is very closely related to the behavior of an elaborate function $\zeta(s)$ called the Riemann Zeta function. The Riemann hypothesis asserts that all interesting solutions of the equation $\zeta(s) = 0$ lie on a straight line. This has been checked for the first 1,500,000,000 solutions. A proof that it is true for every interesting solution would shed light on many of the mysteries surrounding the distribution of prime numbers."

A little more precisely the Riemann Hypothesis is usually formulated as:

> *All the zeros in the right half of the complex plane of the analytic continuation of*
>
> $$\zeta(s) := \sum_{n=0}^{\infty} \frac{1}{n^s}$$
>
> *lie on the vertical line* $\Re(s) = \frac{1}{2}$.

We observe in passing that one of the most famous results in elementary mathematics is Bernoulli's evaluation of $\zeta(2) = \pi^2/6$.

Without doubt this is one of the 'grand challenge' problems of mathematics and for good reason. Large tracts of mathematics fall into place if the Riemann Hypothesis is true. Unlike problems such as Fermat's last problem (now theorem) which may prove to be an isolated mountain peak, even if the proof methods are tremendously significant, [5] the truth of the Riemann Hypothesis is central – its falseness would be disquieting. Most mathematicians believe the Riemann Hypothesis is true though there have been notable dissenters. Littlewood, one of the great analytic number theorists of last century is in print hypothesizing its falseness [6] . Of course, finding just one zero off the line $\Re(s) = \frac{1}{2}$,[7] should it exist, is worth a million dollars (although perhaps the prize is only for a proof not a disproof – certainly a proof is more interesting) and this may provide additional motivation to extend the climb of this particular mountain. The fact that more than the first billion zeros are known, by computation, to satisfy the Riemann hypothesis might be considered "strong numerical evidence" as it is the article by Enrico Bombieri that accompanies the prize citation. But it is far from overwhelming – there are subtle phenomena in this branch of mathematics that only manifest themselves far outside of present computer range.

One reason to extend such computations, which are neither easy nor obvious and rely on some fairly subtle mathematics, is the hope that one will uncover delicate phenomena that give insight for a proof. Greatly more ambitious is the possibility that, in the very long run, it will be possible to machine generate a proof even for problems clearly as difficult as this one.

2. Of the seven million-dollar Millennium Prize problems, the one that is most germane to this discussion is the so called $P \neq NP$ *problem.* Again, we quote from the discussion on the Clay website:

> "It is Saturday evening and you arrive at a big party. Feeling shy, you wonder whether you already know anyone in the room. Your host proposes that you must certainly know Rose, the lady in the corner next to the dessert tray. In a fraction of a second you are able to cast a glance and verify that your host is correct. However,

[5] A much deeper community understanding of modular and elliptic functions may also pay dividends.

[6] J.E. Littlewood, "Some Problems in Real and Complex Analysis," Heath Mathematical Monographs, 1968.

[7] And off the real line where there are 'trivial' zeros at negative even integers.

in the absence of such a suggestion, you are obliged to make a tour of the whole room, checking out each person one by one, to see if there is anyone you recognize. This is an example of the general phenomenon that generating a solution to a problem often takes far longer than verifying that a given solution is correct. Similarly, if someone tells you that the number 13,717,421 can be written as the product of two smaller numbers, you might not know whether to believe him, but if he tells you that it can be factored as 3607 times 3803 then you can easily check that it is true using a hand calculator. One of the outstanding problems in logic and computer science is determining whether questions exist whose answer can be quickly checked (for example by computer), but which require a much longer time to solve from scratch (without knowing the answer). There certainly seem to be many such questions. But so far no one has proved that any of them really does require a long time to solve; it may be that we simply have not yet discovered how to solve them quickly. Stephen Cook formulated the P versus NP problem in 1971."

Although in many instances one may question the practical distinction between polynomial and non polynomial algorithms, this problem really is central to our current understanding of computing. Roughly it conjectures that many of the problems we currently find computationally difficult must per force be be that way. It is a question about methods, not about actual computations, but it underlies many of the challenge problems one can imagine posing. A question that requests one to "compute such and such a sized incidence of this or that phenomena" always risks having the answer "it's just not possible" because $P \neq NP$.

4 Two Specific Challenges

With the 'NP' caveat,[8] let us offer two challenges that are let us offer two challenges that are far fetched but not inconceivable goals for the next few decades.

[8] Though factoring is difficult it is not generally assumed to be in the class of NP-hard problems.

3. *Design an algorithm that can reliably factor a random thousand digit integer.*

Current algorithms even with a huge effort get stuck at about 150 digits. Details lie at `www.rsasecurity.com/rsalabs/challenges/factoring/index.html` where the current factoring challenges are listed. Again, in the cash prize game there is also a $\$100,000$ offered for any honest $10,000,000$ digit prime (`www.mersenne.org/prime.htm`.)

Primality checking is currently easier than factoring, and there are some very fast and powerful *probabilistic* primality tests – much faster than those providing 'certificates'. Given that any computation has potential errors due to: (i) subtle (or even not-so-subtle) programming bugs, (ii) compiler errors, (iii) other software errors, (iv) and undetected hardware integrity errors, it seems increasingly pointless to distinguish between these two types of primality tests. Many would take their chances with a $(1 - 10^{-100})$ probability statistic over a 'proof' any day.

The above questions are intimately related to the Riemann Hypothesis, though not obviously so to the non afficionado. They are also critical to issues of internet security. Learn how to factor large numbers and most current security systems are crackable.

There are many old plum problems that lend themselves to extensive numerical exploration. To name but one other: a problem that arose originally in signal processing called the *Merit Factor problem* that is due in large part to Marcel Golay with closely related versions to Littlewood and Erdős. It has a long pedigree though certainly not as long as the Riemann hypothesis. Recent references and records can be found at (`itp.nat.uni-magdeburg.de/ mertens/`.)

It can be formulated as follows. Suppose $(a_0 := 1, a_1, ..., a_n)$ is a sequence of length $n+1$ where each a_i is either 1 or -1. If

$$c_k = \sum_{j=0}^{n-k} a_j a_{j+k}$$

then the problem is, for each fixed n, to minimize,

$$\sum_{k=-n}^{n} c_k^2.$$

Minima have be found up to about about $n = 50$. The search space of sequences at size 50 is 2^{50} which is about todays limit of a very very large

scale calculation. In fact the records use a branch and bound algorithm which grows more or less like 1.8^n. This is marginally better than the naive 2^n of a completely exhaustive search but is still painfully exponential.

4. *Find the minima in the merit factor problem up to size 100.*

The best hope for a solution is better algorithms. The problem is widely acknowledged as a very hard problem in combinatorial optimization but it isn't known to be in one of the recognized hard classes like NP. The next best hope is radically different computers, perhaps quantum computers. And there is always a remote chance that analysis will lead to a mathematical solution.

5 A Concrete Example

In this section we illustrate some of the mathematical challenges with a specific problem, proposed in the *American Mathematical Monthly* (November, 2000).

10832. *Donald E. Knuth, Stanford University, Stanford, CA.* Evaluate

$$\sum_{k=1}^{\infty} \left(\frac{k^k}{k!\, e^k} - \frac{1}{\sqrt{2\pi k}} \right).$$

1. A very rapid Maple computation yielded $-0.08406950872765600\ldots$ as the first 16 digits of the sum.

2. The Inverse Symbolic Calculator has a 'smart lookup' feature[9] that replied that this was probably $-\frac{2}{3} - \zeta(\frac{1}{2})/\sqrt{2\pi}$.

3. Ample experimental confirmation was provided by checking this to 50 digits. Thus within minutes we *knew* the answer.

4. As to why? A clue was provided by the surprising speed with which Maple computed the slowly convergent infinite sum. The package clearly knew something the user did not. Peering under the covers

[9] Alternatively, a sufficiently robust integer relation finder could be used.

revealed that it was using the *LambertW* function, W, which is the inverse of $w = z\exp(z)$.[10]

5. The presence of $\zeta(1/2)$ and standard Euler-MacLaurin techniques, using Stirling's formula (as might be anticipated from the question), led to

$$\sum_{k=1}^{\infty}\left(\frac{1}{\sqrt{2\pi k}} - \frac{1}{\sqrt{2}}\frac{(\frac{1}{2})_{k-1}}{(k-1)!}\right) = \frac{\zeta(\frac{1}{2})}{\sqrt{2\pi}}, \tag{1}$$

   where the binomial coefficients in (1) are those of $\frac{1}{\sqrt{2-2\,z}}$. Now (1) is a formula Maple can 'prove'.

6. It remains to show

$$\sum_{k=1}^{\infty}\left(\frac{k^k}{k!\;e^k} - \frac{1}{\sqrt{2}}\frac{(\frac{1}{2})_{k-1}}{(k-1)!}\right) = -\frac{2}{3}. \tag{2}$$

7. Guided by the presence of W and its series $\sum_{k=1}^{\infty}\frac{(-k)^{k-1}z^k}{k!}$, an appeal to Abel's limit theorem lets one deduce the need to evaluate

$$\lim_{z\to 1}\left(\frac{d}{dz}\mathrm{W}(-\frac{z}{e}) + \frac{1}{\sqrt{2-2\,z}}\right) = \frac{2}{3}. \tag{3}$$

   Again Maple happily does know (3).

Of course this all took a fair amount of human mediation and insight.

6 Conclusion

In 1996, discussing the philosophy and practice of Experimental Mathematics, we wrote:[11]

[10] A search for 'Lambert W function' on MathSciNet provided 9 references – all since 1997 when the function appears named for the first time in Maple and Mathematica.

[11] J.M. Borwein, P.B. Borwein, R. Girgensohn and S. Parnes, "Making Sense of Experimental Mathematics," Mathematical Intelligencer, 18, Number 4 (Fall 1996), 12-18. The quotes from Zeilberger and Chaitin are also cited therein.

> "As mathematics has continued to grow there has been a recognition that the age of the mathematical generalist is long over. What has not been so readily acknowledged is just how specialized mathematics has become. As we have already observed, sub-fields of mathematics have become more and more isolated from each other. At some level, this isolation is inherent but it is imperative that communications between fields should be left as wide open as possible. As fields mature, speciation occurs. The communication of sophisticated proofs will never transcend all boundaries since many boundaries mark true conceptual difficulties. But experimental mathematics, centering on the use of computers in mathematics, would seem to provide a common ground for the transmission of many insights."

This common ground continues to increase and extends throughout the sciences and engineering.

The corresponding need is to retain the robustness and unusually long-livedness of the rigorous mathematical literature. Doron Zeilberger's proposed *Abstract of the future* (1993) challenges this in many ways.

> "We show in a certain precise sense that the Goldbach conjecture[12] is true with probability larger than 0.99999 and that its complete truth could be determined with a budget of 10 billion."

He goes on to suggest that only the Riemann hypothesis merits paying really big bucks for certainty. Relatedly, Greg Chaitin (1994) argued that we should introduce the Riemann hypothesis as an 'axiom'.

> "I believe that elementary number theory and the rest of mathematics should be pursued more in the spirit of experimental science, and that you should be willing to adopt new principles. I believe that Euclid's statement that an axiom is a self-evident truth is a big mistake[13]. The Schrödinger equation certainly isn't a self-evident truth! And the Riemann hypothesis isn't self-evident either, but it's very useful. A physicist would say that

[12] Every even number is the sum of two primes.

[13] There is no evidence that Euclid ever made such a statement. However, the statement does have an undeniable emotional appeal.

there is ample experimental evidence for the Riemann hypothesis and would go ahead and take it as a working assumption."

How do we reconcile these somewhat combative challenges with the inarguable power of the deductive method? How do we continue to produce rigorous mathematics when more and more research will be performed in large computational environments where one may or not be able to determine what the system has done or why?[14]

At another level we see the core challenge for mathematical computing to be the construction of work spaces that largely or completely automate the diverse steps illustrated in Knuth's and like problems.

[14]This has often been described as "relying on proof by 'Von Neumann says'."

Abstract for R5 of Volume 4(2), 1997

J. M. Borwein, D. M. Bradley, D. J. Broadhurst

Evaluations of k-fold Euler/Zagier sums: a compendium of results for arbitrary k

Euler sums (also called Zagier sums) occur within the context of knot theory and quantum field theory. There are various conjectures related to these sums whose incompletion is a sign that both the mathematics and physics communities do not yet completely understand the field. Here, we assemble results for Euler/Zagier sums (also known as multidimensional zeta/harmonic sums) of arbitrary depth, including sign alternations. Many of our results were obtained empirically and are apparently new. By carefully compiling and examining a huge data base of high precision numerical evaluations, we can claim with some confidence that certain classes of results are exhaustive. While many proofs are lacking, we have sketched derivations of all results that have so far been proved.

ON DIRICHLET SERIES FOR SUMS OF SQUARES

JONATHAN MICHAEL BORWEIN AND KWOK-KWONG STEPHEN CHOI

ABSTRACT. In [14], Hardy and Wright recorded elegant closed forms for the generating functions of the divisor functions $\sigma_k(n)$ and $\sigma_k^2(n)$ in the terms of Riemann Zeta function $\zeta(s)$ only. In this paper, we explore other arithmetical functions enjoying this remarkable property. In Theorem 2.1 below, we are able to generalize the above result and prove that if f_i and g_i are completely multiplicative, then we have

$$\sum_{n=1}^{\infty} \frac{(f_1 * g_1)(n) \cdot (f_2 * g_2)(n)}{n^s} = \frac{L_{f_1 f_2}(s) L_{g_1 g_2}(s) L_{f_1 g_2}(s) L_{g_1 f_2}(s)}{L_{f_1 f_2 g_1 g_2}(2s)}$$

where $L_f(s) := \sum_{n=1}^{\infty} f(n) n^{-s}$ is the Dirichlet series corresponding to f. Let $r_N(n)$ be the number of solutions of $x_1^2 + \cdots + x_N^2 = n$ and $r_{2,P}(n)$ be the number of solutions of $x^2 + Py^2 = n$. One of the applications of Theorem 2.1 is to obtain closed forms, in terms of $\zeta(s)$ and Dirichlet L-functions, for the generating functions of $r_N(n), r_N^2(n), r_{2,P}(n)$ and $r_{2,P}(n)^2$ for certain N and P. We also use these generating functions to obtain asymptotic estimates of the average values for each function for which we obtain a Dirichlet series.

1. INTRODUCTION

Let σ_k denote the sum of kth powers of the divisors of n. It is also quite usual to write d for σ_0 and τ for σ_1. There is a beautiful formula for the generating functions of $\sigma_k(n)$ (see Theorem 291 in Chapter XVII of [14])

$$\sum_{n=1}^{\infty} \frac{\sigma_k(n)}{n^s} = \zeta(s)\zeta(s-k), \qquad \Re(s) > \max\{1, k+1\} \tag{1.1}$$

which is in terms of only the Riemann Zeta function $\zeta(s)$. Following Hardy and Wright, by standard techniques, one can prove the following remarkable identity due to Ramanujan (see [21]) (also see Theorem 305 in Chapter XVII of [14])

$$\sum_{n=1}^{\infty} \frac{\sigma_a(n)\sigma_b(n)}{n^s} = \frac{\zeta(s)\zeta(s-a)\zeta(s-b)\zeta(s-a-b)}{\zeta(2s-a-b)} \tag{1.2}$$

for $\Re(s) > \max\{1, a+1, b+1, a+b+1\}$. In this paper, we identify other arithmetical functions enjoying similarly explicit representations. In Theorem 2.1 of §2 below,

CECM Preprint 01:167.

we are able to generalize the above result and prove that if f_i and g_i are completely multiplicative, then we have

$$\sum_{n=1}^{\infty} \frac{(f_1 * g_1)(n) \cdot (f_2 * g_2)(n)}{n^s} = \frac{L_{f_1 f_2}(s) L_{g_1 g_2}(s) L_{f_1 g_2}(s) L_{g_1 f_2}(s)}{L_{f_1 f_2 g_1 g_2}(2s)}$$

where $L_f(s) := \sum_{n=1}^{\infty} f(n) n^{-s}$ is the Dirichlet series corresponding to f. As we shall see, this result recovers Hardy and Wright's formulae (1.1) and (1.2) immediately.

More generally, for certain classes of Dirichlet series, $\sum_{n=1}^{\infty} A(n) n^{-s}$, our Theorem 2.1 can be applied to obtain closed forms for the series $\sum_{n=1}^{\infty} A^2(n) n^{-s}$. In particular, if the generating function $L_f(s)$ of an arithmetic function f is expressible as a sum of products of two L-functions:

$$L_f(s) = \sum_{\chi_1, \chi_2} a(\chi_1, \chi_2) L_{\chi_1}(s) L_{\chi_2}(s)$$

for certain coefficients $a(\chi_1, \chi_2)$ and Dirichlet characters χ_i, then we are able to find a simple closed form (in term of L-functions) for the generating function $L_f^2(s) := \sum_{n=1}^{\infty} f^2(n) n^{-s}$.

One of our central applications is to the study of the number of representations as a sum of squares. Let $r_N(n)$ be the number of solutions to $x_1^2 + x_2^2 + \cdots + x_N^2 = n$ (counting permutations and signs). Hardy and Wright record a classical closed form, due to Lorenz, of the generating function for $r_2(n)$ in the terms of $\zeta(s)$ and a Dirichlet L-function, namely,

$$\sum_{n=1}^{\infty} \frac{r_2(n)}{n^s} = 4\zeta(s) L_{-4}(s)$$

where $L_\mu(s) = \sum_{n=1}^{\infty} \left(\frac{\mu}{n}\right) n^{-s}$ is the *primitive L-function* corresponding to the *Kronecker symbol* $\left(\frac{\mu}{n}\right)$. Define

$$\mathcal{L}_N(s) := \sum_{n=1}^{\infty} \frac{r_N(n)}{n^s} \qquad \text{and} \qquad \mathcal{R}_N(s) := \sum_{n=1}^{\infty} \frac{r_N^2(n)}{n^s}.$$

Simple closed forms for $\mathcal{L}_N(s)$ are known for $N = 2, 4, 6$ and 8; indeed the corresponding $q-$series were known to Jacobi. The entity $\mathcal{L}_3(s)$ in particular is still shrouded in mystery, as a series relevant to the study of lattice sums in the physical sciences. Lately there has appeared a connection between $\mathcal{L}_3$ and a modern theta-cubed identity of G. Andrews [1] which we list in (6.7), R. Crandall [6] and p.301 of [3]. In §3, we shall obtain simple closed forms for $\mathcal{R}_N(s)$ for these N from the corresponding $\mathcal{L}_N(s)$, via Theorem 2.1. Since the generating functions are accessible, by an elementary convolution argument, see §3 below, we are also able to deduce

$$\sum_{n \le x} r_N^2(n) = W_N x^{N-1} + O(x^{N-2})$$

for $N = 6, 8$ and for $N = 4$ with an error term $O(x^2 \log^5 x)$ where

$$W_N := \frac{1}{(N-1)(1-2^{-N})} \frac{\pi^N}{\Gamma^2(\frac{1}{2}N)} \frac{\zeta(N-1)}{\zeta(N)}, \qquad (N \ge 3). \tag{1.3}$$

This technique can be adjusted to handle all $N \geq 2$ except $N = 3$, see Theorem 3.3, and so to establish all but the most difficult case of the following general conjecture due to Wagon:

Wagon's Conjecture. *For* $N \geq 3, \sum_{n \leq x} r_N^2(n) \sim W_N x^{N-1}$ *as* $x \longrightarrow \infty$.

Now from (3.14) below, one has $\sum_{n \leq x} r_2^2(n) \sim 4x \log x$ so that Wagon's conjecture holds only for $N \geq 3$. This conjecture motivated our interest in such explicit series representations. Recently, it has been proved by Crandall and Wagon in [8]. In fact, they show that

$$\lim_{x \to \infty} x^{1-N} \sum_{n \leq x} r_N^2(n) = W_N,$$

with various rates of convergence (those authors found the $N = 3$ case especially difficult, with relevant computations revealing very slow convergence to the above limit). In their treatment of the Wagon conjecture and related matters, they needed to evaluate the following Dirichlet series

$$\sum_{n=1}^{\infty} \frac{\phi(n)\sigma_0(n^2)}{n^s}$$

and we have established, by an easier version of what follows, that it is

$$\sum_{n=1}^{\infty} \frac{\phi(n)\sigma_0(n^2)}{n^s} = \zeta^3(s-1) \prod_p \left(1 - \frac{3}{p^s} - \frac{1}{p^{2s-2}} + \frac{4}{p^{2s-1}} - \frac{1}{p^{3s-2}}\right)$$

where the product is over all primes. A word is in order concerning the importance of first- and second-order summatories. In a theoretical work [7] and a computational one [8] it is explained that the Wagon conjecture implies that *sums of three squares have positive density.* This interesting research connection is what inspired Wagon to posit his computationally motivated conjecture. Though it is known that the density of the set $S = \{x^2 + y^2 + z^2\}$ is exactly $5/6$ due to Landau (e.g [18] or [11]), there are intriguing signal-processing and analytic notions that lead more easily at least to positivity of said density. Briefly, the summatory connection runs as follows: from the Cauchy-Schwarz inequality we know

$$\#\{n < x; n \in S\} > \frac{\left(\sum_{n<x} r_3(n)\right)^2}{\sum_{n<x} r_3^2(n)},$$

so the Wagon conjecture even gives an explicit numerical lower bound on the density of S. Of course, the density for sums of more than 3 squares is likewise positive, and boundable, yet the Lagrange theorem that sums of four squares comprise *all* nonnegative integers dominates in the last analysis. Still, the signal-processing and computational notions of Crandall and Wagon forge an attractive link between these L-series of our current interest and additive number theory.

In §4 and §5, we similarly study the number of representations by a binary quadratic forms. Let $r_{2,P}(n)$ be the number of solutions of the binary quadratic form $x^2 + Py^2 = n$. Define

$$\mathcal{L}_{2,P}(s) := \sum_{n=1}^{\infty} \frac{r_{2,P}(n)}{n^s} \qquad \text{and} \qquad \mathcal{R}_{2,P}(s) := \sum_{n=1}^{\infty} \frac{r_{2,P}(n)^2}{n^s}.$$

The closed forms of $\mathcal{L}_{2,P}(s)$ has been studied by a number of people, particular by Glasser, Zucker and Robertson (see [10] and [23]). In finding the exact evaluation of lattice sums, they are interested in expressing a multiple sum, such as the generating functions of $r_{2,P}(n)$, as a product of simple sums. As a result, plenty of closed forms of Dirichlet series $\sum_{(n,m)\neq(0,0)}(am^2+bmn+cn^2)^{-s}$ in terms of L-functions have been found. One of the most interesting cases is when the binary quadratic forms have *disjoint discriminants*, i.e, have only one form per genus. Then there are simple closed forms for the corresponding $\mathcal{L}_{2,P}(s)$ (see (4.1) below). By applying Theorem 2.1, we obtain closed forms for $\mathcal{R}_{2,P}(s)$ and from this we also deduce asymptotic estimates for $r_{2,P}(n)$ and $r_{2,P}(n)^2$.

In the last section, we shall discuss $\mathcal{L}_N(s)$ for some other less tractable cases. In particular, we collect some representations of the generating function for $r_3(n), r_N(n)$, and discuss $r_{12}(n)$ and $r_{24}(n)$.

Throughout, our notation is consistent with that in [14, 15] and [16]. We should also remark that we were lead to the structures exhibited herein by a significant amount of numeric and symbolic computation: leading to knowledge of the formulae for $\mathcal{R}_2, \mathcal{R}_4, \mathcal{R}_8, \mathcal{R}_{2,2}$ and $\mathcal{R}_{2,3}$ before finding our general results. And indeed R. Crandall triggered our interest by transmitting his formula for $\mathcal{R}_4$.

2. Basic Results

Let $\sigma(f)$ be the *abscissa* of absolute convergence of the Dirichlet series

$$L_f(s) := \sum_{n=1}^{\infty} f(n)n^{-s}.$$

For any two arithmetic functions f and g, define

$$f*g(n) := \sum_{d|n} f(d)g(n/d)$$

to be the *convolution* of f and g.

Theorem 2.1. *Suppose f_1, f_2 and g_1, g_2 are completely multiplicative arithmetic functions. Then for $\Re(s) \geq \max\{\sigma(f_i), \sigma(g_i)\}$, we have*

$$\sum_{n=1}^{\infty} \frac{(f_1*g_1)(n)\cdot(f_2*g_2)(n)}{n^s} = \frac{L_{f_1f_2}(s)L_{g_1g_2}(s)L_{f_1g_2}(s)L_{g_1f_2}(s)}{L_{f_1f_2g_1g_2}(2s)}. \tag{2.1}$$

Proof. Since $(f_1*g_1)(n)\cdot(f_2*g_2)(n)$ is multiplicative, we only need to consider its values at the prime powers. For any prime p and any $l \geq 0$,

$$(f_i*g_i)(p^l) = \sum_{d|p^l} f_i(d)g_i(p^l/d) = \frac{f_i(p)^{l+1} - g_i(p)^{l+1}}{f_i(p) - g_i(p)},$$

as each of f_1, f_2, g_1, g_2 is completely multiplicative. We intend above that if both $f_i(p)$ and $g_i(p)$ are zero, then

$$(f_i*g_i)(p^l) = \begin{cases} 1 & \text{if } l = 0; \\ 0 & \text{if } l \geq 1. \end{cases}$$

Thus, we have

$$\begin{aligned}\Sigma_p &:= \sum_{l=0}^{\infty}(f_1*g_1)(p^l)(f_2*g_2)(p^l)p^{-ls}\\ &= \sum_{l=0}^{\infty}\frac{(f_1(p)^{l+1}-g_1(p)^{l+1})(f_2(p)^{l+1}-g_2(p)^{l+1})}{(f_1(p)-g_1(p))(f_2(p)-g_2(p))}p^{-ls}\\ &= \frac{\sum_{l=0}^{\infty}\left\{(f_1f_2)(p)^{l+1}p^{-ls}+(g_1g_2)(p)^{l+1}p^{-ls}-(f_1g_2)(p)^{l+1}p^{-ls}-(g_1f_2)(p)^{l+1}p^{-ls}\right\}}{(f_1(p)-g_1(p))(f_2(p)-g_2(p))}.\end{aligned}$$

On summing up all the geometric series, we arrive at

$$\begin{aligned}\Sigma_p &:= \frac{\frac{(f_1f_2)(p)}{1-(f_1f_2)(p)p^{-s}}+\frac{(g_1g_2)(p)}{1-(g_1g_2)(p)p^{-s}}-\frac{(f_1g_2)(p)}{1-(f_1g_2)(p)p^{-s}}-\frac{(g_1f_2)(p)}{1-(g_1f_2)(p)p^{-s}}}{(f_1(p)-g_1(p))(f_2(p)-g_2(p))}\\ &= \frac{1-(f_1f_2g_1g_2)(p)p^{-2s}}{(1-(f_1f_2)(p)p^{-s})(1-(g_1g_2)(p)p^{-s})(1-(f_1g_2)(p)p^{-s})(1-(g_1f_2)(p)p^{-s})}.\end{aligned}$$

In view of the Euler product form for a Dirichlet series, we have

$$\begin{aligned}\sum_{n=1}^{\infty}\frac{(f_1*g_1)(n)\cdot(f_2*g_2)(n)}{n^s} &= \prod_p\left\{\sum_{l=0}^{\infty}\frac{(f_1*g_1)(p^l)(f_2*g_2)(p^l)}{p^{ls}}\right\}\\ &= \frac{L_{f_1f_2}(s)L_{g_1g_2}(s)L_{f_1g_2}(s)L_{g_1f_2}(s)}{L_{f_1f_2g_1g_2}(2s)}.\end{aligned}$$

This proves our theorem. □

A first easy application of Theorem 2.1 is to evaluate the Dirichlet series $\sum_{n=1}^{\infty}\sigma_k(n)n^{-s}$ and $\sum_{n=1}^{\infty}\sigma_a(n)\sigma_b(n)n^{-s}$. If we let $f_1(n):=n^k$, $f_2(n):=\delta(n)$ and $g_1(n)=g_2(n):=1$ where $\delta(n)$ is 1 if $n=1$ and 0 otherwise, then

$$L_{f_1f_2}(s)=L_{g_1f_2}(s)=L_{f_1f_2g_1g_2}(s)=1,$$

$$L_{f_1g_2}(s)=\zeta(s-k),\qquad L_{g_1g_2}(s)=\zeta(s).$$

Thus Theorem 2.1 recovers the identity (1.1)

Similarly, if we let $f_1(n):=n^a$, $f_2(n):=n^b$ and $g_1(n)=g_2(n):=1$, then

$$L_{f_1f_2}(s)=L_{f_1f_2g_1g_2}(s)=\zeta(s-(a+b)),\qquad L_{g_1g_2}(s)=\zeta(s),$$

$$L_{f_1g_2}(s)=\zeta(s-a),\qquad L_{f_2g_1}(s)=\zeta(s-b).$$

and Theorem 2.1 gives (1.2).

In particular, for any real λ,

$$\sum_{n=1}^{\infty}\sigma_\lambda^2(n)n^{-s}=\frac{\zeta(s-2\lambda)\zeta(s-\lambda)^2\zeta(s)}{\zeta(2(s-\lambda))}. \tag{2.2}$$

We shall discuss more elaborate applications of Theorem 2.1 in the latter sections. Before doing this, we give the following example here to explain why Theorem 2.1 cannot in general be extended nicely to higher order.

We are interested in obtaining the generating functions for the *kth moment* of $r_2(n)$. For any $n\geq 1$ and $|x|<1$, in view of

$$\sum_{l=0}^{\infty}lx^l=x(1-x)^{-2}$$

and

$$x\frac{d}{dx}\sum_{l=0}^{\infty} l^n x^l = \sum_{l=0}^{\infty} l^{n+1}x^l \tag{2.3}$$

it is immediate that

$$\sum_{l=0}^{\infty} l^n x^l = \frac{xE_n(x)}{(1-x)^{n+1}}, \qquad n = 1, 2, \cdots \tag{2.4}$$

for a certain polynomial $E_n(x)$ of degree $n-1$. $E_n(x)$ is known as the nth *Euler polynomial* [4] and it is easy to see that (2.3) implies the recursion

$$E_{n+1}(x) = (1+nx)E_n(x) + x(1-x)E_n'(x).$$

Explicitly, the first few Euler polynomials are $E_1(x) = 1, E_2(x) = 1+x, E_3(x) = 1+4x+x^2$ and $E_4(x) = 1+11x+11x^2+x^3$. Equation (2.4) enables us to obtain the generating functions for the higher moments of $r_2(n)$ as follows: for $\mu \equiv 0$ or $1 \pmod 4$, we let $\left(\frac{\mu}{n}\right)$ be the *Jacobi-Legendre-Kronecker symbol* and again consider

$$L_\mu(s) := \sum_{n=1}^{\infty} \left(\frac{\mu}{n}\right) n^{-s}$$

the L-function corresponding to $\left(\frac{\mu}{n}\right)$. It is known (e.g. p. 291 in [3]) that

$$\sum_{n=1}^{\infty} \frac{r_2(n)}{n^s} = 4\zeta(s)L_{-4}(s) = \sum_{n=1}^{\infty} \frac{4(1 * \left(\frac{-4}{n}\right))(n)}{n^s}$$

and $r_2(n) = 4(1 * \left(\frac{-4}{n}\right))(n)$ for any $n \geq 1$. A simple calculation shows that for any $l \geq 0$,

$$\left(1 * \left(\frac{-4}{n}\right)\right)(p^l) = \begin{cases} 1 & \text{if } p = 2; \\ l+1 & \text{if } p \geq 3 \text{ and } \left(\frac{-1}{p}\right) = 1; \\ \frac{(-1)^l+1}{2} & \text{if } p \geq 3 \text{ and } \left(\frac{-1}{p}\right) = -1. \end{cases}$$

We now have

$$\begin{aligned}
\sum_{n=1}^{\infty} \frac{r_2^N(n)}{n^s} &= 4^N \sum_{n=1}^{\infty} \frac{\left\{(1 * \left(\frac{-4}{n}\right))(n)\right\}^N}{n^s} \\
&= 4^N \prod_p \sum_{l=0}^{\infty} \frac{\left\{(1 * \left(\frac{-4}{n}\right))(p^l)\right\}^N}{p^{ls}} \\
&= \frac{4^N}{1-2^{-s}} \left\{ \prod_{\left(\frac{-1}{p}\right)=-1} \sum_{l=0}^{\infty} \left(\frac{(-1)^l+1}{2}\right)^N p^{-ls} \right\} \left\{ \prod_{\left(\frac{-1}{p}\right)=1} \sum_{l=0}^{\infty} (l+1)^N p^{-ls} \right\} \\
&= \frac{4^N}{1-2^{-s}} \prod_{\left(\frac{-1}{p}\right)=-1} \frac{1}{1-p^{-2s}} \prod_{\left(\frac{-1}{p}\right)=1} \frac{E_N(p^{-s})}{(1-p^{-s})^{N+1}}
\end{aligned}$$

on using (2.4). [Here $\prod_p$ denotes the infinite product over all primes.] Firstly, when $N = 2$, we have most pleasingly,

$$\begin{aligned}\sum_{n=1}^{\infty}\frac{r_2^2(n)}{n^s} &= \frac{16}{1-2^{-s}}\prod_{(\frac{-1}{p})=-1}\frac{1}{1-p^{-2s}}\prod_{(\frac{-1}{p})=1}\frac{1+p^{-s}}{(1-p^{-s})^3}\\ &= \frac{16}{1+2^{-s}}\left\{\frac{1}{1-2^{-s}}\prod_{(\frac{-1}{p})=-1}\frac{1}{1-p^{-2s}}\prod_{(\frac{-1}{p})=1}\frac{1}{(1-p^{-s})^2}\right\}^2\prod_p(1-p^{-2s})\\ &= \frac{\left(4\zeta(s)L_{-4}(s)\right)^2}{(1+2^{-s})\zeta(2s)}. \qquad (2.5)\end{aligned}$$

However, when $N \geq 3$, the generating functions cannot be expressed in terms of L-functions as completely as in formula (2.5). For example, when $N = 3$

$$\sum_{n=1}^{\infty}\frac{r_2^3(n)}{n^s} = \frac{64}{1-2^{-s}}\prod_{(\frac{-1}{p})=-1}\frac{1}{1-p^{-2s}}\prod_{(\frac{-1}{p})=1}\frac{1+4p^{-s}+p^{-2s}}{(1-p^{-s})^4},$$

and when $N = 4$

$$\sum_{n=1}^{\infty}\frac{r_2^4(n)}{n^s} = \frac{256}{1-2^{-s}}\prod_{(\frac{-1}{p})=-1}\frac{1}{1-p^{-2s}}\prod_{(\frac{-1}{p})=1}\frac{1+11p^{-s}+11p^{-2s}+p^{-3s}}{(1-p^{-s})^5}.$$

This helps explain why our Theorem 2.1 has no 'closed-form' extension to higher order. For the detailed asymptotic estimate of the generating function of the kth moment of $r_2(n)$, we refer the reader to [5].

3. Sums of a Small Even Number of Squares

In view of Theorem 2.1, whenever a Dirichlet series is expressible as a sum of two-fold products of L-functions:

$$L_f(s) = \sum_{\chi_1,\chi_2} a(\chi_1,\chi_2)L_{\chi_1}(s)L_{\chi_2}(s),$$

we are able to provide a closed form (in terms of L-functions) of the Dirichlet series $L_{f^2}(s) = \sum_{n=1}^{\infty} f^2(n)n^{-s}$, on using (2.1).

In particular, let $r_N(n)$ be the number of solutions to $x_1^2 + x_2^2 + \cdots + x_N^2 = n$ (counting permutations and signs) and let

$$\mathcal{L}_N(s) := \sum_{n=1}^{\infty} r_N(n)n^{-s}, \qquad \mathcal{R}_N(s) := \sum_{n=1}^{\infty} r_N^2(n)n^{-s}$$

be the Dirichlet series corresponding to $r_N(n)$ and $r_N^2(n)$. Closed forms are obtainable for $\mathcal{L}_N(s)$ for certain even N from the explicit formulae known for $r_N(n)$. For example, we have

$$\mathcal{L}_2(s) = 4\zeta(s)L_{-4}(s), \qquad (3.1)$$

$$\mathcal{L}_4(s) = 8(1-4^{1-s})\zeta(s)\zeta(s-1), \qquad (3.2)$$

$$\mathcal{L}_6(s) = 16\zeta(s-2)L_{-4}(s) - 4\zeta(s)L_{-4}(s-2), \qquad (3.3)$$

$$\mathcal{L}_8(s) = 16(1-2^{1-s}+4^{2-s})\zeta(s)\zeta(s-3). \qquad (3.4)$$

The derivation of (3.1) and (3.3) from the formulas for $r_2(n)$ and $r_6(n)$ (e.g. §91 in [20]) is immediate if we write those formulas in the form

$$\begin{aligned} r_2(n) &= 4\sum_{\substack{m,d\geq 1\\ md=n}} \chi(d) \\ r_6(n) &= 16\sum_{\substack{m,d\geq 1\\ md=n}} \chi(m)d^2 - 4\sum_{\substack{m,d\geq 1\\ md=n}} \chi(d)d^2 \end{aligned}$$

where χ denotes the non-principal character modulo 4. For derivation of (3.2) and (3.4) from the formulas for $r_4(n)$ and $r_8(n)$ (e.g. §91 in [20]) is immediate if we write those formulas in the form

$$\begin{aligned} r_4(n) &= 8\sigma_1(n) - 32\sigma_1(n/4) \\ r_8(n) &= 16\sigma_3(n) - 32\sigma_3(n/2) + 256\sigma_3(n/4) \end{aligned}$$

where it is understood that $\sigma_k(n) = 0$ if n is not a positive integer.

In this section, we shall demonstrate how to use our Theorem 2.1 to obtain counterpart closed forms for $\mathcal{R}_N(s)$ from the above expressions for $\mathcal{L}_N(s)$.

Let us start with $\mathcal{R}_2(s)$. It has already been shown in (2.5) that

$$\mathcal{R}_2(s) = \sum_{n=1}^{\infty} \frac{r_2^2(n)}{n^s} = \frac{(4\zeta(s)L_{-4}(s))^2}{(1+2^{-s})\zeta(2s)}$$

but it can also be deduced directly from our Theorem 2.1 and (3.1) by taking $f_1(n) = f_2(n) = 1$ and $g_1(n) = g_2(n) = \left(\frac{-4}{n}\right)$.

We shall consider $\mathcal{R}_4(s)$ and $\mathcal{R}_8(s)$ later. For $\mathcal{R}_6(s)$, we first write

$$\begin{aligned} \mathcal{L}_6(s) &= 16\zeta(s-2)L_{-4}(s) - 4\zeta(s)L_{-4}(s-2) \\ &= 16\sum_{n=1}^{\infty}\left(\sum_{d|n} d^2\left(\frac{-4}{n/d}\right)\right)n^{-s} - 4\sum_{n=1}^{\infty}\left(\sum_{d|n} d^2\left(\frac{-4}{d}\right)\right)n^{-s} \\ &= \sum_{n=1}^{\infty}\left(16(f_1*g_1)(n) - 4(f_2*g_2)(n)\right)n^{-s} \end{aligned}$$

where $f_1(n) = n^2$, $g_1(n) = \left(\frac{-4}{n}\right)$, $f_2(n) = 1$ and $g_2(n) = \left(\frac{-4}{n}\right)n^2$. It follows from our Theorem 2.1 and (3.3) that

$$\begin{aligned} \mathcal{R}_6(s) &= \sum_{n=1}^{\infty}\left(16(f_1*g_1)(n) - 4(f_2*g_2)(n)\right)^2 n^{-s} \\ &= 16^2\sum_{n=1}^{\infty}(f_1*g_1)^2(n)n^{-s} - 128\sum_{n=1}^{\infty}(f_1*g_1)(n)(f_2*g_2)(n)n^{-s} \\ &\qquad +16\sum_{n=1}^{\infty}(f_2*g_2)^2(n)n^{-s} \\ &= 16^2\frac{L_{f_1^2}(s)L_{g_1^2}(s)L_{f_1g_1}(s)^2}{L_{f_1^2g_1^2}(2s)} - 128\frac{L_{f_1f_2}(s)L_{g_1g_2}(s)L_{f_1g_2}(s)L_{g_1f_2}(s)}{L_{f_1f_2g_1g_2}(2s)} \\ &\qquad +16\frac{L_{f_2^2}(s)L_{g_2^2}(s)L_{f_2g_2}(s)^2}{L_{f_2^2g_2^2}(2s)}. \end{aligned} \tag{3.5}$$

It remains to evaluate the component L-functions and they are

$$L_{f_1^2}(s) = \zeta(s-4), \qquad L_{g_1^2}(s) = (1-2^{-s})\zeta(s),$$

$$L_{f_2^2}(s) = \zeta(s), \qquad L_{g_2^2}(s) = (1-16\cdot 2^{-s})\zeta(s-4),$$

$$L_{f_1g_1}(s) = L_{-4}(s-2), \qquad L_{f_1f_2}(s) = \zeta(s-2), \qquad L_{g_1g_2}(s) = (1-4\cdot 2^{-s})\zeta(s-2),$$

$$L_{f_1g_2}(s) = L_{-4}(s-4), \qquad L_{g_1f_2}(s) = L_{-4}(s), \qquad L_{f_2g_2}(s) = L_{-4}(s-2),$$

$$L_{f_1^2g_1^2}(s) = L_{f_2^2g_2^2}(s) = L_{f_1f_2g_1g_2}(s) = (1-16\cdot 2^{-s})\zeta(s-4).$$

Now from (3.5), we have

$$\mathcal{R}_6(s) = 16\frac{(17-32\cdot 2^{-s})}{(1-16\cdot 2^{-2s})}\frac{\zeta(s-4)L_{-4}^2(s-2)\zeta(s)}{\zeta(2s-4)} - \frac{128}{(1+4\cdot 2^{-s})}\frac{L_{-4}(s-4)\zeta^2(s-2)L_{-4}(s)}{\zeta(2s-4)}.$$

For $\mathcal{R}_4(s)$ and $\mathcal{R}_8(s)$, we need the following companion lemma:

Lemma 3.1. *Suppose $f(n)$ is a multiplicative function. Let p be a prime and let the Dirichlet series*

$$\sum_{n=1}^{\infty}\frac{A(n)}{n^s} := \sum_{m=0}^{\infty}\frac{a_m}{p^{ms}}\sum_{n=1}^{\infty}\frac{f(n)}{n^s}$$

be the product of $L_f(s)$ and a power series in p^{-s}. Then

$$\sum_{n=1}^{\infty}\frac{A^2(n)}{n^s} = L_{f^2}(s)\sum_{m=0}^{\infty}\frac{a_m^2}{p^{ms}} + 2L_{f^2}(s)\left(\sum_{l=0}^{\infty}\frac{f^2(p^l)}{p^{ls}}\right)^{-1} \times \sum_{k=1}^{\infty}\left\{\sum_{m=0}^{\infty}\frac{a_{m+k}a_m}{p^{ms}}\right\}\left\{\sum_{l=0}^{\infty}\frac{f(p^l)f(p^{l+k})}{p^{ls}}\right\}p^{-ks}. \tag{3.6}$$

Proof. Since

$$\sum_{n=1}^{\infty}A(n)n^{-s} = \sum_{n=1}^{\infty}\sum_{m=0}^{\infty}a_mf(n)(p^mn)^{-s} = \sum_{n=1}^{\infty}\left\{\sum_{\substack{m=0\\ p^m|n}}^{\infty}a_mf\left(\frac{n}{p^m}\right)\right\}n^{-s},$$

we deduce

$$\begin{aligned}\sum_{n=1}^{\infty}A^2(n)n^{-s} &= \sum_{n=1}^{\infty}\left\{\sum_{\substack{m=0\\ p^m|n}}^{\infty}a_mf\left(\frac{n}{p^m}\right)\right\}^2 n^{-s}\\ &= \sum_{m_1,m_2=0}^{\infty}a_{m_1}a_{m_2}\sum_{\substack{n=1\\ p^{m_1},p^{m_2}|n}}^{\infty}f\left(\frac{n}{p^{m_1}}\right)f\left(\frac{n}{p^{m_2}}\right)n^{-s}. \qquad (3.7)\end{aligned}$$

For any $m_1, m_2 \geq 1$ we let $M := \max(m_1, m_2)$ and $m := \min(m_1, m_2)$. Then the last summation (over n) in (3.7) is

$$\begin{aligned} &= \sum_{\substack{n=1 \\ p^M \mid n}}^{\infty} f\left(\frac{n}{p^M}\right) f\left(\frac{n}{p^m}\right) n^{-s} \\ &= \frac{1}{p^{Ms}} \sum_{n=1}^{\infty} f(n) f(np^{M-m}) n^{-s} \\ &= \frac{1}{p^{Ms}} \sum_{l=0}^{\infty} \sum_{\substack{n=1 \\ (p,n)=1}}^{\infty} f(np^l) f(np^{M-m+l}) p^{-ls} n^{-s} \\ &= \frac{1}{p^{Ms}} \sum_{l=0}^{\infty} f(p^l) f(p^{M-m+l}) p^{-ls} \sum_{\substack{n=1 \\ (p,n)=1}}^{\infty} \frac{f^2(n)}{n^s} \end{aligned} \tag{3.8}$$

since $f(n)$ is multiplicative. By writing

$$\sum_{n=1}^{\infty} \frac{f^2(n)}{n^s} = \sum_{l=0}^{\infty} \sum_{\substack{n=1 \\ (p,n)=1}}^{\infty} \frac{f^2(np^l)}{(np^l)^s} = \sum_{l=0}^{\infty} \frac{f^2(p^l)}{p^{ls}} \sum_{\substack{n=1 \\ (p,n)=1}}^{\infty} \frac{f^2(n)}{n^s},$$

we deduce that

$$\sum_{\substack{n=1 \\ (p,n)=1}}^{\infty} \frac{f^2(n)}{n^s} = L_{f^2}(s) \left(\sum_{l=0}^{\infty} f^2(p^l) p^{-ls} \right)^{-1}. \tag{3.9}$$

Using (3.7), (3.8) and (3.9), we have

$$\begin{aligned} \sum_{n=1}^{\infty} A^2(n) n^{-s} = L_{f^2}(s) \left(\sum_{l=0}^{\infty} f^2(p^l) p^{-ls} \right)^{-1} \times \\ \times \sum_{m_1, m_2 = 0}^{\infty} \frac{a_{m_1} a_{m_2}}{p^{\max(m_1, m_2)s}} \sum_{l=0}^{\infty} \frac{f(p^l) f(p^{l+|m_1 - m_2|})}{p^{ls}}. \end{aligned} \tag{3.10}$$

The contribution corresponding to $m_1 = m_2$ in the above double summation is

$$\sum_{m=0}^{\infty} \frac{{a_m}^2}{p^{ms}} \sum_{l=0}^{\infty} \frac{f^2(p^l)}{p^{ls}} \tag{3.11}$$

and the contribution corresponding to $m_1 \neq m_2$ is

$$\begin{aligned} &= 2 \sum_{m_2 < m_1}^{\infty} \frac{a_{m_1} a_{m_2}}{p^{m_1 s}} \sum_{l=0}^{\infty} \frac{f(p^l) f(p^{l+m_1-m_2})}{p^{ls}} \\ &= 2 \sum_{m=0}^{\infty} \sum_{k=1}^{\infty} \frac{a_{m+k} a_m}{p^{(m+k)s}} \sum_{l=0}^{\infty} \frac{f(p^l) f(p^{l+k})}{p^{ls}} \\ &= 2 \sum_{k=1}^{\infty} \left\{ \sum_{m=0}^{\infty} \frac{a_{m+k} a_m}{p^{ms}} \right\} \left\{ \sum_{l=0}^{\infty} \frac{f(p^l) f(p^{l+k})}{p^{ls}} \right\} \frac{1}{p^{ks}}. \end{aligned} \tag{3.12}$$

Now (3.6) follows from (3.10), (3.11) and (3.12). □

On applying Lemma 3.1 to (3.2) and (3.4) and using (2.2), we have

$$\mathcal{R}_4(s) = 64\frac{(8\cdot 2^{3-3s} - 10\cdot 2^{2-2s} + 2^{1-s} + 1)\zeta(s-2)\zeta^2(s-1)\zeta(s)}{(1+2^{1-s})\zeta(2s-2)};$$

and

$$\mathcal{R}_8(s) = 256\frac{(32\cdot 2^{6-2s} - 3\cdot 2^{3-s} + 1)\zeta(s-6)\zeta^2(s-3)\zeta(s)}{(1+2^{3-s})\zeta(2s-6)}.$$

Therefore, we have completed the proof of the following Theorem.

Theorem 3.2. *We may write*

$$\mathcal{R}_2(s) = \frac{(4\zeta(s)L_{-4}(s))^2}{(1+2^{-s})\zeta(2s)}, \qquad \Re(s) > 1;$$

$$\mathcal{R}_4(s) = 64\frac{(8\cdot 2^{3-3s} - 10\cdot 2^{2-2s} + 2^{1-s} + 1)\zeta(s-2)\zeta^2(s-1)\zeta(s)}{(1+2^{1-s})\zeta(2s-2)}, \qquad \Re(s) > 3;$$

$$\mathcal{R}_6(s) = 16\frac{(17-32\cdot 2^{-s})}{(1-16\cdot 2^{-2s})}\frac{\zeta(s-4)L_{-4}^2(s-2)\zeta(s)}{\zeta(2s-4)} - \frac{128}{(1+4\cdot 2^{-s})}\frac{L_{-4}(s-4)\zeta^2(s-2)L_{-4}(s)}{\zeta(2s-4)}, \qquad \Re(s) > 5;$$

and

$$\mathcal{R}_8(s) = 256\frac{(32\cdot 2^{6-2s} - 3\cdot 2^{3-s} + 1)\zeta(s-6)\zeta^2(s-3)\zeta(s)}{(1+2^{3-s})\zeta(2s-6)} \qquad \Re(s) > 7.$$

Since $\epsilon\zeta(1+\epsilon) \to 1$ as $\epsilon \to 0$, the value of the $\lim_{\epsilon\to 0}\epsilon\mathcal{R}_N(N-1+\epsilon)$ at its largest pole is, respectively:

$$\lim_{\epsilon\to 0}\epsilon\mathcal{R}_4(3+\epsilon) = 96\zeta(3) = 3W_4$$

$$\lim_{\epsilon\to 0}\epsilon\mathcal{R}_6(5+\epsilon) = 240\zeta(5) = 5W_6$$

and

$$\lim_{\epsilon\to 0}\epsilon\mathcal{R}_8(7+\epsilon) = \frac{4480}{17}\zeta(7) = 7W_8.$$

The formulae for $\mathcal{R}_N(s)$ in Theorem 3.2 enable us to estimate the average order of $r_N^2(n)$ for $N = 2, 4, 6, 8$. Following from Sierpinski's result on the circle problem (cf. Satz 509 of [17])

$$\sum_{n\le x} r_2(n) = \pi x + O(x^{1/3}), \tag{3.13}$$

we have

$$\sum_{n\le x} r_2^2(n) = 4x\log x + 4\alpha x + O(x^{2/3}) \tag{3.14}$$

where $\alpha := 2\gamma + \frac{8}{\pi}L'_{-4}(1) - \frac{12}{\pi^2}\zeta'(2) + \frac{1}{3}\log 2 - 1 = 2.0166216\cdots$. Indeed, one can prove (3.14) as follows. Let

$$\sum_{n=1}^{\infty} h_n n^{-s} := \{4\zeta(s)L_{-4}(s)\}^2 = \left(\sum_{n=1}^{\infty} r_2(n)n^{-s}\right)^2. \tag{3.15}$$

By the hyperbola method and (3.13), one has

$$\begin{aligned} H(x) &:= \sum_{n\le x} h_n = \sum_{\substack{m,d\ge 1\\ md\le x}} r_2(m)r_2(d) \\ &= 2\sum_{m\le\sqrt{x}} r_2(m)\sum_{n\le x/m} r_2(n) - \left(\sum_{n\le\sqrt{x}} r_2(n)\right)^2 \\ &= 2\sum_{m\le\sqrt{x}} r_2(m)\left\{\pi\frac{x}{m} + O\left(\frac{x^{1/3}}{m^{1/3}}\right)\right\} - \{\pi x^{1/2} + O(x^{1/6})\}^2 \\ &= \pi^2 x\log x + C_1 x + O(x^{2/3}), \end{aligned}$$

for some constant C_1. Now by (2.5) we have

$$\mathcal{R}_2(s) = \sum_{n=1}^{\infty} r_2^2(n)n^{-s} = \sum_{m=1}^{\infty} h_m m^{-s}\sum_{n=1}^{\infty} l_n n^{-s}$$

where h_n is given (3.15) and

$$\sum_{n=1}^{\infty} l_n n^{-s} = (1+2^{-s})^{-1}\zeta^{-1}(2s) = \sum_{j=0}^{\infty}(-1)^j 2^{-js}\sum_{k=1}^{\infty}\mu(k)k^{-2s}$$

has abscissa of absolute convergence $1/2$ and

$$\sum_{n\le x}|l_n| = O(x^{1/2}\log x).$$

Here $\mu(n)$ is the Möbius function. Now by an elementary convolution argument

$$\begin{aligned} \sum_{n\le x} r_2^2(n) &= \sum_{n\le x} l_n H(x/n) \\ &= \sum_{n\le x} l_n\{\pi^2\frac{x}{n}\log\frac{x}{n} + C_1\frac{x}{n} + O(\frac{x^{2/3}}{n^{2/3}})\} \\ &= 4x\log x + C_2 x + O(x^{2/3}) \qquad (3.16) \end{aligned}$$

for some constant C_2. To evaluate the value of C_2, we first note that for any $\sigma > 1$, we have

$$\sum_{n\le x}\frac{r_2^2(n)}{n^\sigma} = \int_{1-}^{x} u^{-\sigma}d\sum_{n\le u} r_2^2(n)$$

and hence from (3.16) and letting $x\longrightarrow+\infty$, we get

$$\mathcal{R}_2(\sigma) = \sigma\int_1^\infty\left(\frac{\sum_{n\le u} r_2^2(n) - 4u\log u - C_2 u}{u^{\sigma+1}}\right)du + \frac{4}{(\sigma-1)^2} + \frac{4+\sigma C_2}{\sigma-1}.$$

The above integral converges when $\sigma\longrightarrow 1^+$ and hence

$$\lim_{\sigma\longrightarrow 1^+}\left\{\mathcal{R}_2(\sigma) - \frac{4}{(\sigma-1)^2}\right\}(\sigma-1) = 4 + C_2. \qquad (3.17)$$

Now in view of (2.5), $\mathcal{R}_2(s)$ has a pole at $s=1$ of order 2. So the limit in (3.17) in fact is the residue of $\mathcal{R}_2(s)$ at $s=1$ which can be evaluated by the method in §5 below and it is equal to

$$4\left(2\gamma+\frac{8}{\pi}L'_{-4}(1)-\frac{12}{\pi^2}\zeta'(2)+\frac{1}{3}\log 2\right).$$

This completes the proof of (3.14)

It is also worth to note that Sierpinski's result has been slightly improved and so the error term in (3.14) could be improved accordingly. For example, the term $O(x^{2/3})$ can be replaced by $O(x^{284/429})$ if we employ Nowak's result in [19] which replaces the term $O(x^{1/3})$ in (3.13) by $O(x^{139/429})$.

We now consider the case $N=4$. In view of Theorem 3.2, $\mathcal{R}_4(s)/\zeta(s-2)$ is equal to the product of a finite Dirichlet series and the five Dirichlet series $\zeta(s-1),\zeta(s-1),\zeta(s),\zeta^{-1}(2s-2)$ and $(1+2^{1-s})^{-1}$, each of which has the property that the coefficient of n^{-s} is $O(n)$. Hence from the formula for $\mathcal{R}_4(s)$ in Theorem 3.2,

$$\mathcal{R}_4(s)=\zeta(s-2)\sum_{n=1}^{\infty}g_n n^{-s},$$

where $|g_n|=O(nd_5(n))$ and $d_k(n)$ is the number of ways of expressing n in the form $n=n_1n_2\cdots n_k$ with $n_1,n_2,\cdots,n_k$ positive integers. It follows that

$$\begin{aligned}
\sum_{n\le x}r_4^2(n) &= \sum_{n\le x}g_n\sum_{m\le x/n}m^2\\
&= \sum_{n\le x}g_n\left(\frac{1}{3}\left(\frac{x}{n}\right)^3+O\left(\frac{x^2}{n^2}\right)\right)\\
&= \frac{x^3}{3}\sum_{n=1}^{\infty}\frac{g_n}{n^3}+O\left(x^3\left|\sum_{n>x}\frac{g_n}{n^3}\right|\right)+O\left(x^2\sum_{n\le x}\frac{|g_n|}{n^2}\right)\\
&= \frac{x^3}{3}\sum_{n=1}^{\infty}\frac{g_n}{n^3}+O\left(x^3\sum_{n>x}\frac{d_5(n)}{n^2}\right)+O\left(x^2\sum_{n\le x}\frac{d_5(n)}{n}\right)\\
&= \frac{x^3}{3}\sum_{n=1}^{\infty}\frac{g_n}{n^3}+O(x^2\log^5 x)
\end{aligned}$$

because $\sum_{n\le x}d_k(n)\sim xP_k(\log x)$ for some polynomial $P_k(X)$ of degree $k-1$ (see Chapter XII in [26]). Now since

$$\sum_{n=1}^{\infty}\frac{g_n}{n^3}=\lim_{s\longrightarrow 3^+}\mathcal{R}_4(s)/\zeta(s-2)=\lim_{\epsilon\longrightarrow 0}\epsilon\mathcal{R}_4(3+\epsilon)=3W_4$$

so we have

$$\sum_{n\le x}r_4^2(n)=W_4x^3+O(x^2\log^5 x).$$

The cases for $N=6$ and $N=8$ can be treated in the same manner as

$$\mathcal{R}_6(s)=\zeta(s-4)\sum_{n=1}^{\infty}\frac{b_n}{n^s}+L_{-4}(s-4)\sum_{n=1}^{\infty}\frac{c_n}{n^s}$$

and

$$\mathcal{R}_8(s) = \zeta(s-6)\sum_{n=1}^{\infty}\frac{d_n}{n^s}$$

where b_n and c_n are $\ll n^2 d_5(n)$ and d_n is $\ll n^3 d_5(n)$. Therefore, we have

$$\sum_{n\le x} r_N^2(n) = W_N x^{N-1} + O(x^{N-2}) \tag{3.18}$$

for $N = 6, 8$ with W_N given by (1.3).

For $N \neq 2, 4, 6, 8$, lacking the closed forms for $\mathcal{R}_N(s)$, we can't follow the argument above to estimate the average order for $r_N^2(n)$. However, as suggested by the referee, the asymptotic value for $\sum_{n\le x} r_N^2(n)$, at least for $N \ge 5$, can be obtained from the singular series formula for $r_N(n)$ given by Hardy (see p.342 of [12] or p.155 of [11]), which may be written as

$$r_N(n)\frac{\Gamma(N/2)}{\pi^{N/2}}n^{1-N/2} = \sum_{k=1}^{\infty}\sum_{\substack{1\le h\le k\\(h,k)=1}}\left(\frac{G(h,k)}{k}\right)^N e^{-2\pi i h n/k} + O(n^{1-N/4}) \tag{3.19}$$

where $G(h,k) = \sum_{j=1}^{k} e^{2\pi i h j^2/k}$ is the standard quadratic Gauss sum. In fact, using a well-known result on quadratic Gauss sum (e.g. p.138 of [11])

$$|G(h,k)| = \begin{cases} \sqrt{k} & \text{if } k \equiv 1 \pmod 2;\\ 0 & \text{if } k \equiv 2 \pmod 4;\\ \sqrt{2k} & \text{if } k \equiv 0 \pmod 4; \end{cases} \tag{3.20}$$

for $(h,k) = 1$, we have

$$\begin{aligned} r_N(n)\frac{\Gamma(N/2)}{\pi^{N/2}}n^{1-N/2} &= \sum_{k\le x^{1/2}}\sum_{\substack{1\le h\le k\\(h,k)=1}}\left(\frac{G(h,k)}{k}\right)^N e^{-2\pi i h n/k} + O(x^{1-N/4})\\ &:= P(n) + O(x^{1-N/4}) \end{aligned}$$

for $N \ge 5$ and $n \le x$. By (3.20), we have $|P(n)| \ll 1$ and hence

$$r_N(n)^2 = \frac{\pi^N}{\Gamma(N/2)^2}n^{N-2}|P(n)|^2 + O(x^{3N/4-1}).$$

It follows that

$$\sum_{n\le x} r_N(n)^2 = \frac{\pi^N}{\Gamma(N/2)^2}\sum_{n\le x} n^{N-2}|P(n)|^2 + O(x^{3N/4}). \tag{3.21}$$

It remains to estimate the sum $\sum_{n\le x} n^{N-2}|P(n)|^2$ which is equal to

(3.22)

$$\sum_{1\le k_1,k_2\le x^{1/2}}\sum_{\substack{1\le h_i\le k_i\\(h_i,k_i)=1,i=1,2}}\left(\frac{G(h_1,k_1)}{k_1}\right)^N\left(\frac{\overline{G(h_2,k_2)}}{k_2}\right)^N\sum_{n\le x} n^{N-2}e^{-2\pi i n(\frac{h_1}{k_1}-\frac{h_2}{k_2})}.$$

We now note that when $\frac{h_1}{k_1} \neq \frac{h_2}{k_2}$, we have

$$\left| \sum_{n \leq x} e^{-2\pi i n(\frac{h_1}{k_1} - \frac{h_2}{k_2})} \right| \leq k_1 k_2$$

and hence the contribution for those terms $\frac{h_1}{k_1} \neq \frac{h_2}{k_2}$ to (3.22) is

$$\ll x^{N-2} \left(\sum_{k \leq x^{1/2}} k^{2-N/2} \right)^2.$$

Using this, (3.22) and (3.21), we have

$$\begin{aligned} \sum_{n \leq x} r_N(n)^2 &= \frac{\pi^N}{(N-1)\Gamma(N/2)^2} \left(\sum_{k \leq x^{1/2}} B(k) \right) x^{N-1} + O(x^{N-2} + x^{3N/4}) \\ &= \frac{\pi^N}{(N-1)\Gamma(N/2)^2} \left(\sum_{k=1}^{\infty} B(k) \right) x^{N-1} + O(x^{N-2} + x^{3N/4}) \end{aligned}$$

where

$$B(k) := \sum_{\substack{1 \leq h \leq k \\ (h,k)=1}} \left| \frac{G(h,k)}{k} \right|^{2N}.$$

Note that when $N = 6$, we have a better error term in (3.18). The function $k \to B(k)$ is multiplicative in k (see p.156 of [11]) and from (3.20), $B(1) = 1, B(2) = 0, B(2^l) = 2^{-N(l-1)}\phi(2^l)$ for any $l \geq 2$ and $B(p^j) = p^{-Nj}\phi(p^j)$ for any $j \geq 1$ and odd prime p. It then follows from the Euler product formula that

$$\sum_{k=1}^{\infty} B(k) = (1 - 2^{-(N-1)})^{-1} \prod_{p>3} \frac{1 - p^{-N}}{1 - p^{-(N-1)}} = \frac{1}{(1 - 2^{-N})} \frac{\zeta(N-1)}{\zeta(N)}.$$

We finally conclude that

Theorem 3.3. *We have*

$$\sum_{n \leq x} r_2^2(n) = 4x \log x + 4\alpha x + O(x^{2/3})$$

$$\sum_{n \leq x} r_4^2(n) = W_4 x^3 + O(x^2 \log^5 x)$$

and

$$\sum_{n \leq x} r_6^2(n) = W_6 x^5 + O(x^4)$$

For $N \geq 5, N \neq 6$ and $x \geq 1$, we have

$$\sum_{n \leq x} r_N^2(n) = W_N x^{N-1} + O(x^{N-2} + x^{3N/4}).$$

Here $\alpha = 2\gamma + \frac{8}{\pi} L'_{-4}(1) - \frac{12}{\pi^2}\zeta'(2) + \frac{1}{3}\log 2 - 1 = 2.0166216\cdots$.

This proves Wagon's conjecture for $N \geq 4$. Theorem 3.3 can also be found in [8] and it contains the same basic arguments for getting the error bounds on $r_N^2(n)$ summatory for $N \geq 5$. The estimate $O(x^{N-2})$ in fact is the best possible as will be discussed elsewhere.

4. Closed Forms for Dirichlet Series of Quadratic Forms

There is a rich parallel theory of L-functions over imaginary quadratic fields. In this vein, let $r_{2,P}(n)$ be the number of solutions to $x^2 + Py^2 = n$ (again counting sign and order). Denote

$$\mathcal{L}_{2,P}(s) := \sum_{n=1}^{\infty} r_{2,P}(n) n^{-s}, \qquad \mathcal{R}_{2,P}(s) := \sum_{n=1}^{\infty} r_{2,P}(n)^2 n^{-s}.$$

It is known that when the quadratic form $x^2 + Py^2$ has disjoint discriminants (that is, it has exactly one form per genus), then one has the following formula (see (9.2.8) in [3])

$$\begin{aligned} \mathcal{L}_{2,P} &= 2^{1-t} \sum_{\mu | P} L_{\epsilon_\mu \mu}(s) L_{-4P\epsilon_\mu/\mu}(s) \\ &= \sum_{n=1}^{\infty} \left\{ 2^{1-t} \sum_{\mu | P} \left(\frac{\epsilon_\mu \mu}{n}\right) * \left(\frac{-4P\epsilon_\mu/\mu}{n}\right) \right\} n^{-s} \end{aligned} \tag{4.1}$$

where P is an odd square-free number, t is the number of distinct factors of P and $\epsilon_\mu := \left(\frac{-1}{\mu}\right)$.

Explicitly, (4.1) holds for all *type one* numbers. These include and may comprise:

$$P = 5, 13, 21, 33, 37, 57, 85, 93, 105, 133, 165, 177, 253, 273, 345, 357, 385, 1365.$$

It is known that there are only finitely many such disjoint discriminants. We call such P **solvable**. Using (4.1), we have

$$\begin{aligned} \mathcal{R}_{2,P}(s) &= \sum_{n=1}^{\infty} 2^{2-2t} \sum_{\mu_1 \mu_2 | P} \left[\left(\frac{\epsilon_{\mu_1}\mu_1}{n}\right) * \left(\frac{-4P\epsilon_{\mu_1}/\mu_1}{n}\right) \right] \cdot \left[\left(\frac{\epsilon_{\mu_2}\mu_2}{n}\right) * \left(\frac{-4P\epsilon_{\mu_2}/\mu_2}{n}\right) \right] n^{-s} \\ &= 2^{2-2t} \sum_{\mu_1 \mu_2 | P} \sum_{n=1}^{\infty} \left[\left(\frac{\epsilon_{\mu_1}\mu_1}{n}\right) * \left(\frac{-4P\epsilon_{\mu_1}/\mu_1}{n}\right) \right] \cdot \left[\left(\frac{\epsilon_{\mu_2}\mu_2}{n}\right) * \left(\frac{-4P\epsilon_{\mu_2}/\mu_2}{n}\right) \right] n^{-s}. \end{aligned}$$

We now notice that $\mathcal{R}_{2,P}(s)$ is a sum of Dirichlet series in the form of Theorem 2.1. We may apply Theorem 2.1 on letting

$$f_i(n) := \left(\frac{\epsilon_{\mu_i}\mu_i}{n}\right), \qquad g_i(n) := \left(\frac{-4P\epsilon_{\mu_i}/\mu_i}{n}\right),$$

for $i = 1, 2$. Then

$$\begin{aligned} L_{f_1 f_2}(s) &= \sum_{n=1}^{\infty} \left(\frac{\epsilon_{\mu_1}\mu_1}{n}\right)\left(\frac{\epsilon_{\mu_2}\mu_2}{n}\right) n^{-s} \\ &= \sum_{\substack{n=1 \\ (n,(\mu_1,\mu_2))=1}}^{\infty} \left(\frac{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}{n}\right) n^{-s} \\ &= L_{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}(s) \prod_{p|(\mu_1,\mu_2)} \left(1 - \left(\frac{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}{p}\right) p^{-s}\right) \end{aligned}$$

where $\mu_i^* := \mu_i/(\mu_1, \mu_2)$ and $\prod_{p|n}$ denotes the product over all prime factors of n. Similarly, we have

$$L_{g_1 g_2}(s) = L_{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}(s) \prod_{p|\frac{2P}{(\mu_1,\mu_2)}} \left(1 - \left(\frac{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}{p}\right) p^{-s}\right);$$

$$L_{f_1 g_2}(s) = L_{-4P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}(s) \prod_{p|\mu_1^*} \left(1 - \left(\frac{-4P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}{p}\right) p^{-s}\right);$$

$$L_{f_2 g_1}(s) = L_{-4P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}(s) \prod_{p|\mu_2^*} \left(1 - \left(\frac{-4P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}{p}\right) p^{-s}\right)$$

and

$$L_{f_1 f_2 g_1 g_2}(s) = \zeta(s) \prod_{p|2P} (1 - p^{-s}).$$

Our basic Theorem 2.1 gives

$$\begin{aligned} \mathcal{R}_{2,P}(s) = 2^{2(1-t)} &\sum_{\mu_1,\mu_2|P} L^2_{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}(s) L^2_{-4P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}(s) \zeta(2s)^{-1} \\ &\times \prod_{p|2P} \left\{1 + \left[\left(\frac{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}{p}\right) + \left(\frac{-4P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}{p}\right)\right] p^{-s}\right\}^{-1}. \end{aligned}$$

We have similar closed forms of L-functions for the quadratic form $x^2 + 2Py^2$ with discriminant $-8P$ (see (9.2.9) in [3]):

$$\mathcal{L}_{2,2P} = 2^{1-t} \sum_{\mu|P} L_{\epsilon_\mu \mu}(s) L_{-8P\epsilon_\mu/\mu}(s).$$

We deduce from Theorem 2.1, in the same way, that

$$\begin{aligned} \mathcal{R}_{2,2P}(s) = 2^{2(1-t)} &\sum_{\mu_1,\mu_2|P} L^2_{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}(s) L^2_{-8P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}(s) \zeta(2s)^{-1} \\ &\times \prod_{p|2P} \left\{1 + \left[\left(\frac{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}{p}\right) + \left(\frac{-8P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}{p}\right)\right] p^{-s}\right\}^{-1} \end{aligned}$$

for the *type two* integers

$$P = 1, 3, 5, 11, 15, 21, 29, 35, 39, 51, 65, 95, 105, 165, 231.$$

We note that $210 = 2 \times 105$ yields the invariant which Ramanujan sent to Hardy in his famous letter.

We may reprise with the following theorem:

Theorem 4.1. *Let P be a solvable square-free integer and let t be the number of distinct factors of P. We have for P respectively of type one and type two:*

$$\mathcal{R}_{2,P}(s) = 2^{2(1-t)} \sum_{\mu_1,\mu_2|P} L^2_{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}(s) L^2_{-4P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}(s)\zeta(2s)^{-1} \times \prod_{p|2P}\left\{1+\left[\left(\frac{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}{p}\right)+\left(\frac{-4P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}{p}\right)\right]p^{-s}\right\}^{-1}, \tag{4.2}$$

and

$$\mathcal{R}_{2,2P}(s) = 2^{2(1-t)} \sum_{\mu_1,\mu_2|P} L^2_{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}(s) L^2_{-8P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}(s)\zeta(2s)^{-1} \times \prod_{p|2P}\left\{1+\left[\left(\frac{\epsilon_{\mu_1^*\mu_2^*}\mu_1^*\mu_2^*}{p}\right)+\left(\frac{-8P\epsilon_{\mu_1^*\mu_2^*}/\mu_1^*\mu_2^*}{p}\right)\right]p^{-s}\right\}^{-1}$$

where $\epsilon_\mu = \left(\frac{-1}{\mu}\right)$ and $\mu_i^* = \mu_i/(\mu_1,\mu_2)$.

In particular, the prime cases provide:

Corollary 4.2. *We have*

$$\mathcal{R}_{2,p}(s) = \frac{2\zeta^2(s)L^2_{-4p}(s)}{(1+2^{-s})(1+p^{-s})\zeta(2s)} + \frac{2L^2_p(s)L^2_{-4}(s)}{(1-2^{-s})(1+p^{-s})\zeta(2s)}$$

for $p = 5, 13, 37$, while

$$\mathcal{R}_{2,2}(s) = \frac{4\zeta^2(s)L^2_{-8}(s)}{(1+2^{-s})\zeta(2s)}.$$

Similarly,

$$\mathcal{R}_{2,2p}(s) = \frac{2\zeta^2(s)L^2_{-8p}(s)}{(1+2^{-s})(1+p^{-s})\zeta(2s)} + \frac{2L^2_{-p}(s)L^2_8(s)}{(1-2^{-s})(1-p^{-s})\zeta(2s)},$$

for $p = 3, 11$ while

$$\mathcal{R}_{2,2p}(s) = \frac{2\zeta^2(s)L^2_{-8p}(s)}{(1+2^{-s})(1+p^{-s})\zeta(2s)} + \frac{2L^2_p(s)L^2_{-8}(s)}{(1-2^{-s})(1-p^{-s})\zeta(2s)}$$

for $p = 5, 29$.

Closed forms for $\mathcal{L}_{2,P}(s)$ are also accessible for some P other than those of *type one* or *type two*. For example, (see Table VI of [10]) one has

$$\mathcal{L}_{2,3}(s) = (2+4^{1-s})\,\zeta(s)L_{-3}(s). \tag{4.3}$$

and hence by Theorem 2.1 and Lemma 3.1, we obtain

$$\mathcal{R}_{2,3}(s) = 4\frac{1+2^{3-2s}}{1+3^{-s}}\frac{(\zeta(s)\,L_{-3}(s))^2}{\zeta(2s)}. \tag{4.4}$$

We may also derive many formulae for non-square free integers via modular transformations [3]. We contain ourselves with the simplest example which is

$$\mathcal{R}_{2,4}(s) = \frac{4 - 2^{2-s} + 2^{4-2s}}{1 + 2^{-s}} \frac{(\zeta(s)\, L_{-4}(s))^2}{\zeta(2s)}$$

as a consequence of a quadratic transformation leading to

$$\mathcal{L}_{2,4}(s) = (2^{-1} - 2^{-1-s} + 4^{-s})\mathcal{L}_2(s).$$

There are some simple closed forms of the generating functions for more general binary quadratic forms found in [10]. Let

$$\mathcal{L}_{(a,b,c)}(s) := \sum_{(n,m)\neq(0,0)} \frac{1}{(am^2 + bmn + cn^2)^s} = \sum_{n=1}^{\infty} \frac{r_{(a,b,c)}(n)}{n^s}$$

and $\mathcal{R}_{(a,b,c)}(s) := \sum_{n=1}^{\infty} \frac{r_{(a,b,c)}(n)^2}{n^s}$ where $r_{(a,b,c)}(n)$ is the number of representations of n by the quadratic form $ax^2 + bxy + cy^2$. Then, we have (e.g. (26) of [25])

$$\sum_{h(D)} \mathcal{L}_{(a,b,c)}(s) = \omega(D)\zeta(s)L_D(s)$$

where the sum is taken over the $h(D)$ inequivalent reduced quadratic forms of discriminant $D := b^2 - 4ac$ and $\omega(-3) = 6, \omega(-4) = 4$ and $\omega(D) = 2$ for $D < -4$. In particular, for $c = 2, 3, 5, 11, 17, 41$, $h(D) = 1$ and the result is especially simple:

$$\mathcal{L}_{(1,1,c)}(s) = 2\zeta(s)L_D(s).$$

Hence from Theorem 2.1, we have

$$\mathcal{R}_{(1,1,c)}(s) = \frac{4(\zeta(s)L_D(s))^2}{(1 + |D|^{-s})\zeta(2s)},$$

with similar formulae for $(a, b, c) = (1, 1, 1)$ and $(1, 0, 1)$.

Thanks to the *On-Line Encyclopedia of Integer Sequences*

`http://www.research.att.com/~njas/sequences/`

we discover that the sequence $2, 3, 5, 11, 17, 41$ is exactly the so-called Euler "lucky" numbers which are the numbers n such that $m \to m^2 - m + n$ has prime values for $m = 0, \cdots, n - 1$.

5. The Average Order of $r_{2,P}(n)$

We start with the average order of $r_{2,P}$. The results in this section, in fact, can be obtained by a convolution argument such as we used to prove (3.18) in §3. This, however, does not seem to yield better error estimates, especially in the power of N, in Theorem 5.1 and 5.3 below. So we instead apply Perron's formula. Both methods would seem to add an unnecessary if unobtrusive 'ε'.

Theorem 5.1. *Let P be a solvable square-free integer, $x > 1$ and $\epsilon > 0$. We have for either $N = P$ of type one or $N = 2P$ of type two:*

$$\sum_{n\leq x} r_{2,N}(n) = \frac{\pi}{\sqrt{N}}x + O((xN)^{\frac{1}{2}+\epsilon}).$$

where the implicit constants are independent of x and P.

Proof. In view of (4.1), we have for $n \geq 1$

$$r_{2,P}(n) = 2^{1-t} \sum_{\mu|P} \left(\frac{\epsilon_\mu \mu}{n}\right) * \left(\frac{-4P\epsilon_\mu/\mu}{n}\right) \leq 2^{1-t} \sum_{\mu|P} \sigma_0(n) \leq 2\sigma_0(n). \tag{5.1}$$

It follows from (1.1) that

$$\mathcal{L}_{2,P}(\sigma) \ll \sum_{n=1}^{\infty} \frac{\sigma_0(n)}{n^\sigma} = \zeta(\sigma)^2 \ll \frac{1}{(\sigma-1)^2}$$

as $\sigma \to 1^+$. Now in view of Perron's formula (see Theorem 1 in §1 of Chapter V in [16]), for any $c > 1$, $\epsilon > 0$ and $x, T \geq 1$ we have

$$\sum_{n \leq x} r_{2,P}(n) = \frac{1}{2\pi i} \int_{c-iT}^{c+iT} \mathcal{L}_{2,P}(s) \frac{x^s}{s} ds + O(x^c T^{-1}(c-1)^{-2} + x^{1+\epsilon} T^{-1}). \tag{5.2}$$

In order to evaluate the above integral, we need the following well-known estimates for $\zeta(s)$ and L-functions.

Lemma 5.2. *We have*

$$\zeta(\sigma + i\xi) \ll \begin{cases} \frac{1}{\sigma-1} & \text{if } 1 < \sigma \leq 2 \text{ and } \xi = 0 \\ \log|\xi| & \text{if } 1 \leq \sigma \text{ and } |\xi| \geq e \\ |\xi|^{\frac{1-\sigma}{2}} \log|\xi| & \text{if } 0 \leq \sigma \leq 1 \text{ and } |\xi| \geq e \end{cases}$$

and

$$\frac{1}{\zeta(\sigma + i\xi)} \ll \log^7 |\xi|$$

if $\sigma \geq 1$ and $|\xi| \geq e$. If χ is a non-principal character modulo q, we have

$$L(\sigma + i\xi, \chi) \ll \log q(|\xi| + 2)$$

for $\sigma \geq 1$ while if χ is a primitive character modulo $q \geq 3$ and $0 \leq \sigma \leq 1$, then

$$L(\sigma + i\xi, \chi) \ll (q(|\xi| + 2))^{\frac{1-\sigma}{2}} \log q(|\xi| + 2).$$

As usual, we estimate the integral in (5.2) by replacing the integral over the rectangle R with vertices $b \pm iT$ and $c \pm iT$ with $b = \frac{1}{\log x}$ and then calculate the residues of the poles of the integrand inside R. In view of (4.2), the only pole of $\mathcal{R}_{2,P}(s)\frac{x^s}{s}$ inside R is $s = 1$, which comes from $\zeta(s)$, and its residue at $s = 1$ is $2^{1-t} L_{-4P}(1)x$ because $\lim_{s\to 1}(s-1)\zeta(s) = 1$.

For solvable P, i.e, $x^2 + Py^2$ having one form per genus, the class number equals the number of genera — which is 2^t (see p. 198 of [24]). Hence $L_{-4P}(1) = \frac{2^{t-1}\pi}{\sqrt{P}}$ for type one P and $L_{-8P}(1) = \frac{2^{t-1}\pi}{\sqrt{2P}}$ for type two P by (4.11) in [11]. Thus, the residue of $\mathcal{R}_{2,P}(s)\frac{x^s}{s}$ at $s = 1$ is $\frac{\pi}{\sqrt{P}}x$.

Next, using the estimates in Lemma 5.2 and (4.2), we may prove that for $|\xi| \leq T$,

$$\mathcal{L}_{2,P}(\sigma + i\xi) \ll \begin{cases} (P(|\xi| + 2))^{(1-\sigma)} \log^2(PT) & \text{if } b \leq \sigma \leq 1, \\ \log^2(PT) & \text{if } 1 \leq \sigma \leq c. \end{cases}$$

It then follows that

$$\begin{aligned}\frac{1}{2\pi i}\int_{b-iT}^{b+iT}\mathcal{L}_{2,P}(s)\frac{x^s}{s}ds &\ll \int_{-T}^{T}|\mathcal{L}_{2,P}(b+i\xi)|\frac{x^b}{|b+i\xi|}d\xi \\ &\ll PT\log^2(PT) \qquad (5.3)\end{aligned}$$

and

$$\begin{aligned}&\frac{1}{2\pi i}\int_{b\pm iT}^{c\pm iT}\mathcal{L}_{2,P}(s)\frac{x^s}{s}ds \\ &\ll \left\{\int_b^1+\int_1^c\right\}|\mathcal{L}_{2,P}(\sigma\pm iT)|\frac{x^\sigma}{T}d\sigma \\ &\ll P(\log PT)^2\int_b^1\left(\frac{x}{PT}\right)^\sigma d\sigma + T^{-1}(\log PT)^2\int_1^c x^\sigma d\sigma \\ &\ll x^cT^{-1}\log^2(PT)\log x. \qquad (5.4)\end{aligned}$$

Now by choosing $c=1+\frac{1}{\log x}$ and $T=(x/P)^{\frac{1}{2}}$, we get from (5.2)–(5.4) that

$$\sum_{n\le x}r_{2,P}(n)=\frac{\pi}{\sqrt{P}}x+O((xP)^{\frac{1}{2}+\epsilon}).$$

The case for type two P can be proved in the same way. This completes the proof of Theorem 5.1. □

For any square-free integer N, we define a constant α by:

$$\alpha(N):=2\gamma+\sum_{p|2N}\frac{\log p}{p+1}+2\frac{L'_{-4N}(1)}{L_{-4N}(1)}-\frac{12}{\pi^2}\zeta'(2)-1 \qquad (5.5)$$

where γ is Euler's constant and $\sum_{p|n}$ is the summation over all prime factors of n.

Theorem 5.3. *Let P be a solvable square-free integer. Let $x>1$ and $\epsilon>0$. We have for either $N=P$ of type one or $N=2P$ of type two:*

$$\sum_{n\le x}r_{2,N}(n)^2=\frac{3}{N}\left(\prod_{p|2N}\frac{2p}{p+1}\right)(x\log x+\alpha(N)x)+O(N^{\frac{1}{4}+\epsilon}x^{\frac{3}{4}+\epsilon})$$

where the implicit constants are independent of both x and P.

Proof. It follows from (1.2) and (5.1) that

$$\mathcal{R}_{2,P}(\sigma)\ll\sum_{n=1}^{\infty}\frac{\sigma_0(n)^2}{n^\sigma}=\frac{\zeta^4(\sigma)}{\zeta(2\sigma)}\ll\frac{1}{(\sigma-1)^4}$$

as $\sigma\to1^+$. Similar to (5.2), for any $c>1$, $\epsilon>0$ and $x,T\ge1$, we have

$$\sum_{n\le x}r_{2,P}(n)^2=\frac{1}{2\pi i}\int_{c-iT}^{c+iT}\mathcal{R}_{2,P}(s)\frac{x^s}{s}ds+O(x^cT^{-1}(c-1)^{-4}+x^{1+\epsilon}T^{-1}). \qquad (5.6)$$

We estimate the integral in (5.3) by replacing the integral over the rectangle R with vertices $\frac{1}{2}\pm iT$ and $c\pm iT$ and then calculate the residues of the poles of the integrand inside R. In view of (4.2), the only pole of $\mathcal{R}_{2,P}(s)\frac{x^s}{s}$ inside R is $s=1$

of order 2 which comes from $\zeta(s)^2$ and corresponds to the terms when $\mu_1 = \mu_2$ in the double summation of (4.2):

$$2^{2(1-t)}\sigma_0(P)\zeta(s)^2 L_{-4P}(s)^2\zeta(2s)^{-1}\prod_{p|2P}(1+p^{-s})^{-1}\frac{x^s}{s} := F(s) \tag{5.7}$$

and its residue at $s = 1$ is

$$\begin{aligned} &= \lim_{s\to 1}\frac{d}{ds}\left\{(s-1)^2F(s)\right\} \\ &= \lim_{s\to 1}(s-1)^2F(s)\lim_{s\to 1}\frac{d}{ds}\log\left\{(s-1)^2F(s)\right\}. \end{aligned}$$

Since P is solvable, so

$$\begin{aligned} \lim_{s\to 1}(s-1)^2F(s) &= 2^{2(1-t)}\sigma_0(P)L_{-4P}^2(1)\zeta(2)^{-1}\prod_{p|2P}(1+p^{-1})^{-1}x \\ &= \frac{3}{P}\left(\prod_{p|2P}\frac{2p}{p+1}\right)x. \end{aligned}$$

In view of (5.5) and (5.7), we have

$$\begin{aligned} &\lim_{s\to 1}\frac{d}{ds}\log\left\{(s-1)^2F(s)\right\} \\ = \;& 2\gamma + \sum_{p|2P}\frac{\log p}{p+1} + 2\frac{L'_{-4P}(1)}{L_{-4P}(1)} - \frac{12}{\pi^2}\zeta'(2) - 1 + \log x \\ = \;& \alpha(P) + \log x \end{aligned}$$

because $\lim_{s\to 1}\left(\frac{1}{s-1} + \frac{\zeta'(s)}{\zeta(s)}\right) = \gamma$. Therefore the residue of $\mathcal{R}_{2,P}(s)\frac{x^s}{s}$ at $s = 1$ is

$$\frac{3}{P}\left(\prod_{p|2P}\frac{2p}{p+1}\right)(x\log x + \alpha(P)x). \tag{5.8}$$

Next using the estimates in Lemma 5.2 and (4.2), one can prove that for $|\xi| \le T$,

$$\mathcal{R}_{2,P}(\sigma + i\xi) \ll \begin{cases} P^{(1-\sigma)+\epsilon}(|\xi|+2)^{2(1-\sigma)}\log^A T & \text{if } \frac{1}{2} \le \sigma \le 1, \\ P^{\epsilon}\log^A T & \text{if } 1 \le \sigma \le c. \end{cases}$$

It then follows that

$$\begin{aligned} \frac{1}{2\pi i}\int_{\frac{1}{2}-iT}^{\frac{1}{2}+iT}\mathcal{R}_{2,P}(s)\frac{x^s}{s}ds &\ll \int_{-T}^{T}|\mathcal{R}_{2,P}(\frac{1}{2}+i\xi)|\frac{x^{\frac{1}{2}}}{|\frac{1}{2}+i\xi|}d\xi \\ &\ll P^{\frac{1}{2}+\epsilon}x^{\frac{1}{2}}T\log^A T \end{aligned} \tag{5.9}$$

and

$$\begin{aligned}
&\frac{1}{2\pi i}\int_{\frac{1}{2}\pm iT}^{c\pm iT}\mathcal{R}_{2,P}(s)\frac{x^s}{s}ds\\
\ll\ &\left\{\int_{\frac{1}{2}}^{1}+\int_{1}^{c}\right\}|\mathcal{R}_{2,P}(\sigma\pm iT)|\frac{x^\sigma}{T}d\sigma\\
\ll\ &P^{1+\epsilon}T(\log T)^A\int_{\frac{1}{2}}^{1}\left(\frac{x}{PT^2}\right)^\sigma d\sigma+P^\epsilon T^{-1}(\log T)^A\int_1^c x^\sigma\,d\sigma\\
\ll\ &P^\epsilon x^c T^{-1}\log^A T. \qquad (5.10)
\end{aligned}$$

Now by choosing $c=1+\frac{1}{\log x}$ and $T=(x/P)^{\frac{1}{4}}$, we get from (5.6) and (5.8)-(5.10) that

$$\sum_{n\le x}r_{2,P}(n)^2=\frac{3}{P}\left(\prod_{p|2P}\frac{2p}{p+1}\right)(x\log x+\alpha(P)x)+O(P^{\frac{1}{4}+\epsilon}x^{\frac{3}{4}+\epsilon}).$$

The case for type two P can be proved in the same way. This completes the proof of Theorem 5.3. □

In particular, we have established:

Theorem 5.4. *For any $x\ge 1$, we have*

$$\sum_{n\le x}r_{2,p}(n)^2=\frac{8}{p+1}(x\log x+\alpha(p)x)+O(x^{\frac{3}{4}+\epsilon})$$

for $p=5,13,37$ and

$$\sum_{n\le x}r_{2,2p}(n)^2=\frac{4}{p+1}(x\log x+\alpha(2p)x)+O(x^{\frac{3}{4}+\epsilon})$$

for $p=1,3,5,11,29$. Here the implicit constants are again independent of x.

Similarly, in view of (4.3) and (4.4), we have for $x>1$,

$$\sum_{n\le x}r_{2,3}(n)=\frac{\pi}{\sqrt{3}}x+O(x^{\frac{1}{2}+\epsilon})$$

and

$$\sum_{n\le x}r_{2,3}(n)^2=2(x\log x+\alpha_3 x)+O(x^{\frac{3}{4}+\epsilon}) \qquad (5.11)$$

where $\alpha_3:=2\gamma-\frac{4}{3}\log 2+\frac{1}{4}\log 3+\frac{6\sqrt{3}}{\pi}L'_{-3}(1)-\frac{12}{\pi^2}\zeta'(2)-1$.

Also

$$\sum_{n\le x}r_{2,4}(n)=\frac{\pi}{2}x+O(x^{\frac{1}{2}+\epsilon})$$

and

$$\sum_{n\le x}r_{2,4}(n)^2=\frac{3}{2}(x\log x+\alpha_4 x)+O(x^{\frac{3}{4}+\epsilon})$$

where $\alpha_4:=2\gamma-\frac{2}{3}\log 2+\frac{8}{\pi}L'_{-4}(1)-\frac{12}{\pi^2}\zeta'(2)-1$.

Akin to Wagon's conjecture, we make the following conjecture.

Quadratic Conjecture. *For any square-free P,*

$$\sum_{n\le x} r_{2,P}(n) \sim \frac{\pi}{\sqrt{P}}x$$

and

$$\sum_{n\le x} r_{2,P}(n)^2 \sim \frac{3}{P}\left(\prod_{p|2P}\frac{2p}{p+1}\right) x\log x$$

as $x\to\infty$.

In view of Theorem 5.3, (3.14) and (5.11), our conjecture is true for solvable P and for $P=1,3$. We have also confirmed it for $P=7$ and 15 from the representations of

$$\mathcal{L}_{2,7}(s) = 2\,(1-2^{1-s}+2^{1-2s})\zeta(s)L_{-7}(s)$$

and

$$\mathcal{L}_{2,15}(s) = (1-2^{1-s}+2^{1-2s})\zeta(s)L_{15}(s) + (1+2^{1-s}+2^{1-2s})L_{-3}(s)L_5(s)$$

again given in [10], which leads to

$$\mathcal{R}_{2,7}(s) = 4\frac{(1-3\cdot 2^{-s}+2^{2-2s})}{(1+2^{-s})(1+7^{-s})}\frac{(\zeta(s)L_{-7}(s))^2}{\zeta(2s)}$$

and

$$\mathcal{R}_{2,15}(s) = \frac{2(1-3\cdot 2^{-s}+2^{2-2s})}{(1+2^{-s})(1+3^{-s})(1+5^{-s})}\frac{(\zeta(s)L_{-15}(s))^2}{\zeta(2s)} + \frac{2(1+3\cdot 2^{-s}+2^{2-2s})}{(1-2^{-s})(1-3^{-s})(1-5^{-s})}\frac{(L_{-3}(s)L_5(s))^2}{\zeta(2s)},$$

and may be analyzed by the methods above.

6. Sums of Three Squares and Other Powers

6.1. **Three Squares.** Odd squares are notoriously less amenable to closed forms. In this subsection, we primarily record some results for $r_3(n)$, the number of representations of n as a sum of three squares. Following Hardy, Bateman in [2] gives the following formula for $r_3(n)$. Let

$$\chi_2(n) := \begin{cases} 0 & \text{if } 4^{-a}n \equiv 7 \pmod 8;\\ 2^{-a} & \text{if } 4^{-a}n \equiv 3 \pmod 8;\\ 3\cdot 2^{-1-a} & \text{if } 4^{-a}n \equiv 1,2,5,6 \pmod 8\end{cases}$$

where a is the highest power of 4 dividing n.

Then

$$r_3(n) = \frac{16\sqrt{n}}{\pi}L_{-4n}(1)\,\chi_2(n) \times \prod_{p^2|n}\left(\frac{p^{-\tau}-1}{p^{-1}-1}+p^{-\tau}\left(1-\frac{1}{p}\left(\frac{-p^{-2\tau}n}{p}\right)\right)^{-1}\right) \tag{6.1}$$

where $\tau=\tau_p$ is the highest power of p^2 dividing n.

The Dirichlet series for $r_3(n)$ deriving from (6.1) is not as malleable as those of (3.1)-(3.4), but we are able to derive a nice expression in terms of Bessel functions.

Let K_s be the *modified Bessel function of the second kind.* Then we have (see [27], p. 183)

$$K_s(x) = \frac{1}{2}\left(\frac{x}{2}\right)^s \int_0^\infty e^{-t-\frac{x^2}{4t}} \frac{dt}{t^{s+1}}. \tag{6.2}$$

By the substitution $t = \frac{1}{u}$ in (6.2), we get

$$K_s(x) = \frac{1}{2}\left(\frac{x}{2}\right)^s \int_0^\infty e^{-\frac{x^2 u}{4}-\frac{1}{u}} u^{s-1} du. \tag{6.3}$$

Let

$$\theta_3(q) := \sum_{n=-\infty}^{\infty} q^{n^2}$$

be the classical Jacobean theta function. In view of the Poisson summation formula, we have, for $t > 0$

$$\theta_3(e^{-\pi t}) = t^{-\frac{1}{2}}\theta_3(e^{-\pi/t}).$$

Since the Mellin transform of $e^{-\alpha t}$ for $\alpha \neq 0$ is $M_s(e^{-\alpha t}) = \Gamma(s)\alpha^{-s}$, so we have (letting $q = e^{-\pi t}$)

$$\begin{aligned}
\mathcal{L}_3(s) &= 3\sum_{n,m,p\in\mathbb{Z}} \frac{n^2}{(n^2+m^2+p^2)^{s+1}} \\
&= \frac{3\pi^{s+1}}{\Gamma(s+1)} \sum_{n,m,p\in\mathbb{Z}} n^2 M_{s+1}(q^{n^2+m^2+p^2}) \\
&= \frac{3\pi^{s+1}}{\Gamma(s+1)} M_{s+1}\left(\sum_{n\in\mathbb{Z}} n^2 q^{n^2}\theta_3^2(q)\right) \\
&= \frac{3\pi^{s+1}}{\Gamma(s+1)} \sum_{n\in\mathbb{Z}} n^2 \int_0^\infty e^{-n^2\pi t}\theta_3^2(e^{-\pi/t}) t^{s-1} dt \\
&= \frac{3\pi^{s+1}}{\Gamma(s+1)} \sum_{n\in\mathbb{Z}} n^2 \sum_{m=1}^{\infty} r_2(m) \int_0^\infty e^{-n^2\pi t-\frac{\pi m}{t}} t^{s-1} dt \\
&\quad + \frac{3\pi^{s+1}}{\Gamma(s+1)} \sum_{n\in\mathbb{Z}} n^2 \int_0^\infty e^{-n^2\pi t} t^{s-1} dt. \qquad (6.4)
\end{aligned}$$

The first term of (6.4) is

$$\begin{aligned}
&= \frac{6\pi^{s+1}}{\Gamma(s+1)} \sum_{n=1}^{\infty} n^2 \sum_{m=1}^{\infty} r_2(m) \int_0^\infty e^{-n^2\pi t-\frac{\pi m}{t}} t^{s-1} dt \\
&= \frac{6\pi^{s+1}}{\Gamma(s+1)} \sum_{m=1}^{\infty} r_2(m)(\pi m)^s \sum_{n=1}^{\infty} n^2 \int_0^\infty e^{-n^2\pi^2 m x - 1/x} x^{x-1} dx, \qquad (x = \frac{t}{\pi m}) \\
&= \frac{12\pi^{s+1}}{\Gamma(s+1)} \sum_{m=1}^{\infty} r_2(m) m^{s/2} \sum_{n=1}^{\infty} \frac{1}{n^{s-2}} K_s(2\pi n\sqrt{m})
\end{aligned}$$

by (6.3) and the second term is

$$\begin{aligned} &= \frac{6\pi^{s+1}}{\Gamma(s+1)} \sum_{n=1}^{\infty} \frac{1}{n^{2s-2}\pi^s} \int_0^{\infty} e^{-x} x^{s-1} ds \\ &= \frac{6\pi}{s} \zeta(2s-2). \end{aligned}$$

This proves the following result:

$$\mathcal{L}_3(s) = \frac{6\pi}{s}\zeta(2s-2) + \frac{12\pi^{s+1}}{\Gamma(s+1)} \sum_{m=1}^{\infty} r_2(m) m^{s/2} \sum_{n=1}^{\infty} \frac{1}{n^{s-2}} K_s(2\pi n\sqrt{m}). \tag{6.5}$$

There is a corresponding formula for $\sum(-1)^n r_3(n)/n^s$ which corresponds to Madelung's constant (see p. 301 in [3]). The second term of (6.5) can be rewritten as

$$\frac{12\pi^{s+1}}{\Gamma(s+1)} \sum_{k>0} k^{\frac{s}{2}} K_s(2\pi\sqrt{k}) \sum_{n^2|k} \frac{r_2(k/n^2)}{n^{2s-2}}.$$

Moreover, these Bessel functions are elementary when s is a half-integer. Most nicely, for 'jellium', which is the Wigner sum analogue of Madelung's constant, we have

$$\mathcal{L}_3(1/2) = -\pi + 3\pi \sum_{m>0} \frac{r_2(m)}{\sinh^2(\pi\sqrt{m})},$$

and the exponential convergence is entirely apparent.

For a survey of other rapidly convergent lattice sums of this type see [3] and [6].

There is a corresponding formula for $\mathcal{L}_N(s)$, for all $N \geq 2$, in which we obtain a Bessel-series in $r_{N-1}(m)$:

$$\begin{aligned} \mathcal{L}_N(s) = \sum_{n>0} \frac{r_N(n)}{n^s} &= \frac{2N\,\Gamma(s-\frac{N-3}{2})}{\Gamma(s+1)} \pi^{\frac{N-1}{2}} \zeta(2s-N+1) \\ &+ \frac{4N\,\pi^{s+1}}{\Gamma(s+1)} \sum_{m>0} \frac{m^{\frac{1}{2}s}\, r_{N-1}(m)}{m^{\frac{N-3}{4}}} \sum_{n>0} \frac{n^{\frac{N+1}{2}}}{n^s} K_{s-\frac{N-3}{2}}(2n\pi\sqrt{m}). \end{aligned} \tag{6.6}$$

There is an equally attractive integral representation (see [27] p. 172) for:

$$K_s(x) = \left(\frac{2}{x}\right)^s \frac{\Gamma(s+1/2)}{\Gamma(1/2)} \int_0^{\infty} \frac{\cos(xt)}{(1+t^2)^{s+1/2}}\, dt$$

at least when $x > 1/2$. This leads to

$$\sum_{n>0} \frac{r_3(n)}{n^s} = 2L_{-4}(s+\frac{1}{2},\frac{1}{2}) \sum_{m>0} r_2(m) \int_0^{\infty} \frac{C_{s-2}(\sqrt{m}t)}{(1+t^2)^{s+1/2}}\, dt$$

where

$$C_s(x) = \sum_{n>0} \frac{\cos(2\pi nx)}{n^s}$$

is a *Clausen-type* function. For $s = 2k$, even integer, this evaluates to

$$C_{2k}(x) = \frac{(2\pi)^{2k}}{(-1)^{k-1}2(2k)!} B_{2k}(x)$$

where B_k is a Bernoulli polynomial.

Obviously this also extends to reworkings of (6.6). For example, the $N = 2$ case yields

$$4\,L_{-4}(s+\frac{1}{2},\frac{1}{2})\zeta(2\,s-1)+\frac{16\,\pi^{1+s}}{\Gamma(s+1)}\sum_{n=1}^{\infty}\frac{\sigma_{2\,s-1}(n)}{n^{s-\frac{3}{2}}}K_{s+\frac{1}{2}}(2\,n\pi)=4\,\zeta(s)L_{-4}(s).$$

This in turn, with $s = 2$, becomes

$$4\,\pi^3\sum_{n=1}^{\infty}\sigma_3(n)e^{-2\,n\pi}\left(1+\frac{3}{2}\,\frac{1}{n\pi}+\frac{3}{4}\,\frac{1}{n^2\pi^2}\right)\frac{1}{n}=\frac{2}{3}\pi^2\mathrm{G}-\frac{3}{2}\zeta(3),$$

where $\mathrm{G} := \sum_{\mathrm{n}\geq 0}(-1)^{\mathrm{n}}\,(2\mathrm{n}+1)^{-2}$ is *Catalan's constant.*

There is a puissant formula for θ_2^3 due to Andrews [1] (given with a typographical error in [3] p. 286). It is

$$\theta_2^3(q)=8\sum_{n=0}^{\infty}\sum_{j=0}^{2\,n}\left(\frac{1+q^{4\,n+2}}{1-q^{4\,n+2}}\right)q^{(2\,n+1)^2-(j+1/2)^2}. \tag{6.7}$$

Lamentably we have not been able to use it to study $\mathcal{R}_3$, or even $\mathcal{L}_3$ any further than was achieved in [6].

6.2. **Twelve and Twenty-four Squares.** Explicit 'divisor' formulae for $r_{12}(n)$ and $r_{24}(n)$ are also known (e.g. p. 200 of [20] and §9 of Chapter 9 in [15]): they are

$$r_{12}(n)=8(-1)^{n-1}\sum_{d|n}(-1)^{d+n/d}d^5+16\omega(n)$$

and

$$r_{24}(n)=\frac{16}{691}\sigma_{11}^*(n)+\frac{128}{691}\left((-1)^{n-1}259\tau(n)-512\tau(\frac{1}{2}n)\right)$$

where $\sigma_{11}^*(n)=\sum_{d|n}d^{11}$ if n is odd and $\sigma_{11}^*(n)=\sum_{d|n}(-1)^d d^{11}$ if n is even,

$$q((1-q^2)(1-q^4)(1-q^6)\cdots)^{12}=\sum_{n=1}^{\infty}\omega(n)q^n$$

and

$$q((1-q)(1-q^2)(1-q^3)\cdots)^{24}=\sum_{n=1}^{\infty}\tau(n)q^n.$$

Here $\tau(n)$ is the famous Ramanujan's τ-function.

We have recorded these representations because, while $N = 12$ and $N = 24$ (due to Ramanujan, see Chapter IX of [13]) are the next most accessible even cases, neither directly lead to an appropriate closed form for $\mathcal{L}_N$ let alone for $\mathcal{R}_N$. This is thanks to the impediment offered by ω and τ respectively: which encode knowledge, via the Jacobi triple-product, of all the representations of n as a sum of 4 or 8 squares. The divisor functions do produce appropriate L-function representations. Thus, using Ramanujan's ζ-function

$$g_{24}(s):=\sum_{n=1}^{\infty}\frac{\tau(n)}{n^s}=\prod_p\left(1-\tau(p)p^{-s}+p^{11-2s}\right)^{-1},$$

which is discussed in detail in Chapter X of [13], it transpires that τ is multiplicative, with the preceding lovely Euler product. Additionally,

$$\begin{aligned}\mathcal{L}_{24}(s) = \sum_{n=1}^{\infty} \frac{r_{24}(n)}{n^s} &= \frac{16}{691}(2^{12-2s} - 2^{1-s} + 1)\zeta(s)\zeta(s-11) \\ &+ \frac{128}{691}(259 + 745 \cdot 2^{4-s} + 259 \cdot 2^{12-2s})g_{24}(s).\end{aligned}$$

Similarly with $g_{12}(s) := \sum_{n=1}^{\infty} \frac{\omega(n)}{n^s}$ one has

$$\mathcal{L}_{12}(s) = \sum_{n=1}^{\infty} \frac{r_{12}(n)}{n^s} = 8(1 - 2^{6-2s})\zeta(s)\zeta(s-5) + 16g_{12}(s).$$

We also note that the analysis in [13], due to Rankin (see [22]), provides an 'almost closed form' for

$$f(s) := \sum_{n=1}^{\infty} \frac{\tau^2(n)}{n^s} = \prod_p \left(1 + \tau^2(p)p^{-s} - p^{22-2s} - \frac{2\tau^2(p)p^{-s}}{1+p^{11-s}}\right)^{-1}.$$

Rankin studied the above function $f(s)$ in [22] and showed that $f(s)$ has an analytic continuation to a meromorphic function on $\mathbb{C}$ with the only poles at $s = 12$ and at the complex zeros of $\zeta(2s-22)$, all lying to the left of $\Re(s) = 12$. In [22], Rankin proved his famous result that $\tau(n) = O(n^{29/5})$. His proof depends on a functional equation of $f(s)$, namely,

$$\begin{aligned}&(2\pi)^{-2s}\Gamma(s)\Gamma(s-11)\zeta(2s-22)f(s) = \\ &(2\pi)^{2s-46}\Gamma(23-s)\Gamma(12-s)\zeta(24-2s)f(23-s).\end{aligned}$$

is invariant as $s \to 23 - s$. Finally, we note that a recent paper by Ewell [9] has a new divisor like recursion for τ.

Acknowledgments

The second author wishes to thank Professor P. Borwein for his support concerning this paper. The authors also wish to thank Greg Fee for some useful computational assistance and Stan Wagon and Richard Crandall for many stimulating exchanges. Finally, the authors wish to express their gratitude to Professor Paul Bateman for his thoughtful and gracious comments and suggestions, especially for improving and simplifying the error estimates to the average order of $r_N^2(n)$ in §3.

CONTINUED FRACTIONS OF TAILS OF HYPERGEOMETRIC SERIES

JONATHAN MICHAEL BORWEIN, KWOK-KWONG STEPHEN CHOI AND WILFRIED PIGULLA

1. Motivation

The tails of the Taylor series for many standard functions such as arctan and log can be expressed as continued fractions in a variety of ways. A surprising side effect is that some of these continued fractions provide a dramatic acceleration for the underlying power series. These investigations were motivated by a surprising observation about Gregory's series. Gregory's series for π, truncated at $500,000$ terms gives to forty places

$$4\sum_{k=1}^{500,000}\frac{(-1)^{k-1}}{2k-1} = 3.14159\underline{0}65358979324\underline{0}4626433832\underline{6}9502884197\cdots. \tag{1}$$

To one's initial surprise only the underlined digits are wrong — differ from those of π. This is explained, ex post facto, by setting N equal to one million in the result below:

Theorem 1. *For integer N divisible by 4 the following asymptotic expansion holds:*

$$\begin{aligned}\frac{\pi}{2} - 2\sum_{k=1}^{N/2}\frac{(-1)^{k-1}}{2k-1} &\sim \sum_{m=0}^{\infty}\frac{E_{2m}}{N^{2m+1}} \\ &= \frac{1}{N} - \frac{1}{N^3} + \frac{5}{N^5} - \frac{61}{N^7} + \cdots,\end{aligned} \tag{2}$$

where the numerators $1, -1, 5, -61, 1385, -50521, \cdots$ are the Euler numbers E_0, E_2, E_4, E_6, E_8, $E_{10}, \cdots$.

The observation (1) arrived in the mail from Roy North in 1987. After verifying its truth numerically (which is much quicker today), it was an easy matter to generate a large number of the "errors" to high precision. The authors of [1] then recognized the sequence of errors in (1) as the Euler numbers — with the help of Sloane's 'Handbook of Integer Sequences'. The presumption that (1) is a form of Euler-Maclaurin summation is now formally verifiable for any fixed N in Maple. This allowed them to determine that (1) is equivalent to a set of identities between Bernoulli and Euler numbers that could with considerable effort have been established. Secure in the knowledge that (1) holds it is easier, however, to use the *Boole Summation formula* which applies directly to alternating series and *Euler*

numbers (see [1]). Because N was a power of ten, the asymptotic expansion was obvious on the computer screen.

This is a good example of a phenomenon which really does not become apparent without working to reasonably high precision (who recognizes 2, -2, 10 ?), and which highlights the role of pattern recognition and hypothesis validation in experimental mathematics.

It was an amusing additional exercise to compute Pi to $5,000$ digits from (1). Indeed, with $N = 200,000$ and correcting using the first thousand even Euler numbers, Borwein and Limber [2] obtained $5,263$ digits of Pi (plus 12 guard digits). Thus, while the alternating Gregory series is very slowly convergent, the errors are highly predictable.

2. Three Continued Fraction Classes

We will discuss three classes of continued fractions: Euler, Gauss and Perron in this section.

2.1. **Euler's Continued Fraction.** Using the following notation for continued fraction:

$$\frac{a_1}{b_1} \pm \frac{a_2}{b_2} \pm \frac{a_3}{b_3} \pm \cdots = \cfrac{a_1}{b_1 \pm \cfrac{a_2}{b_2 \pm \cfrac{a_3}{b_3 \pm \ddots}}},$$

identities such as

$$a_0 + a_1 + a_1a_2 + a_1a_2a_3 + a_1a_2a_3a_4 = a_0 + \cfrac{a_1}{1 - \cfrac{a_2}{1+a_2 - \cfrac{a_3}{1+a_3 - \cfrac{a_4}{1+a_4}}}}$$

are easily verified symbolically. The general form

$$\begin{aligned}(3)\quad a_0 + a_1 + a_1a_2 + a_1a_2a_3 + \cdots + a_1a_2a_3\cdots a_N \\ = a_0 + \cfrac{a_1}{1 - \cfrac{a_2}{1+a_2 - \cfrac{a_3}{1+a_3 - \cdots - \cfrac{a_N}{1+a_N}}}}\end{aligned}$$

can then be obtained by substituting $a_N + a_N\, a_{N+1}$ for a_N and checking that the shape of the right hand side is preserved. This allows many series to be re-expressed as continued fractions. For example, with $a_0 = 0, a_1 = z, a_2 = -z^2/3, a_3 = -3z^2/5, \cdots,$

$$\arctan(z) = z - \frac{z^3}{3} + \frac{z^5}{5} - \frac{z^7}{7} + \frac{z^9}{9} - \cdots$$

we obtain, in the limit, the continued fraction for arctan due to Euler:

$$\arctan(z) = \cfrac{z}{1 + \cfrac{z^2}{3 - z^2 + \cfrac{9z^2}{5 - 3z^2 + \cfrac{25z^2}{7 - 5z^2 + \cdots}}}}.$$

When $z = 1$, this becomes the first infinite continued fraction, given by Lord Brouncker (1620-1684):

$$\frac{4}{\pi} = 1 + \frac{1}{2} \underset{+}{} \frac{9}{2} \underset{+}{} \frac{25}{2} \underset{+}{} \frac{49}{2} \underset{+}{} \cdots . \tag{4}$$

If we let $a_0 = \sum_1^N b_k$ be the initial segment of a similar series we may use (3) to replace the remaining terms by a continued fraction. For example, if we put

$$a_0 = \sum_{n=1}^{N} \frac{(-1)^{n-1} z^{2n-1}}{2n-1}, a_1 = \frac{(-1)^N z^{2N+1}}{2N+1}, a_2 = -\frac{2N+1}{2N+3} z^2, a_3 = -\frac{2N+3}{2N+5} z^2, \cdots$$

then we get

$$\arctan(z) = \sum_{n=1}^{N} (-1)^{n-1} \frac{z^{2n-1}}{2n-1} + \frac{(-1)^N z^{2N+1}}{2N+1} \underset{+}{} \frac{(2N+1)^2 z^2}{(2N+3) - (2N+1)z^2} \underset{+}{} \frac{(2N+3)^2 z^2}{(2N+5) - (2N+3)z^2} \underset{+}{} \frac{(2N+5)^2 z^2}{(2N+7) - (2N+5)z^2} \underset{+}{} \cdots . \tag{5}$$

2.2. **Gauss's Continued Fraction.** A rich vein lies in Gauss's continued fraction for the ratio of two hypergeometric functions $\dfrac{\mathrm{F}(a, b+1; c+1; z)}{\mathrm{F}(a, b; c; z)}$, see [5]. Recall that within its radius of convergence, the Gaussian hypergeometric function is defined by

$$\begin{aligned} \mathrm{F}(a, b; c; z) &= 1 + \frac{ab}{c} z + \frac{a(a+1)b(b+1)}{2!c(c+1)} z^2 \\ &+ \frac{a(a+1)(a+2)b(b+1)(b+2)}{3!c(c+1)(c+2)} z^3 + \cdots . \end{aligned} \tag{6}$$

The general continued fraction is developed by a reworking of the *contiguity relation*

$$\mathrm{F}(a, b; c; z) = \mathrm{F}(a, b+1; c+1; z) - \frac{a(c-b)}{c(c+1)} z \, \mathrm{F}(a+1, b+1; c+2; z), \tag{7}$$

and formally at least is quite easy to derive. Convergence and convergence estimates are more delicate. We therefore have

$$\frac{\mathrm{F}(a, b+1; c+1; z)}{\mathrm{F}(a, b; c; z)} = \left(1 - \frac{a(c-b)}{c(c+1)} z \frac{\mathrm{F}(a+1, b+1; c+2; z)}{\mathrm{F}(a, b+1; c+1; z)}\right)^{-1}$$

and this yields the recursive process for the continued fraction. In the limit, for $b = 0$ and replacing c by $c - 1$, this process yields

$$\mathrm{F}(a, 1; c; z) = \frac{1}{1} \underset{-}{} \frac{a_1 z}{1} \underset{-}{} \frac{a_2 z}{1} \underset{-}{} \frac{a_3 z}{1} \underset{-}{} \cdots \tag{8}$$

which is the case of present interest. Here

$$a_{2l+1} = \frac{(a+l)(c-1+l)}{(c+2l-1)(c+2l)} \qquad a_{2l+2} = \frac{(l+1)(c-a+l)}{(c+2l)(c+2l+1)}$$

for $l = 0, 1, \cdots$. We also let

$$F_M(a, 1; c; z) = \frac{1}{1} \underset{-}{} \frac{a_1 z}{1} \underset{-}{} \frac{a_2 z}{1} \underset{-}{} \cdots \underset{-}{} \frac{a_{M-1} z}{1}$$

denote the Mth convergent of the continued fraction to $F(a,1;c;z)$.

It is well known and easy to verify that $\log(1+z) = z\,\mathrm{F}(1,1;2;-z)$. It is then a pleasant surprise to discover that $\log(1+z) - z = -\frac{1}{2}z^2\,\mathrm{F}(2,1;3;-z)$, $\log(1+z) - z + \frac{1}{2}z^2 = \frac{1}{3}z^3\,\mathrm{F}(3,1;4;-z)$ and to conjecture that

$$\log(1+z) + \sum_{n=1}^{N-1} \frac{(-1)^n z^n}{n} = -\frac{(-1)^N z^N}{N}\,\mathrm{F}(N,1;N+1;-z). \tag{9}$$

This is easy to first verify for a few cases and then confirm rigorously. As always, a formula for log leads correspondingly to one for arctan:

$$\arctan(z) - \sum_{n=0}^{N-1} \frac{(-1)^n z^{2n+1}}{2n+1} = \frac{(-1)^N z^{2N+1}}{2N+1}\,\mathrm{F}\left(N+\frac{1}{2},1;N+\frac{3}{2};-z^2\right). \tag{10}$$

Happily, in both cases (8) is applicable — as it is for a variety of other functions such as $\log\left(\frac{1+z}{1-z}\right)$, $(1+z)^k$, and $\int_0^z (1+t^n)^{-1}\,dt = z\,\mathrm{F}\left(\frac{1}{n},1;1+\frac{1}{n};-z^n\right)$. Note that this last function recaptures $\log(1+z)$ and $\arctan(z)$ for $n=1$ and 2 respectively.

We next give the explicit continued fractions for (9) and (10).

Theorem 2. *Gauss's continued fractions for (9) and (10) are:*

$$\begin{aligned}\log(1+z) + \sum_{n=1}^{N-1} \frac{(-1)^n z^n}{n} \\ = \frac{(-1)^{N+1}z^N}{N} + \frac{N^2 z}{N+1} + \frac{1^2 z}{N+2} + \frac{(N+1)^2 z}{N+3} + \frac{2^2 z}{N+4} + \cdots\end{aligned} \tag{11}$$

and

$$\begin{aligned}\arctan(z) - \sum_{n=0}^{N-1} \frac{(-1)^n z^{2n+1}}{2n+1} \\ = \frac{(-1)^N z^{2N+1}}{2N+1} + \frac{(2N+1)^2 z^2}{2N+3} + \frac{2^2 z^2}{2N+5} + \frac{(2N+3)^2 z^2}{2N+7} + \frac{4^2 z^2}{2N+9} + \cdots.\end{aligned} \tag{12}$$

Suppose we return to Gregory's series, but add a few terms of the continued fraction for (10). One observes numerically that if the results are with $N = 500,000$, adding only six terms of the continued fraction has the effect of increasing the precision by 40 digits.

Example 3.

Let

$$E_1(N,M,z) := \log(1+z) - \left(-\sum_{n=1}^{N} \frac{(-z)^n}{n} - \frac{(-z)^{N+1}}{N+1}\mathrm{F}_M(N+1,1;N+2;-z)\right)$$

and

$$E_2(N,M,z) := \arctan(z) - \left(\sum_{n=0}^{N-1} \frac{(-1)^n z^{2n+1}}{2n+1} + \frac{(-1)^N z^{2N+1}}{2N+1}\mathrm{F}_M(N+\frac{1}{2},1;N+\frac{3}{2};-z^2)\right).$$

Then $E_1(N,M,z)$ and $E_2(N,M,z)$ measure the precision of the approximations to $\log(1+z)$ and $\arctan(x)$ obtained by computing the first N terms of Taylor series and then adding M terms of their continued fractions respectively. Tables 1, 2,

TABLE 3. Error $|E_2(N,M,1)|$ for $N=5\times 10^k(1\le k\le 6)$ and $0\le M\le 6$.

3 and 4 record those data for the approximations to $\log(1.9), \log(2), \arctan(1)$ and $\arctan(1/2)+\arctan(1/5)+\arctan(1/8)$ respectively. Note that

$$\frac{\pi}{4}=\arctan(\frac{1}{2})+\arctan(\frac{1}{5})+\arctan(\frac{1}{8})$$

is a formula of Machin type used by Johann Dase to compute 205 digits of π in his head in 1844.

After some further numerical experimentation it is clear that for large a, c the continued fraction $\mathrm{F}(a,1,c;z)$ is rapidly convergent. And indeed the rough rate is apparent.

This is part of the content of the next theorem:

		5×10	5×10^2
M	0	0.31×10^{-32}	0.37×10^{-304}
	1	0.19×10^{-33}	0.23×10^{-305}
	2	0.11×10^{-37}	0.15×10^{-311}
	3	0.26×10^{-38}	0.37×10^{-312}
	4	0.56×10^{-42}	0.92×10^{-318}
	5	0.13×10^{-42}	0.23×10^{-318}
	6	0.59×10^{-46}	0.13×10^{-323}

TABLE 4. Error $|E_2(N+1,M,1/2)+E_2(N+1,M,1/5)+E_2(N+1,M,1/8)|$ for $N=5\times 10^k (1\le k\le 2)$ and $0\le M\le 6$.

Theorem 4. *Suppose* $2 \le a, a+1 \le c \le 2a$ *and* $M \ge 2$. *Then for* $-1 \le z < 0$ *one has*

$$\begin{aligned} & |\mathrm{F}(a,1;c;z) - \mathrm{F}_M(a,1;c;z)| \\ \le\ & \frac{\Gamma(n+1)(n+a)\Gamma(n+c-a)\Gamma(a)\Gamma(c)}{\Gamma(n+a)\Gamma(n+c)a\Gamma(c-a)} \left(\frac{2a}{(c-2)\left(1-\frac{2}{z}\right)+(2a-c)} \right)^M \end{aligned}$$

where $n = [M/2]$ *and* $\mathrm{F}_M(a,1;c;z)$ *is the* M*-th convergent of the continued fraction to* $F(a,1,c;z)$.

The proof of Theorem 4 will be given in the Appendix below.

In [5] one can find listed many explicit continued fractions which can be derived from Gauss's continued fraction or various of its limiting cases. These include exp, tanh, tan and various less elementary functions. One especially attractive fraction is that for $J_{n-1}(z)/J_n(z)$ and $I_{n-1}(z)/I_n(z)$ where J and I are *Bessel functions of the first kind.* In particular,

$$\frac{J_{n-1}(2z)}{J_n(2z)} = \frac{n}{z} - \cfrac{\frac{z}{(n+1)}}{1} - \cfrac{\frac{z^2}{(n+1)(n+2)}}{1} - \cfrac{\frac{z^2}{(n+2)(n+3)}}{1} - \cdots . \tag{13}$$

Setting $z = i$ and $n = 1$ leads to the very beautiful continued fraction

$$\frac{I_1(2)}{I_0(2)} = [1,2,3,4,\cdots] .$$

In general, arithmetic simple continued fractions correspond to such ratios.

An example of a more complicated situation is:

$$\frac{(2\,z)^{2\,N+1}\,\mathrm{F}\left(N+\frac{1}{2},\frac{1}{2};N+\frac{3}{2};z^2\right)}{(N+1)\binom{2\,N+2}{N+1}\mathrm{F}\left(\frac{1}{2},-\frac{1}{2};\frac{1}{2};z^2\right)} = \frac{\arcsin(z)}{\sqrt{1-z^2}} - \sigma_{2N}(z) \tag{14}$$

where σ_{2N} is the $2N$-th Taylor polynomial for $\frac{\arcsin(z)}{\sqrt{1-z^2}}$. Only for $N = 0$ is this precisely of the form of Gauss's continued fraction.

2.3. **Perron's Continued Fraction.** Another continued fraction expansion is based on Stieltjes work on the moment problem (see Perron [4]) and leads to similar acceleration. In volume 2, page 18 of [4] one finds a beautiful continued fraction for

$$\frac{1}{z^\mu}\int_0^z \frac{t^\mu}{1+t}\,dt = \frac{z}{\mu+1} + \frac{(\mu+1)^2 z}{(\mu+2)-(\mu+1)z} + \frac{(\mu+2)^2 z}{(\mu+3)-(\mu+2)z} + \cdots . \tag{15}$$

valid for $\mu > -1, -1 < z \leq 1$. One may deduce this as a consequence of Euler's continued fraction if we write

$$\frac{1}{z^\mu}\int_0^z \frac{t^\mu}{1+t}\,dt = \frac{z}{\mu+1} - \frac{z^2}{\mu+2} + \frac{z^3}{\mu+3} - \frac{z^4}{\mu+4} + \cdots$$

and observe that (15) follows from (3) in the limit.

Since

$$\frac{z^{\mu+1}}{\mu+1}\,\mathrm{F}\left(\mu+1, 1; \mu+2; -z\right) = \int_0^z \frac{t^\mu}{1+t}\,dt, \tag{16}$$

$$\frac{z^{2\,\mu+1}}{2\,\mu+1}\,\mathrm{F}\left(\mu+\frac{1}{2}, 1; \mu+\frac{3}{2}; -z^2\right) = \int_0^z \frac{t^{2\,\mu}}{1+t^2}\,dt, \tag{17}$$

for $\mu > 0$, on examining (9) and (10) this is immediately applicable to provide Euler continued fractions for the tail of the log and arctan series. Explicitly, we obtain:

Theorem 5. *Perron's continued fractions for (9) and (10) are:*

$$\log(1+z) + \sum_{n=1}^{N-1} \frac{(-1)^n z^n}{n} = \frac{(-1)^{N+1} z^N}{N} + \frac{N^2 z}{(N+1)-Nz} + \frac{(N+1)^2 z}{(N+2)-(N+1)z} + \cdots \tag{18}$$

and

$$\arctan(z) - \sum_{n=0}^{N-1} \frac{(-1)^n z^{2\,n+1}}{2\,n+1} = \frac{(-1)^N z^{2N+1}}{2N+1} + \frac{(2N+1)^2 z^2}{(2N+3)-(2N+1)z^2} + \frac{(2N+3)^2 z^2}{(2N+5)-(2N+3)z} + \cdots . \tag{19}$$

Moreover, while the Gauss and Euler/Perron continued fractions obtained are quite distinct the convergence behaviour is very similar to that of the previous section. Note also the coincidence of (19) and (5). Indeed as we have seen Theorem 5 coincides with a special case of (3).

3. Appendix

Recall that Gauss's continued fraction for $\mathrm{F}(a, 1; c; z)$ is

$$\mathrm{F}(a, 1; c; z) = \frac{1}{1} - \frac{a_1 z}{1} - \frac{a_2 z}{1} - \frac{a_3 z}{1} - \cdots$$

where

$$a_{2l+1} = \frac{(a+l)(c-1+l)}{(c+2l-1)(c+2l)} \qquad a_{2l+2} = \frac{(l+1)(c-a+l)}{(c+2l)(c+2l+1)}$$

for $l = 0, 1, \cdots$. Let

$$\frac{A_n(z)}{B_n(z)} = \frac{1}{1} - \frac{a_1 z}{1} - \frac{a_2 z}{1} - \cdots - \frac{a_{n-1} z}{1} = \mathrm{F}_n(a, 1; c; z)$$

be the n-th convergent of the continued fraction. It can be proved by induction that $A_1(z) = A_2(z) = B_1(z) = 1, B_2(z) = 1 - a_1 z$ and

$$A_k(z) = A_{k-1}(z) - a_{k-1} z A_{k-2}(z),$$

and

$$B_k(z) = B_{k-1}(z) - a_{k-1} z B_{k-2}(z),$$

for $k \geq 3$. Hence for $k \geq 2$, we have

$$A_k(z) B_{k-1}(z) - A_{k-1}(z) B_k(z) = a_1 \cdots a_{k-1} z^{k-1}.$$

Using the estimation in Theorem 8.9 of [3], we find that if $a_i > 0$ for all i, then

$$\left| \mathrm{F}(a, 1; c; z) - \frac{A_n(z)}{B_n(z)} \right| \leq \left| \frac{A_n(z)}{B_n(z)} - \frac{A_{n-1}(z)}{B_{n-1}(z)} \right| = \left| \frac{a_1 \cdots a_{n-1} z^{n-1}}{B_n(z) B_{n-1}(z)} \right|$$

One may verify that $B_n(z)$ are hypergeometric polynomials (see [5]) and explicitly

$$B_{2k}(z) = F(-k, 1 - a - k, 2 - c - 2k; z)$$

and

$$B_{2k+1}(z) = F(-k, -a - k, 1 - c - 2k; z).$$

These may also be written in terms of Jacobi Polynomials so that

$$B_{2k}(z) = \binom{2k + c - 2}{k}^{-1} (-z)^k P_k^{(a-1, c-a-1)} \left(1 - \frac{2}{z}\right)$$

and

$$B_{2k+1}(z) = \binom{2k + c - 1}{k}^{-1} (-z)^k P_k^{(a, c-a-1)} \left(1 - \frac{2}{z}\right).$$

We let

$$E_n := E_n(a, c, z) = \frac{a_1 a_2 \cdots a_n z^n}{B_n(z) B_{n+1}(z)} \qquad \text{and} \qquad F_n := \mathrm{F}_n(a, c, z) = \frac{E_{n+1}}{E_n}.$$

Then we get

$$F_{2n} = \frac{a_{2n+1} z B_{2n}(z)}{B_{2n+2}(z)} = \frac{(n + a)}{(n + 1)} \frac{P_n^{(a-1, c-a-1)}}{P_{n+1}^{(a-1, c-a-1)}} \left(1 - \frac{2}{z}\right)$$

and

$$F_{2n-1} = \frac{a_{2n} z B_{2n-1}(z)}{B_{2n+1}(z)} = \frac{(n + c - a - 1)}{(n + c - 1)} \frac{P_n^{(a, c-a-1)}}{P_{n+1}^{(a, c-a-1)}} \left(1 - \frac{2}{z}\right).$$

We need the following estimation. Assume $0 \leq \beta \leq \alpha, 1 \leq \alpha, 1 \leq n$ and $0 < x \leq 1$. We shall show

$$\frac{P_n^{(\alpha, \beta)}}{P_{n-1}^{(\alpha, \beta)}} \left(1 + \frac{2}{x}\right) \geq \frac{(n + \alpha - 1) \left((\alpha + \beta) \left(1 + \frac{2}{x}\right) + (\alpha - \beta)\right)}{2n\alpha}. \tag{20}$$

The Jacobi polynomials satisfy the recurrence relation

$$
\begin{aligned}
(21)\quad & 2n(n+\alpha+\beta)(2n+\alpha+\beta-2)P_n^{(\alpha,\beta)}(x) \\
&= (2n+\alpha+\beta-1)\left((2n+\alpha+\beta)(2n+\alpha+\beta-2)x+\alpha^2-\beta^2\right)P_{n-1}^{(\alpha,\beta)}(x) \\
&\qquad -2(n+\alpha-1)(n+\beta-1)(2n+\alpha+\beta)P_{n-2}^{(\alpha,\beta)}(x)
\end{aligned}
$$

for $n = 2, 3, \cdots$ where

$$P_0^{(\alpha,\beta)}(x) \equiv 1 \qquad P_1^{(\alpha,\beta)}(x) = \frac{1}{2}(\alpha+\beta+2)x + \frac{1}{2}(\alpha-\beta).$$

We let

$$R_n := \frac{P_n^{(\alpha,\beta)}}{P_{n-1}^{(\alpha,\beta)}}\left(1+\frac{2}{x}\right)$$

and

$$T_n := \frac{(n+\alpha-1)\left((\alpha+\beta)\left(1+\frac{2}{x}\right)+(\alpha-\beta)\right)}{2n\alpha}.$$

For $n = 1$,

$$
\begin{aligned}
R_1 &= \frac{1}{2}(\alpha+\beta+2)\left(1+\frac{2}{x}\right)+\frac{1}{2}(\alpha-\beta) \\
&\geq \frac{(\alpha+\beta)\left(1+\frac{2}{x}\right)+(\alpha-\beta)}{2} = T_1.
\end{aligned}
$$

So (20) is true for $n = 1$. By the recurrence relation (21), we get

$$
\begin{aligned}
R_n &= \frac{(2n+\alpha+\beta-1)\left\{(2n+\alpha+\beta)(2n+\alpha+\beta-2)\left(1+\frac{2}{x}\right)+\alpha^2-\beta^2\right\}}{2n(n+\alpha+\beta)(2n+\alpha+\beta-2)} \\
&\qquad -\frac{(n+\alpha-1)(n+\beta-1)(2n+\alpha+\beta)}{n(n+\alpha+\beta)(2n+\alpha+\beta-2)}\frac{1}{R_{n-1}} \\
&:= \alpha_n - \beta_n\frac{1}{R_{n-1}}
\end{aligned}
$$

for $n \geq 2$. Suppose (20) is true for $n-1$. Then

$$R_n \geq \alpha_n - \frac{\beta_n}{T_{n-1}}.$$

For convenience, we write $f(n,\alpha,\beta,x)$ for the numerator of the expression $\alpha_n - \frac{\beta_n}{T_{n-1}} - T_n$ after simplification to a fractional form, that is

$$
\begin{aligned}
&\frac{f(n,\alpha,\beta,x)}{x(n-2+\alpha)(\alpha x+\alpha+\beta)n(n+\alpha+\beta)(2n+\alpha+\beta-2)\alpha} \\
:= \quad &\alpha_n - \frac{\beta_n}{T_{n-1}} - T_n.
\end{aligned}
$$

The function $f(n,\alpha,\beta,x)$ is a polynomial in n of degree 4 and can be shown that subject to our conditions on α, β and x, that it is increasing on n and $f(1,\alpha,\beta,x) > 0$. It follows that $\alpha_n - \frac{\beta_n}{T_{n-1}} > T_n$ and $R_n \geq T_n$. This proves (20).

In view of (20), we have

$$F_{2n} \leq \frac{(n+a)}{(n+a-1)}\frac{2(a-1)}{\left((c-2)\left(1-\frac{2}{x}\right)+(2a-c)\right)}$$

and

$$F_{2n-1} \leq \frac{n(n+c-a-1)}{(n+c-1)(n+a-1)} \frac{2a}{\left((c-1)\left(1-\frac{2}{z}\right)+(2a-c+1)\right)}.$$

Thus for $n \geq 1$,

$$F_{2n}F_{2n-1} \leq \frac{(n+a)n(n+c-a-1)}{(n+c-1)(n+a-1)^2} \left\{ \frac{2a}{(c-2)\left(1-\frac{2}{z}\right)+(2a-c)} \right\}^2.$$

We are now ready to estimate E_n. Note that

$$\begin{aligned} E_{2n+1} &= E_1 F_{2n} \cdots F_1 \\ &= E_1 \left\{ \prod_{i=1}^{n} \frac{(i+a)i(i+c-a-1)}{(i+c-1)(i+a-1)^2} \right\} \left(\frac{2a}{(c-2)\left(1-\frac{2}{z}\right)+(2a-c)} \right)^{2n} \\ &\leq \frac{\Gamma(n+1)(n+a)\Gamma(n+c-a)\Gamma(a)\Gamma(c)}{\Gamma(n+a)\Gamma(n+c)a\Gamma(c-a)} \left(\frac{2a}{(c-2)\left(1-\frac{2}{z}\right)+(2a-c)} \right)^{2n+1} \end{aligned}$$

as claimed, because

$$E_1 = \frac{a_1 z}{B_1(z)B_2(z)} \leq \frac{2a}{(c-2)\left(1-\frac{2}{z}\right)+(2a-c)}.$$

The bound for E_{2n} can be obtained similarly. This proves Theorem 4. **QED**

SIAM Review of ``An Encyclopedia of Integer Sequences" by N. J. A. Sloane & Simon Plouffe

J. M. Borwein and Robert M. Corless

In SIAM REVIEW, **38**, (1996), 333-337.

``The Encyclopedia of Integer Sequences" by Sloane and Plouffe, published by Academic Press, is not a normal book. It contains a lexicographically ordered collection of integer sequences together with references to these sequences where they appear in the literature. The idea is that a researcher who encounters a sequence in her or his work, and wishes to quickly find out what is known about the sequence (does it have a name, for example, such as ``the Euler numbers" or ``the Stirling numbers of the first kind"?), can look it up here.

On the face of it this seems a difficult task to accomplish, because surely there are very many sequences of interest. However, by Pareto's principle (80% of your work is done with 20% of your tools) we would expect that simple sequences would occur often, and thus such a book would be useful.

Indeed, this is the case, and even if the book were no more than the handsomely bound physical collection it is, it would have been worthwhile to create, publish, or buy, because it provides a very cheap and efficient route to answers that will work sometimes: if it doesn't work on a particular problem, no big effort has been expended, while if it *does* work you may save a lot of time.

But the physical book is *not* the whole story. Sloane and Plouffe have also created two ``avatars" of the book, as freely available online computer programs (which we will call `sequences` and `superseeker`) for people to send their sequences to. Because the programs can be accessed by people who do not own the book, we think that Academic Press deserves considerable praise for its enlightened attitude towards the changing shape of publishing.

This is not the first, but is one of the first, of a growing list of sophisticated tools which are accessible to even relatively naive users, and which dramatically illustrate a positive use of the Internet. Our dream work environment would provide us with a whole palette of such tools and a simple key to what exists and how to use it. These tools should ideally be immediately integratable with your favourite working environment (MATLAB, Axiom, Maple, Mathematica, Whatever).

In our opinion the physical book is itself worthwhile not only because it is pleasant to browse in

(electrons are so cold, in comparison) but also because of the discussion at the beginning on analysis of sequences. Some of the heuristics discussed in chapters 1, 2, and 3 (before the table of sequences proper begins) give useful hints as to what to do when the computer programs don't work; they also give a nice conceptual model of the inner workings of the programs.

One can turn the tables (so to speak) and use the sequences from the book as a test of each of the subprograms in `sequences` and `superseeker`. Simon Plouffe tells us that each subprogram was considered useful enough to be included if it could identify on the order of 10-100 of the sequences from the book. Further, about 25% of the sequences in the book are obtained from a rational generating function or elementary manipulation thereof (reversion, undoing a logarithmic differentiation, etc.). Addition of various other classes such as hypergeometric functions and pre-processing (adding `1' to each term or doubling the terms, etc) significantly increased the hit rate. It is to be emphasized that not every plausible transformation was included, and much expertise on the part of the authors was needed to choose useful transformations and to avoid `the curse of exponentiality'.

Finally, some `off-the-wall' sequences are also included, such as the numbers on the New York Subway stops, in Figure M5405.

Incidentally, due to a printer's error the table of Figures was not included in the book, and as the `silly' sequences are not actually indexed or numbered in the book, one must either use the programs or know that they are contained in Figure M5405 to find them.

We now give some examples of the uses of the book and the programs therein, to demonstrate their utility (and also some limitations).

EXPLICIT GALOIS GROUPS OF INFINITE p-EXTENSIONS UNRAMIFIED AT p

Nigel Boston

Abstract. Galois groups of infinite p-extensions of number fields unramified at p are a complete mystery. We find by computer a family of pro-p groups that satisfy everything that such a Galois group must, and give evidence for the conjecture that these are the only such groups. This suggests that these mysterious Galois groups indeed have a specific form of presentation. There are surprising connections with knot theory and quantum field theory. Finally, the Fontaine-Mazur conjecture here reduces to a purely group-theoretic conjecture, and evidence for this conjecture and an extension of it is given.

0. Introduction.

Whereas much is now known about Galois groups of p-extensions of number fields when the extension is ramified at the primes above p and these extensions have been successfully related to the theory of p-adic Galois representations, not one Galois group of an infinite p-extension unramified at the primes above p has been written down. Wingberg [14] calls them amongst the most mysterious objects in algebraic number theory. In this paper we gather together the properties that such a Galois group must satisfy and observe that there is just one family of such groups.

These groups are then studied as abstract groups and some links with other areas of mathematics surprisingly arise. The conjecture of Fontaine-Mazur [8] then simply says that no subgroup of finite index has an infinite, analytic quotient. This appears to be true of all groups in the family. Moreover, all these groups are conjecturally just-infinite, and it is shown that in that case they are branch, confirming the author's proposed extension [5] of the Fontaine-Mazur conjecture. This is apparently a new collection of just-infinite branch groups, not among those introduced in section 8 of [11], unusually having such a simple, finite presentation.

1. Galois Pro-p Groups Unramified at p.

We shall focus on the simplest, most concrete situation available to us. Namely, let S be a finite set of odd primes, $\mathbf{Q}_S$ denote the maximal 2-extension of $\mathbf{Q}$ unramified outside S (allowing ramification at ∞), and $G_S = \mathrm{Gal}(\mathbf{Q}_S/\mathbf{Q})$. Then G_S is a pro-2 group with the following properties:

(a) (Shafarevich) $d(G_S) = r(G_S) = |S|$, and in fact the generators can be taken as the tame inertia generators $\{\tau_p : p \in S\}$ and the relations of the form $\tau_p^{r_p} = \tau^p (p \in S)$, where the r_p are as yet unknown [9];

(b) (Class Field Theory) every finite-index subgroup H of G_S has $|H/H'| < \infty$;

1991 *Mathematics Subject Classification.* 11R32, 11Y40, 12F10, 20D15.

Key words and phrases. Explicit Galois group, class tower, just-infinite.

The author thanks Y. Barnea, L. Bartholdi, M. Bush, F. Hajir, J. Klüners, T. Kuhnt, and B. Mazur for useful discussions. He was supported by NSF DMS 99-70184

(c) conjecturally (Fontaine-Mazur [8]), every finite-index subgroup H of G_S has no infinite analytic quotient.

Remarks. $d(H)$ and $r(H)$ denote the generator and relation ranks of H respectively. By (a), G_S is finite if $|S| = 1$ and is infinite (thanks to Golod-Shafarevich [10]) if $|S| \geq 4$. It can go either way if $|S| = 2$ or 3 (see [6],[12]). Property (b) follows from the finiteness of certain ray class groups.

In property (c), "analytic" means a closed subgroup of $GL_n(\mathbf{Z}_2)$ for some n. Extensions [3], [5] of (c) conjecture that H has no infinite quotient embeddable in $GL_n(R)$, where R is any complete, Noetherian local ring with finite residue field, and that the just-infinite quotients of H are all branch groups [11]. Just-infinite groups are ones all of whose proper quotients are finite.

Our objective now is to find all abstract presentations of infinite pro-2 groups that satisfy properties (a) and (b) above, and test whether (c) and its extensions hold for such groups.

2. A Computer Experiment.

If $S = \{p, q\}$, then G_S is a sometimes infinite pro-2 group with presentation of the form $< x, y | x^r = x^p, y^s = y^q >$, where r and s are certain (unknown) elements of the free pro-2 group on x and y. Here, x^r stands for $r^{-1}xr$. Since in [6] every case with $p \equiv 3 (\text{mod } 4), q \equiv 5 (\text{mod } 8)$, i.e. G_S having abelianization $C_2 \times C_4$, denoted $[2, 4]$ for short, leads to a finite G_S, we focus on the next simplest case, namely $p, q \equiv 5 (\text{mod } 8)$, i.e. $G_S/G'_S \cong [4, 4]$. In the group $(\mathbf{Z}/2^n)^*$, any n, the subgroup generated by 5 is the same as that generated by any integer that is 5(mod 8), and so G_S actually has presentation $< x, y | x^a = x^5, y^b = y^5 >$ for certain a, b in the free pro-2 group on x and y.

Given a finitely presented group G, let $P_n(G) = [P_{n-1}(G), G]P_{n-1}(G)^2$, where $P_0(G) = G$. We say that G has 2-class c if $P_c(G) = \{1\}$ but $P_{c-1}(G) \neq \{1\}$. Let Q_n denote the maximal 2-class n 2-group quotient of G.

The computer algebra system MAGMA [2] allows us to start with an abstract group presentation $G =< x, y | x^a = x^5, y^b = y^5 >$, where a, b are randomly chosen words of the free group in x, y, and to check and see if

(i) $|Q_n| \neq |Q_{n+1}|$ for fairly large n (up to 63, if desired);

(ii) $|H/H'| < \infty$ for all subgroups H of index ≤ 16 with core of 2-power index (these subgroups arise in the pro-2 completion of G).

The reason for conducting such an experiment is that by the properties of section 1, if $S = \{p, q\}$, then G_S is a sometimes infinite pro-2 group that, if it is the pro-2 completion of G, satisfies these conditions (and more).

This was tried for $15,000$ choices of a, b, producing 92 presentations. The outcome of the experiment is that we obtained just one class $\mathcal{C}$ of very similar groups. If we let $|Q_n| = 2^{f(n)}$, then the sequence $(f(n))$ was always:

$(\Sigma) : 2, 5, 8, 11, 14, 16, 20, 24, 30, 36, 44, 52, 64, 76, 93, 110, 135, 160, 196, 232, 286,$

$340, 419, 498, 617, 736, 913, 1090, 1357, 1634, ...$

What is Σ? Consider the derived sequence $\Delta f(n) := f(n+1) - f(n) = \log_2 |P_n(G)/P_{n+1}(G)|$. This is:

$3, 3, 3, 3, 2, 4, 4, 6, 6, 8, 8, 12, 12, 17, 17, 25, 25, 36, 36, 54, 54, 79, 79, 119, 119, 177, 177, 267, 267, ...$

Plugging this sequence (ignoring repetitions) into Neal Sloane's On-Line Encyclopedia of Integer Sequences http://www.research.att.com/∼ njas/sequences/Seis.html yields A001461, arising in the paper [7] concerning knot theory and quantum field theory. If so, $\Delta f(2n-2) = \Delta f(2n-1) = \sum_{m=1}^{n}(1/m)\sum_{d|m}\mu(m/d)(F_{d-1}+F_{d+1})$. Each term in the inner sum counts aperiodic binary necklaces with no subsequence 00, excluding the necklace "0". Here μ is the usual Möbius function and F_n the nth Fibonacci number.

Note that, for the free pro-2 group F on k generators, Witt's formula [15] gives that $\log_2|P_n(F)/P_{n+1}(F)| = \sum_{m=1}^{n}(1/m)\sum_{d|m}\mu(m/d)k^d$ and so since $F_{d-1}+F_{d+1}$ is approximately ϕ^d for large d, where ϕ is the golden ratio $(1+\sqrt{5})/2$, this suggests that G is something like a free pro-2 group on ϕ generators.

Moreover, in each case, a change of variable made the presentation $G =< x, y|x^a = x^5, y^4 = 1 >$ for some word a in x and y. This extensive evidence leads to the conjecture:

Conjecture 1. Let G be an infinite pro-2 group with presentation of the form $< x, y|x^a = x^5, y^b = y^5 >$ such that every subgroup of finite index has finite abelianization. Then G is isomorphic to $< x, y|x^a = x^5, y^4 = 1 >$ for $a \in \mathcal{F}$, a certain subset of the free pro-2 group on x, y, and $\log_2|G/P_c(G)|$ $(c = 1, 2, ...)$ is the sequence Σ. Here $\mathcal{F}$ consists of ...

The shortest elements in $\mathcal{F}$ have length 6 and there are 48 of them, for instance $y^2xyxy, y^2xyx^{-1}y^{-1}, ...$ There are 256 elements in $\mathcal{F}$ of length 7, 960 of length 8, 2880 of length 9, 8960 of length 10, and so on.

Group-Theoretic Consequences of Conjecture 1. If G is as in conjecture 1, then its three subgroups of index 2 have abelianization $[2, 4, 4]$. For the 13104 elements of $\mathcal{F}$ just listed, the abelianizations of its index 4 subgroups are always the same except that one subgroup H, normal with cyclic quotient, has $H/H' \cong [2, 4, 4, 8]$ for some groups G, $[4, 4, 4, 4]$ for others, and $[2, 2, 8, 16]$ for yet others. These subgroups, which we shall denote *critical*, always have 4 generators and 4 relations. The collection of abelianizations of the index 8 subgroups come in 8 flavors, of which 5 correspond to there being a critical subgroup with abelianization $[4, 4, 4, 4]$.

3. Number-Theoretical Evidence and Consequences.

All the groups G in our class $\mathcal{C}$ satisfy $G/G' \cong [4, 4]$. If this is isomorphic to some G_S with $S = \{p, q\}$, then both p and q are 5(mod 8). Suppose this is the case. We find the following possibilities for H/H' for the three subgroups of G_S of index 2 (from computing ray class groups):

(i) If p is not a square mod q, then $[2, 8]$ twice and $[4, 4]$.

Suppose p is a square mod q (so by quadratic reciprocity q is a square mod p).

(ii) If p is not a 4th power mod q and q not a 4th power mod p, then $[2, 4, 4]$

twice and $[2,2,8]$.

(iii) If p is a 4th power mod q but q not a 4th power mod p, then $[2,4,4]$ three times.

(iv) If p is a 4th power mod q and q is a 4th power mod p, then $[2,4,4]$ twice and $[2,2,2^n]$ for some $n \geq 4$.

Case (i) forces (by my method with Leedham-Green [5]) G_S to be finite. I believe that cases (ii) and (iv) will lead to the same conclusion (but the computations are prohibitive - there is combinatorial explosion with thousands of candidate groups produced). Since the groups in $\mathcal{C}$ all have abelianizations of index 2 subgroups of type (iii), we focus on that case. The examples of such S with $p,q \leq 61$ are $\{13,29\},\{29,53\},\{37,53\},\{5,61\}$.

Corollary to Conjecture 1. If $p,q \equiv 5 (\mathrm{mod}\ 8)$, then G_S is infinite and $\cong <x,y|x^a = x^5, y^4>$ for $a \in \mathcal{F}$ if p is a 4th power modulo q but not vice versa, and G_S is finite otherwise.

Proof. By a modified Golod-Shafarevich inequality, due to Thomas Kuhnt (to appear), applied to the quartic subfield of the cyclotomic field $\mathbf{Q}(\zeta_q)$, it follows that G_S is infinite.

In the other cases, if G_S were infinite, then its abelianizations of index 2 subgroups would have to be all $[2,4,4]$, but as noted above the corresponding ray class groups are not this.

Note that the quartic subfield used is the fixed field of the critical subgroup. Next, we look at subgroups of index 4 of G_S of type (iii). We find that their abelianizations match those of G in $\mathcal{C}$ exactly, which is strong evidence for conjecture 1, since one set of abelianizations is computed by number theory, the other by group theory, by completely different algorithms. Since the quartic subfield of $\mathbf{Q}(\zeta_q)$ always has 2-part of its pq-ray class group isomorphic to $[4,4,4,4]$, we thereby exclude some groups in $\mathcal{C}$.

Looking further at ray class groups of degree 8 fields, we find exact matching of abelianizations again, yielding further strong evidence for conjecture 1. The Galois group G_S with $S = \{13,29\}$ has such subgroups with abelianization $[2,4,4,16]$, corresponding to the root field of $x^8 + 1044x^6 + 273702x^4 - 98397x^2 + 142129$, which matches one of the five flavors. Again, this excludes some groups in $\mathcal{C}$. Ray class computations suggest that it is unlikely that all Galois groups in (iii) have this same behavior.

4. Fontaine-Mazur by Group Theory.

Proof of the Fontaine-Mazur conjecture and related conjectures now amounts to proving purely group-theoretical properties of groups in $\mathcal{C}$. Let G be such a group and $\rho : G \to GL_n(\mathbf{Z}_2)$ a continuous representation. Since $\rho(x)$ is conjugate to $\rho(x)^5$, its eigenvalues are a permutation of their 5th powers. In the semisimple case, where all these eigenvalues are distinct, this implies that $\rho(x)$ has finite order and now Fontaine-Mazur follows from the conjecture that if $a \in \mathcal{F}$, then $< x,y|x^a =$

$x^5, y^4, x^k >$ is finite for every 2-power k.

A lot more, however, appears to be true. Namely, $200,000$ times I added a random relation s of length ≤ 16 to the relations of various G in $\mathcal{C}$ and each time either got back G or a finite group. This suggests:

Conjecture 2. Each group in $\mathcal{C}$ is just-infinite.

The classification of just-infinite pro-p groups is a major topic, and as noted in [11], they come in two flavors, namely those which are branch and those which have a normal open subgroup which is a direct product of hereditarily just-infinite groups.

Corollary to Conjecture 2. Each group in $\mathcal{C}$ is a branch just-infinite group.

Proof This follows from the last comment, together with the observation that these groups have a subgroup H of index 4 with 4 generators and 4 relations. Since H thereby fails the Golod-Shafarevich test, it is not just-infinite, and so G is not hereditarily just-infinite. A modification of this argument shows that G can have no open subgroup that is a direct product of herditarily just-infinite groups.

In particular, this confirms my extension of the Fontaine-Mazur conjecture [2],[4]. It should be possible to construct G in $\mathcal{C}$ explicitly as a branch group, but note that G cannot be one of the special groups G_ω constructed in section 8 of [11], since those groups are generated by torsion elements (rooted and directed automorphisms), whereas (see below) our groups are not. This is therefore a new construction, surprising because the nicest branch groups have so far not been finitely presented [1]. The techniques of [11] then show that G is just-infinite.

Note that in the introduction to [11] Grigorchuk suggests that his construction might produce all branch groups. The above suggests not (and in fact since [11], articles have found new more general constructions - see e.g. [13]). In particular, Grigorchuk's special branch groups are all torsion-generated, whereas as noted below ours are not, although the (closed) subgroup generated by torsion is of finite index.

Let T_4 be the rooted tree with 4 vertices above each vertex, so having 4^n vertices at level n. Let W_n be the iterated wreath product given by $W_1 = C_4, W_n = W_{n-1} \wr C_4$. Then W_n acts on the subtree of T_4 consisting of vertices up to and including level n and their inverse limit W acts on T_4, i.e. $W \leq \mathrm{Aut}(T_4)$. $W_2 = C_4 \wr C_4 \cong G/H'$, where G is a typical group in $\mathcal{C}$ and H its critical subgroup. W_3 is of order 2^{42} and I have found subgroups K of it generated by elements x, y such that x is conjugate to x^5 and y has order 4 and such that the abelianizations of their index 2 subgroups are all $[2, 4, 4]$. The abelianizations of their index 4 subgroups do not always match the data for groups in $\mathcal{C}$. In particular, many of them have non-normal subgroups of index 4 with abelianization $[2, 8, 8]$, too large for K to be a quotient of a group in $\mathcal{C}$. If, however, we take certain x of order 64 such that $K =< x, y >$ has order 2^{18}, then the abelianizations of index 4 subgroups are small enough.

For certain groups in $\mathcal{C}$, the critical subgroup of index 4 can be nicely described. For instance, suppose $a = y^2xyxy$. Then $H =< x, u, v, w | x^{vu} = x^5, u^{wv} = u^5, v^{xw} = v^5, w^{ux} = w^5 >$ and it embeds in G by having $u = x^y, v = x^{y^2}, w = x^{y^3}$. Note that then $vu = a$ and the relations are obtained by conjugating the first relation by the powers of y. G is the semidirect product of H by $< y >$. On the number-theoretic side, H is generated by the inertia groups at p, four conjugate ones since p splits completely in the critical quartic field.

Apparently, the sequence $\log_2|P_n(H)/P_{n+1}(H)| = 2\sum_{m=1}^{n}(1/m)\sum_{d|m}\mu(m/d)2^d$, so by Witt's formula [15] grows like that of $F \times F$, where F is the free pro-2 group on 2 generators.

As for Fontaine-Mazur holding for open subgroups of G, rather than just G itself, the following might be true:

Question 3. If H is an open subgroup of a group in $\mathcal{C}$, then is the closed subgroup $T(H)$ generated by all its torsion elements also open?

This has been checked for various groups in $\mathcal{C}$ and their subgroups. For instance, $T(G)$ is always of index 4 in G. Since $T(G) \neq G$, we obtain that G is not itself torsion-generated. A positive answer to question 3 implies that G is torsion-riddled, as proposed in [4], but is stronger. Note, however, that it is still unknown as to whether the critical subgroups have torsion, an important case for question 3 and the conjecture of [4]. We have:

Corollary to Positive Answer to Question 3. If G is in $\mathcal{C}$, then no open subgroup of G has a 2-adic representation with infinite image, i.e. the Fontaine-Mazur conjecture.

Proof The point is that if H is an open subgroup with such a representation, then it has an open subgroup with an infinite torsion-free quotient, which is forbidden by an affirmative answer to question 3.

5. Speculation.

Let G_S be of type (iii), with $S = \{p, q\}$. Let $T = \{2, p, q\}$. Consider G_T acting on π_1, the algebraic fundamental pro-2 group of P^1 minus three points $0, p, q$ in the usual way. π_1 is isomorphic to the free pro-2 group F on 2 generators. The normal subgroup N generated by inertia at 2 acts wildly on the $\mathbf{F}_p$-Lie algebra $L(F) = \sum P_n(F)/P_{n+1}(F)$, but the suggestion is that the subgroup H fixed by N is large enough to provide the indicated action of G_S on a necklace algebra, namely that provided by conjecture 1.

More generally, note that the groups G_S are interrelated - if $T = S \cup \{p\}$, then there is a natural surjection $G_T \to G_S$. The kernel of this map can be studied. For instance, for our situation, with $S = \{q\}, T = \{p, q\}$, the kernel is the critical subgroup. Note that since this is not just-infinite, there are many quotients of G_T mapping onto G_S.

Oene Bottema, The Malfatti Problem

Forum Geometricorum, 1 (2001) 43 -- 50; supplement, 50a.

Abstract: A solution is given of Steiner's variation of the classical Malfatti problem in which the triangle is replaced by three circles mutually tangent to each other externally. The two circles tangent to the three given ones, presently known as Soddy's circles, are encountered as well.

Enumeration of planar two-face maps ⋆

Michel Bousquet, Gilbert Labelle, Pierre Leroux

Lacim, Département de Mathématiques, Université du Québec à Montréal.

Abstract

We enumerate unrooted planar maps (up to orientation preserving homeomorphism) having two faces, according to the number of vertices and to their vertex and face degree distributions, both in the (vertex) labelled and unlabelled cases. We first consider plane maps, i.e., maps which are embedded in the plane, and then deduce the case of planar (or sphere) maps, embedded on the sphere. A crucial step is the enumeration of two-face plane maps having an antipodal symmetry and use is made of Liskovets' method in the process. The motivation for this research comes from the topological classification of Belyi functions.

Résumé

Nous dénombrons les cartes planaires (à homéomorphisme préservant l'orientation près) non pointées à deux faces, selon le nombre de sommets et selon la distribution des degrés des sommets et des faces, étiquetées (aux sommets) ou non. Nous abordons d'abord les cartes planes, c'est-à-dire plongées dans le plan, et déduisons ensuite le cas des cartes planaires (ou sphériques), plongées sur la sphère. Une étape cruciale est le dénombrement des cartes planes à deux faces admettant une symétrie antipodale et la méthode de Liskovets est utilisée pour cela. La motivation de cette recherche provient de la classification topologique des fonctions de Belyi.

Key words: Planar maps, unrooted maps, plane maps, sphere maps, degree distributions, species, Belyi functions,

1 Introduction.

The interest of studying maps is now well established. Not only are they interesting on their own, but the combinatorics of maps is also closely related to other topics, such as Galois theory, algebraic number theory or the theory of Riemann surfaces and algebraic combinatorics (see Arnold [1], Goulden

⋆ Work was partially supported by NSERC (Canada) and FCAR (Québec)

and Jackson [11] and Shabat and Zvonkin [21]). The enumeration of maps is a difficult problem. One way to approach this problem is to consider *rooted* maps, that is, maps with a distinguished and directed edge. The fact that rooted maps have only the trivial automorphism facilitates their enumeration. For papers on the enumeration of rooted planar maps, see Tutte ([24],[26]), Cori [8], Arquès [2], Bender and Wormald [5].

This paper deals with the enumeration of *unrooted planar maps having two faces*. Our main objective is to enumerate these maps according to their vertex and face degree distributions. This problem is motivated by the classification of Belyi functions, which are in correspondance with planar (hyper)maps; see Magot [18], Magot and Zvonkin [19], and Shabat and Zvonkin [21]. The case of only one face reduces to plane trees and has been completely solved; see Harrary, Prins and Tutte [12] and Tutte [25] for rooted trees, and Walkup [27] and Labelle and Leroux [14] for unrooted trees.

For other work on the enumeration of unrooted maps, see Liskovets [15]–[16], Liskovets and Walsh [17], Tutte [23] and Wormald [28], [29]. Note also that Magot [18] has given an algorithm for the generation of non rooted planar two-face maps, according to their face degree distribution.

A *planar map* m is a cellular embedding of a connected graph (multiple edges and loops permitted) into the 2-sphere S^2. This defines a partition of S^2 into vertices (points), edges (open arcs whose endpoints are vertices) and faces (regions of S^2 obtained by deletion of the vertices and edges, which are homeomorphic to open discs). Two planar maps are called *equivalent* if there exists an orientation preserving homeomorphism of S^2 which sends one into the other.

By contrast, a *plane* map, or graph, is a proper embedding of a connected graph into the plane. It can be seen as a planar map with a distinguished (exterior) face. Although not traditional, the more precise terminology of *sphere maps*, for planar maps, seems appropriate here to distinguish them from plane maps. This terminology will be used in the rest of this paper.

We will consider sphere and plane maps (up to equivalence) as structures on the set of labelled vertices. Let m and m' be two sphere maps (resp. plane maps) with vertex sets $U = \mathcal{V}(\mathsf{m})$ and $U' = \mathcal{V}(\mathsf{m}')$ respectivly. Then an *isomorphism* of maps $\mathsf{m} \tilde{\to} \mathsf{m}'$ is a bijection of the vertices $\sigma : U \tilde{\to} U'$ which is induced by an orientation preserving (possibly trivial) homeomorphism of the sphere (resp. of the plane) sending the map m into m'. In this manner, *unlabelled maps*, that is isomorphism classes, correspond exactly to the topological equivalence classes of maps.

In order to enumerate two-face maps, we first express the species of two-face *plane* maps in terms of circular permutations and of planted plane trees (see

section 2). This yields the enumeration of both labelled and unlabelled two-face plane maps with n vertices, using Lagrange inversion. Moreover, the above expression can be refined, using appropriate weights, to incorporate the vertex degree and the face degree distributions.

In a second stage, two-face *sphere* maps are considered as orbits of two-face plane maps, under the antipodal transformation which exchanges the interior and the exterior faces. A crucial step then is to enumerate plane maps having an antipodal symmetry. In the labelled case, this is easily done since only the one-vertex and two-vertex cycles have this symmetry. In the unlabelled case one can use a direct bijective approach or compute the cycle index polynomial of a particular action of the dihedral group; see Bousquet [6]. Here, we rather adopt a hybrid but simpler approach which makes use of Liskovets' method [15,16], for the enumeration of sphere maps: unlabelled two-face sphere maps on $n \geq 3$ vertices can be considered as orbits of the symmetric group acting on labelled sphere maps. One difference with [15] is that the symmetric group acts on the vertices here instead of the half-edges or bits (or "brins").

An important use is made of the following fact:

Lemma 1 (See [3]). *Any periodic orientation preserving homeomorphism of the 2-sphere is conjugate by an orientation preserving homeomorphism to a rotation around a certain axis.*□

It follows that a non trivial automorphism of a sphere map leaves exactly two cells (vertex, edge, or face) fixed and that for $n \geq 3$, the representation of map automorphisms by vertex permutations is faithful. For two-face sphere maps, we can classify all possible automorphisms and enumerate their fixed points, using the concept of quotient maps as in [15,16]. This approach is easily adapted to include the vertex and face degree distributions and gives the desired results. See section 3.

We would like to thank A. Zvonkin for suggesting and motivating this work, R. Cori and G. Schaeffer for useful discussions, and the referees for helpful suggestions.

2 Two-face plane maps.

Our analysis of two-face plane maps will involve the species A of *planted plane trees*, that is, of rooted plane trees with a half edge attached to the root, which contributes one unit to the root degree and prevents the other incident edges from fully rotating around the root (see Figure 1).

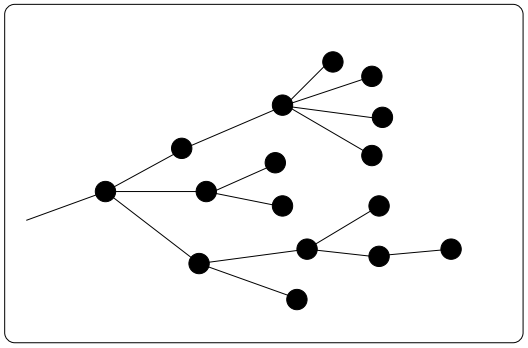

Fig. 1. A planted plane tree.

A planted plane tree is therefore an asymmetric structure. If the sets of labelled and unlabelled planted plane trees with n vertices are respectively denoted by A_n and $\widetilde{A}_n$, then their cardinalities satisfy the relation

$$|A_n| = n!|\widetilde{A}_n|$$

and the corresponding generating series

$$A(x) = \sum_{n\geq 1} |A_n| \frac{x^n}{n!} \quad \text{and} \quad \widetilde{A}(x) = \sum_{n\geq 1} |\widetilde{A}_n| x^n$$

of labelled (exponential series) and of unlabelled planted plane trees, are equal: $A(x) = \widetilde{A}(x)$. The species A of planted plane trees satisfies the combinatorial identity

$$A = XL(A), \tag{1}$$

where X is the species of singletons, and L, that of total orders (lists). This implies the following well known relation (see Tutte [25]) on the generating series :

$$A(x) = \frac{x}{1 - A(x)},$$

which can be solved algebraically to obtain

$$A(x) = \sum_{n\geq 1} \frac{1}{n} \binom{2n-2}{n-1} x^n. \tag{2}$$

More generally, by Lagrange inversion, for any integer $\alpha \geq 0$, we have

$$A^\alpha(x) = \sum_{n\geq \alpha} \frac{\alpha}{2n-\alpha} \binom{2n-\alpha}{n} x^n. \tag{3}$$

To keep track of the vertex degree distribution in a planted plane tree, we introduce a sequence $\boldsymbol{r} = (r_1, r_2, r_3, \ldots)$ of formal variables and a weight function w which assigns to each planted plane tree a, the weight

$$w(a) = r_1^{d_1} r_2^{d_2} r_3^{d_3} \cdots, \tag{4}$$

where d_i is the number of vertices of degree i in a. The vertex degree distribution is thus described by a vector $\boldsymbol{d} = (d_1, d_2, \ldots)$ and the following notations are used throughout this paper:

$$|\boldsymbol{d}| = \sum_i d_i \quad \text{and} \quad ||\boldsymbol{d}|| = \sum_i i d_i \tag{5}$$

corresponding respectively to the number of vertices and the total degree. The corresponding weighted species, denoted by $A_{\boldsymbol{r}}$, satisfies the combinatorial identity

$$A_{\boldsymbol{r}} = X L_{\boldsymbol{r}}(A_{\boldsymbol{r}}), \tag{6}$$

where

$$L_{\boldsymbol{r}} = 1_{r_1} + X_{r_2} + X^2_{r_3} + \cdots$$

is the weighted species of lists where a list of length i has the weight r_{i+1}. We then have $A_{\boldsymbol{r}}(x) = x \sum_{j \geq 0} r_{j+1} A^j_{\boldsymbol{r}}(x)$, $\tilde{A}_{\boldsymbol{r}}(x) = A_{\boldsymbol{r}}(x)$, and it follows from Lagrange inversion (see Tutte [25]) that

$$A^{\alpha}_{\boldsymbol{r}}(x) = \sum_{\beta, \boldsymbol{h}} \frac{\alpha}{\beta} \binom{\beta}{\boldsymbol{h}} \boldsymbol{r}^{\boldsymbol{h}} x^{\beta}, \tag{7}$$

where

$$\binom{\beta}{\boldsymbol{h}} = \binom{\beta}{h_1, h_2, h_3, \ldots} \quad \text{and} \quad \boldsymbol{r}^{\boldsymbol{h}} = r_1^{h_1} r_2^{h_2} r_3^{h_3} \cdots,$$

the sum being taken over all integers $\beta \geq \alpha$, and vectors $\boldsymbol{h}$ such that $|\boldsymbol{h}| = \beta$ and $||\boldsymbol{h}|| = 2\beta - \alpha$.

Let C denotes the species of oriented cycles, for which

$$C(x) = \sum_{\gamma \geq 1} \frac{x^{\gamma}}{\gamma} = \log \frac{1}{1-x}, \quad \tilde{C}(x) = \frac{1}{1-x}, \tag{8}$$

and the cycle index series Z_C is given by (see [4], [13])

$$Z_C(x_1, x_2, x_3, \ldots) = \sum_{m \geq 1} \frac{\phi(m)}{m} \log \frac{1}{1 - x_m}, \tag{9}$$

where ϕ is the Euler phi function.

Recall that a two-face plane map is a two-face sphere map with a distinguished face. See Figure 2 for an example where the exterior (infinite) face is the distinguished one. We see that any two-face plane map can be decomposed as an oriented cycle of $XL^2(A)$-structures, where an $XL^2(A)$-structure is interpreted as a vertex to which is attached an ordered pair of lists of planted plane trees (Figure 3). In conclusion, we have the following structure theorem for the species of two-face plane maps, denoted by M.

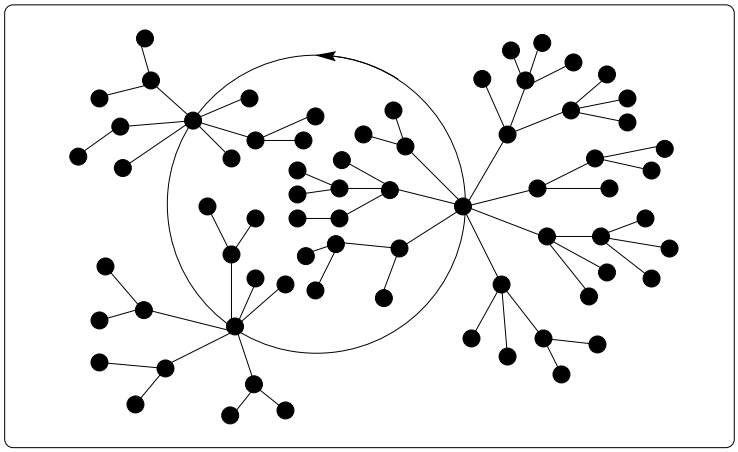

Fig. 2. A two-face plane map.

Theorem 2 *The species* M *of two-face plane maps satisfies the following combinatorial identity:*

$$\mathsf{M} = C(XL^2(A)). \tag{10}$$

□

Note that since $A = XL(A)$, we have

$$(XL^2(A))(x) = \frac{A^2(x)}{x}. \tag{11}$$

Let M_n be the set of labelled two-face plane maps over the vertex set $[n] = \{1, 2, \ldots, n\}$ and $\widetilde{\mathsf{M}}_n$ the corresponding set of unlabelled maps. We have

$$|\mathsf{M}_n| = n![x^n]\mathsf{M}(x) \quad \text{and} \quad |\widetilde{\mathsf{M}}_n| = [x^n]\widetilde{\mathsf{M}}(x). \tag{12}$$

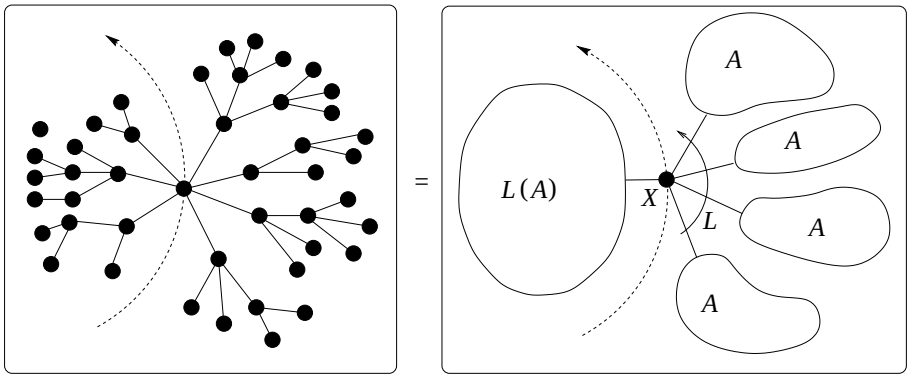

Fig. 3. An $XL^2(A)$-structure.

By using (10) and (11), we have

$$\mathsf{M}(x) = \sum_{\gamma \geq 1} \frac{A^{2\gamma}(x)}{\gamma x^\gamma}. \tag{13}$$

Using (3), we deduce that

$$\begin{aligned} |\mathsf{M}_n| &= (n-1)! \sum_{\gamma=1}^{n} \binom{2n}{n+\gamma} \\ &= \frac{(n-1)!}{2} \left(2^{2n} - \binom{2n}{n} \right). \end{aligned}$$

It follows from Theorem 2 and (9) and from general principles (see Theorem 1.4.2 of [4]) that

$$\begin{aligned} \widetilde{\mathsf{M}}(x) &= Z_C \left((XL^2(A_L))^{\sim}(x^m) \right)_{m \geq 1} \\ &= \sum_{m \geq 1} \frac{\phi(m)}{m} \log \left(1 - \frac{A^2(x^m)}{x^m} \right)^{-1} \end{aligned}$$

from which we deduce the value (15) of $|\widetilde{\mathsf{M}}_n|$ below. Hence, we have:

Theorem 3 *The numbers $|\mathsf{M}_n|$ and $|\widetilde{\mathsf{M}}_n|$ of labelled and unlabelled two-face plane maps on n vertices are respectively given by*

$$|\mathsf{M}_n| = \frac{(n-1)!}{2} \left(2^{2n} - \binom{2n}{n} \right). \tag{14}$$

and

$$|\widetilde{\mathsf{M}}_n| = \frac{1}{2n}\sum_{d|n}\phi(\frac{n}{d})\left(2^{2d} - \binom{2d}{d}\right). \tag{15}$$

□

Remark 4 *Let t_n be the number of (unlabelled) rooted sphere maps having two faces and n vertices (or n edges). It is easy to see that $n|\mathsf{M}_n| = n!t_n$ so that $t_n = \frac{1}{(n-1)!}|\mathsf{M}_n|$ and formula* (14) *is equivalent to*

$$t_n = \frac{1}{2}\left(2^{2n} - \binom{2n}{n}\right) = 2^{2n-1} - \binom{2n-1}{n-1}. \tag{16}$$

The sequence $\{t_n\}$, whose first terms are $1, 5, 22, 93, 386, 1586, \ldots$ appears in Tutte rm [26] and is presented in Sloane-Plouffe's Encyclopedia of integer sequences [22] *under* #M3920. *Similarly formulas* (28), (37) *and* (44) *below could be reformulated in terms of rooted sphere maps.*

Vertex degree distribution.

To enumerate two-face plane maps according to their vertex degree distribution, we define the weight function w_v on the species M: given a two-face map m, we set

$$w_v(\mathsf{m}) = r_1^{d_1} r_2^{d_2} r_3^{d_3} \cdots, \tag{17}$$

where d_k is the number of vertices of m of degree k. For example, the map in Figure 2 has the weight $r_1^{46} r_2^2 r_3^{13} r_4^7 r_8^2 r_9$. It is well known (see J.W. Moon [20]) that there exists a tree having $\boldsymbol{d} = (d_1, d_2, \ldots)$ as vertex degree distribution if and only if $||\boldsymbol{d}|| = 2|\boldsymbol{d}| - 2$. It easily follows that a two-face map with vertex degree distribution $\boldsymbol{d}$ exists if and only if

$$||\boldsymbol{d}|| = 2|\boldsymbol{d}|. \tag{18}$$

Theorem 2 can be generalized to express the species M_{w_v} of two-face plane maps weighted by vertex degree in terms of the species $A_{\boldsymbol{r}}$ of planted plane trees weighted by vertex degree, defined by (6):

$$\begin{aligned}\mathsf{M}_{w_v} &= C\Big(\sum_{m,k\geq 0} X_{r_{m+k+2}} A_{\boldsymbol{r}}^{m+k}\Big)\\ &= C\Big(\sum_{\lambda\geq 1} \lambda X_{r_{\lambda+1}} A_{\boldsymbol{r}}^{\lambda-1}\Big).\end{aligned} \tag{19}$$

where X_{r_i} denotes the species of singletons, with weight r_i.

Let $\mathsf{M}_{\boldsymbol{d}}$ denote the set of labelled two-face plane maps over the set $[|\boldsymbol{d}|]$ and having $\boldsymbol{d}$ as vertex degree distribution. From (19), we deduce that

$$|\mathsf{M}_{\boldsymbol{d}}| = |\boldsymbol{d}|![\boldsymbol{r}^{\boldsymbol{d}} x^{|\boldsymbol{d}|}]\mathsf{M}_{w_v}(x), \tag{20}$$

where

$$\begin{aligned}\mathsf{M}_{w_v}(x) &= \sum_{\gamma\geq 1} \frac{x^\gamma}{\gamma}\left(r_2 + 2r_3 A_{\boldsymbol{r}}(x) + 3r_4 A_{\boldsymbol{r}}^2(x) + 4r_5 A_{\boldsymbol{r}}^3(x) + \cdots\right)^\gamma \\ &= \sum_{\substack{\gamma\geq 1 \\ g_2+g_3+\cdots=\gamma}} \frac{x^\gamma}{\gamma}\binom{\gamma}{g_2, g_3, \ldots} r_2^{g_2}(2r_3)^{g_3}(3r_4)^{g_4}\cdots(A_{\boldsymbol{r}}(x))^{g_3+2g_4+\cdots}. \end{aligned}\tag{21}$$

In this sum, g_i corresponds to the number of vertices of degree i on the cycle. Note that g_1 does not appear, which is consistant with the fact that there cannot be any vertices of degree one on the cycle. We also have $|\boldsymbol{g}| = \gamma$ and $g_3 + 2g_4 + 3g_5 + \cdots = ||\boldsymbol{g}|| - 2|\boldsymbol{g}| = ||\boldsymbol{g}|| - 2\gamma$, so we can write (21) as

$$\mathsf{M}_{w_v}(x) = \sum_{\gamma\geq 1}\frac{x^\gamma}{\gamma}\sum_{\alpha\geq 0}\sum_{\substack{|\boldsymbol{g}|=\gamma \\ ||\boldsymbol{g}||=\alpha+2\gamma}}\binom{\gamma}{\boldsymbol{g}} 2^{g_3}3^{g_4}\cdots \boldsymbol{r}^{\boldsymbol{g}} A_{\boldsymbol{r}}^\alpha(x). \tag{22}$$

In this sum, α represents the number of planted plane trees which lie around the cycle. If $\alpha = 0$, all the vertices are on the cycle. Using (7), we can rewrite (22) as

$$\mathsf{M}_{w_v}(x) = \sum_{n\geq 1}\frac{x^n}{n} r_2^n + \sum \frac{\alpha}{\gamma\beta}\binom{\gamma}{\boldsymbol{g}}\binom{\beta}{\boldsymbol{h}} 2^{g_3}3^{g_4}\cdots \boldsymbol{r}^{\boldsymbol{g}+\boldsymbol{h}} x^{\gamma+\beta}, \tag{23}$$

the second sum being taken over all integers $\gamma, \alpha, \beta \geq 1$ and all vectors $\boldsymbol{g} = (g_1, g_2, \ldots)$ and $\boldsymbol{h} = (h_1, h_2, \ldots)$ such that $|\boldsymbol{g}| = \gamma$, $||\boldsymbol{g}|| = \alpha + 2\gamma$, $g_1 = 0$, $|\boldsymbol{h}| = \beta$, and $||\boldsymbol{h}|| = 2\beta - \alpha$. One can write α, β and γ in terms of $\boldsymbol{g}$ and $\boldsymbol{h}$, that is

$$\alpha = ||\boldsymbol{g}|| - 2|\boldsymbol{g}|, \quad \beta = |\boldsymbol{h}| \quad \text{and} \quad \gamma = |\boldsymbol{g}|. \tag{24}$$

A pure coefficient extraction, in the case $\alpha \geq 1$, gives

$$\begin{aligned} H(\boldsymbol{d}) &:= [\boldsymbol{r}^{\boldsymbol{d}} x^{|\boldsymbol{d}|}]\mathsf{M}_{w_v}(x) \\ &= \sum_{\boldsymbol{g},\boldsymbol{h}} \frac{||\boldsymbol{g}|| - 2|\boldsymbol{g}|}{|\boldsymbol{g}|\,|\boldsymbol{h}|}\binom{|\boldsymbol{g}|}{\boldsymbol{g}}\binom{|\boldsymbol{h}|}{\boldsymbol{h}} 2^{g_3}3^{g_4}\cdots, \end{aligned}\tag{25}$$

the sum being taken over all pairs of non-zero vectors $(\boldsymbol{g}, \boldsymbol{h})$ such that $\boldsymbol{g}+\boldsymbol{h} = \boldsymbol{d}$ and $g_1 = 0$.

For unlabelled two-face plane maps having $\boldsymbol{d}$ as vertex degree distribution, we deduce from (19) that

$$|\widetilde{\mathsf{M}}_{\boldsymbol{d}}| = [\boldsymbol{r}^{\boldsymbol{d}} x^{|\boldsymbol{d}|}]\widetilde{\mathsf{M}}_{w_v}(x), \tag{26}$$

with, by the composition theorem for weighted species (see [4], section 4.3),

$$\widetilde{\mathsf{M}}_{w_v}(x) = Z_C\left(\sum_{\lambda\geq 1} \lambda r_{\lambda+1}^m x^m A_{\boldsymbol{r}^m}^{\lambda-1}(x^m)\right)_{m\geq 1}, \tag{27}$$

where $A_{\boldsymbol{r}^m}$ is the weighted species of planted plane trees in which the weight of each structure, as defined in (4), is raised to the m-th power. After expanding and extracting coefficients we obtain the following result.

Theorem 5 *Let $\boldsymbol{d}$ be a vector satisfying $||\boldsymbol{d}|| = 2|\boldsymbol{d}|$. Then the number $|\mathsf{M}_{\boldsymbol{d}}|$ of labelled two-face plane maps having $\boldsymbol{d}$ as vertex degree distribution is given by $(|\boldsymbol{d}|-1)!$ if $|\boldsymbol{d}| = d_2$, and otherwise, by*

$$|\mathsf{M}_{\boldsymbol{d}}| = |\boldsymbol{d}|!H(\boldsymbol{d}), \tag{28}$$

where $H(\boldsymbol{d})$ is given by (25). Also the number $|\widetilde{\mathsf{M}}_{\boldsymbol{d}}|$ of unlabelled two-face plane maps having $\boldsymbol{d}$ as vertex degree distribution is given by $|\widetilde{\mathsf{M}}_{\boldsymbol{d}}| = 1$ if $|\boldsymbol{d}| = d_2$, and otherwise by

$$|\widetilde{\mathsf{M}}_{\boldsymbol{d}}| = \sum_{m|\boldsymbol{d}} \frac{\phi(m)}{m} H(\boldsymbol{d}/m), \tag{29}$$

the sum being taken over common divisors m of all components of $\boldsymbol{d}$, with $\boldsymbol{d}/m = (d_1/m, d_2/m, \ldots)$. □

Face degree distribution.

In order to enumerate two-face plane maps according to their face degree distribution, we introduce a new weight function w_f defined, for a two-face map m, by

$$w_f(\mathsf{m}) = s^{\gamma} t^m u^k, \tag{30}$$

where s, t and u are formal variables and γ, m and k respectively denote the number of vertices lying *on*, *outside* and *inside* the cycle. For example, the map appearing on Figure 2 has the weight $s^3t^{43}u^{25}$.

Let α denote the degree of the outer face and β, the degree of the inner face. The triplet (γ, m, k) is sufficient to determine this degree distribution. Indeed, we have

$$\alpha = \gamma + 2m \quad \text{and} \quad \beta = \gamma + 2k, \tag{31}$$

and $\alpha + \beta = 2(\gamma + k + m) = 2n$, where n is the number of vertices of the map. We then deduce that α and β must have the same parity. One can easily verify that this condition is also sufficient for the existence of a two-face sphere map having face degree distribution (α, β).

The species M_{w_f} of two-face plane maps, weighted by w_f, can then be expressed as

$$\mathsf{M}_{w_f} = C\left(X_s \cdot L(A(X_t)) \cdot L(A(X_u))\right), \tag{32}$$

where X_s is the species of singletons weighted by s and similarly for X_t and X_u. Let $\alpha > 0$ and $\beta > 0$ have the same parity and set $n = (\alpha + \beta)/2$. Let $\mathsf{M}_{(\alpha,\beta)}$ denote the set of all two-face plane maps on $[n]$ having (α, β) as face degree distribution. We have

$$|\mathsf{M}_{(\alpha,\beta)}| = n! \sum_{\substack{1 \le \gamma \le min(\alpha,\beta) \\ 2|\gamma+\alpha}} [s^\gamma t^{(\alpha-\gamma)/2} u^{(\beta-\gamma)/2} x^n] \mathsf{M}_{w_f}(x). \tag{33}$$

Note that

$$A(X_t) = X_t L(A(X_t)), \tag{34}$$

so that at the level of generating series,

$$L(A(X_t))(x) = \frac{A(xt)}{xt}, \tag{35}$$

and similarly for $A(X_u)$. Therefore, using (32) and (3), we have

$$\mathsf{M}_{w_f}(x) = \sum_{\gamma \ge 1} \frac{s^\gamma}{\gamma (tux)^\gamma} A^\gamma(xt) A^\gamma(xu)$$

$$= \sum_{\gamma,i,j} \frac{1}{\gamma} \frac{\gamma}{2i-\gamma} \binom{2i-\gamma}{i} \frac{\gamma}{2j-\gamma} \binom{2j-\gamma}{j} s^\gamma t^{i-\gamma} u^{j-\gamma} x^{i+j-\gamma}$$
$$= \sum_{\gamma,m,k} \frac{\gamma}{(2m+\gamma)(2k+\gamma)} \binom{2m+\gamma}{m+\gamma} \binom{2k+\gamma}{k+\gamma} s^\gamma t^m u^k x^{\gamma+m+k}$$
$$= \sum_{\gamma,\alpha,\beta} \frac{\gamma}{\alpha\beta} \binom{\alpha}{\frac{\alpha+\gamma}{2}} \binom{\beta}{\frac{\beta+\gamma}{2}} s^\gamma t^{(\alpha-\gamma)/2} u^{(\beta-\gamma)/2} x^{(\alpha+\beta)/2}, \tag{36}$$

the last sum being taken over all triplets of integers γ, α, β such that $\gamma \geq 1, \alpha, \beta \geq \gamma, 2|\alpha-\gamma, 2|\beta-\gamma$. The next result follows, using the identity, for $\alpha \equiv \beta \pmod 2$,

$$\sum_{\substack{\gamma=1 \\ 2|\alpha+\gamma}}^{\min(\alpha,\beta)} \gamma \binom{\alpha}{\frac{1}{2}(\alpha+\gamma)} \binom{\beta}{\frac{1}{2}(\beta+\gamma)} = \frac{\alpha\beta}{\frac{1}{2}(\alpha+\beta)} \binom{\alpha-1}{\lfloor \alpha/2 \rfloor} \binom{\beta-1}{\lfloor \beta/2 \rfloor}$$

which can be deduced from a formula due to Knuth (see [10], eq. 3.152), with similar computations in the unlabelled case.

Theorem 6 *Let α and β be two strictly positive integers having the same parity. The number $|\mathsf{M}_{(\alpha,\beta)}|$ of labelled two-face plane maps having (α,β) as face degree distribution is given by*

$$|\mathsf{M}_{(\alpha,\beta)}| = (n-1)! \binom{\alpha-1}{\lfloor \alpha/2 \rfloor} \binom{\beta-1}{\lfloor \beta/2 \rfloor}, \tag{37}$$

where $n = (\alpha+\beta)/2$ is the number of vertices. Moreover, the corresponding number $|\widetilde{\mathsf{M}}_{(\alpha,\beta)}|$ of unlabelled 2-face plane maps is given by

$$|\widetilde{\mathsf{M}}_{(\alpha,\beta)}| = \frac{1}{n} \sum_{\ell|(\alpha,\beta)} \phi(\ell) \binom{\frac{\alpha}{\ell}-1}{\lfloor \frac{\alpha}{2\ell} \rfloor} \binom{\frac{\beta}{\ell}-1}{[\frac{\beta}{2\ell}]}. \tag{38}$$

□

Joint vertex and face degree distributions.

Consider the plane map shown in Figure 2. The vertex and face degree distributions are respectively given by

$$\boldsymbol{d} = (46, 2, 13, 7, 0, 0, 0, 2, 1, 0, \ldots) \text{ and } (\alpha, \beta) = (89, 53). \tag{39}$$

The vector $\boldsymbol{d}$ decomposes as the sum of the three vectors

$$\boldsymbol{d} = \boldsymbol{g} + \boldsymbol{h} + \boldsymbol{k},$$

where $\boldsymbol{g}, \boldsymbol{h}$ et $\boldsymbol{k}$ respectively denote the degree distributions of vertices that lie on, outside and inside the cycle. In our example, we have

$$\boldsymbol{g} = (0,0,0,0,0,0,0,2,1,0,\ldots),\ \boldsymbol{h} = (29,1,7,6,0,\ldots)$$
$$\text{and } \boldsymbol{k} = (17,1,6,1,0,\ldots).$$

We note that $2|\boldsymbol{h}| - ||\boldsymbol{h}|| = 10$ and $2|\boldsymbol{k}| - ||\boldsymbol{k}|| = 9$, which are respectively the number of outer and inner ordered rooted trees. The term $2|\boldsymbol{h}| - ||\boldsymbol{h}||$ is called the *residual degree* of $\boldsymbol{h}$ and is denoted by $\mathrm{res}(\boldsymbol{h})$.

Let $\boldsymbol{s} = (s_1, s_2, s_3, \ldots)$, $\boldsymbol{t} = (t_1, t_2, t_3, \ldots)$ and $\boldsymbol{u} = (u_1, u_2, u_3, \ldots)$ be three infinite sequences of formal variables and m be a two-face plane map. We consider the weight function w_{vf} defined by:

$$w_{vf}(\mathsf{m}) = \boldsymbol{s}^{\boldsymbol{g}}\boldsymbol{t}^{\boldsymbol{h}}\boldsymbol{u}^{\boldsymbol{k}},$$

where

$$\boldsymbol{s}^{\boldsymbol{g}} = s_1^{g_1}s_2^{g_2}s_3^{g_3}\cdots,\ \ \boldsymbol{t}^{\boldsymbol{h}} = t_1^{h_1}t_2^{h_2}t_3^{h_3}\cdots,\ \text{ and }\ \boldsymbol{u}^{\boldsymbol{k}} = u_1^{k_1}u_2^{k_2}u_3^{k_3}\cdots,$$

respectively describe the distributions of degrees of vertices which lie on, outside and inside the cycle. For instance, the map shown in Figure 2 has the weight $s_8^2 s_9^1 t_1^{29} t_2 t_3^7 t_4^6 u_1^{17} u_2 u_3^6 u_4$. Note that this weight is sufficient to fully describe both vertex and face degree distributions, since

$$\boldsymbol{d} = \boldsymbol{g} + \boldsymbol{h} + \boldsymbol{k},\ \alpha = 2|\boldsymbol{h}| + |\boldsymbol{g}|,\ \text{and } \beta = 2|\boldsymbol{k}| + |\boldsymbol{g}|.$$

The corresponding weighted species is then expressed by

$$\mathsf{M}_{w_{vf}} = C\Big(\sum_{\ell,m\geq 0} X_{s_{\ell+m+2}} A_{\boldsymbol{t}}^{\ell} A_{\boldsymbol{u}}^{m}\Big). \tag{40}$$

Let $\mathsf{M}_{\boldsymbol{d},(\alpha,\beta)}$ be the set of two-face plane maps over the set $[n]$, where $n = |\boldsymbol{d}| = (\alpha+\beta)/2$, having $\boldsymbol{d}$ and (α,β) as joint vertex and face degree distributions. Let $\mathsf{M}_{(\boldsymbol{g},\boldsymbol{h},\boldsymbol{k})}$ be the set of all two-face plane maps having $(\boldsymbol{g},\boldsymbol{h},\boldsymbol{k})$ as vertex degree distributions respectively on, outside and inside the cycle. We have

$$|\mathsf{M}_{\boldsymbol{d},(\alpha,\beta)}| = \sum_{\boldsymbol{g},\boldsymbol{h},\boldsymbol{k}} |\mathsf{M}_{(\boldsymbol{g},\boldsymbol{h},\boldsymbol{k})}|, \tag{41}$$

the sum being taken over all triplets $(\boldsymbol{g},\boldsymbol{h},\boldsymbol{k})$ satisfying the following conditions

$$\begin{aligned}
&1.\ \boldsymbol{d}=\boldsymbol{g}+\boldsymbol{h}+\boldsymbol{k};\\
&2.\ \alpha=2|\boldsymbol{h}|+|\boldsymbol{g}|,\ \ \beta=2|\boldsymbol{k}|+|\boldsymbol{g}|;\\
&3.\ g_1=0,\ \ \boldsymbol{g}\neq\mathbf{0};\\
&4.\ \mathrm{res}(\boldsymbol{h})\geq 0,\ \ \text{and}\ \ \mathrm{res}(\boldsymbol{h})=0\Rightarrow\boldsymbol{h}=\mathbf{0};\\
&5.\ \mathrm{res}(\boldsymbol{k})\geq 0,\ \ \text{and}\ \ \mathrm{res}(\boldsymbol{k})=0\Rightarrow\boldsymbol{k}=\mathbf{0};
\end{aligned}\tag{42}$$

We find, after computations,

$$\begin{aligned}
|\mathsf{M}_{(\boldsymbol{g},\boldsymbol{h},\boldsymbol{k})}| &= |\boldsymbol{d}|![\boldsymbol{s}^{\boldsymbol{g}}\boldsymbol{t}^{\boldsymbol{h}}\boldsymbol{u}^{\boldsymbol{k}}x^n]\mathsf{M}_{w_{vf}}(x)\\
&= \frac{|\boldsymbol{d}|!\Phi(\boldsymbol{h})\Phi(\boldsymbol{k})\Theta(\boldsymbol{g},\boldsymbol{h})}{|\boldsymbol{g}|}\binom{|\boldsymbol{g}|}{\boldsymbol{g}}\binom{|\boldsymbol{h}|}{\boldsymbol{h}}\binom{|\boldsymbol{k}|}{\boldsymbol{k}},
\end{aligned}\tag{43}$$

where the functions Θ and Φ are defined by

$$\Theta(\boldsymbol{g},\boldsymbol{h})=[z^{\mathrm{res}(\boldsymbol{h})}](1+z)^{g_3}(1+z+z^2)^{g_4}(1+z+z^2+z^3)^{g_5}\cdots$$

and

$$\Phi(\boldsymbol{h})=\begin{cases}\mathrm{res}(\boldsymbol{h})/|\boldsymbol{h}|,\ \text{if}\ \mathrm{res}(\boldsymbol{h})\geq 1,\\ 1,\ \text{if}\ \boldsymbol{h}=0,\\ 0,\ \text{otherwise.}\end{cases}$$

Similar techniques are used for the unlabelled case. We then have the following result.

Theorem 7 *Let $\boldsymbol{d}$, satisfying $||\boldsymbol{d}||=2|\boldsymbol{d}|$ and $\alpha,\beta>0$, two integers having the same parity, where $|\boldsymbol{d}|=(\alpha+\beta)/2=n$. Then the number $|\mathsf{M}_{\boldsymbol{d},(\alpha,\beta)}|$ of labelled two-face plane maps on $[n]$ having joint vertex and face degree distributions $\boldsymbol{d}$ and (α,β) is given by*

$$|\mathsf{M}_{\boldsymbol{d},(\alpha,\beta)}|=n!H(\boldsymbol{d},(\alpha,\beta)).\tag{44}$$

and the corresponding number $|\widetilde{\mathsf{M}}_{\boldsymbol{d},(\alpha,\beta)}|$ of unlabelled two-face plane maps is given by

$$|\widetilde{\mathsf{M}}_{d,(\alpha,\beta)}|=\sum_{m|(\boldsymbol{d},\alpha,\beta)}\frac{\phi(m)}{m}\,H\left(\frac{\boldsymbol{d}}{m},(\frac{\alpha}{m},\frac{\beta}{m})\right)\tag{45}$$

with

$$H(\boldsymbol{d},(\alpha,\beta)) = \sum_{\boldsymbol{g},\boldsymbol{h},\boldsymbol{k}} \frac{\Phi(\boldsymbol{h})\Phi(\boldsymbol{k})\Theta(\boldsymbol{g},\boldsymbol{h})}{|\boldsymbol{g}|} \binom{|\boldsymbol{g}|}{\boldsymbol{g}} \binom{|\boldsymbol{h}|}{\boldsymbol{h}} \binom{|\boldsymbol{k}|}{\boldsymbol{k}},$$

where the sum runs over all $\boldsymbol{g},\boldsymbol{h}$ *and* $\boldsymbol{k}$ *satisfying conditions 1–5 in* (42). □

3 Sphere maps.

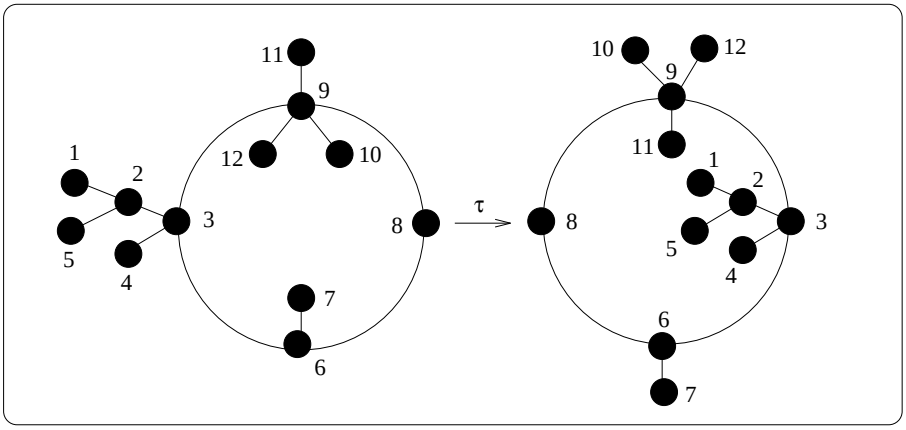

Fig. 4. Antipodal involution of a plane map.

Consider the two plane maps shown in Figure 4. Embedded in the plane, these two maps are distinct. No orientation preserving homeomorphism of the plane can send one onto the other. However, when considered embedded on the oriented sphere, both structures represent the *same* map. Imagine that the cycle lies along the equator. The left structure represents a north pole view of the map while the right structure represents a south pole view. We observe that this transformation essentially exchanges the choice of the distinguished face. Equivalently, it can be seen as a 180° rotation around an axis which passes through the equator. This transformation is clearly involutive, therefore it will be called the *antipodal involution*, and will be denoted by τ. A two-face plane map m is said to have an *antipodal symmetry* if $\tau(\mathsf{m}) = \mathsf{m}$.

Consider the group $<\tau> = \{\mathrm{Id}, \tau\}$, where Id is the identity transformation, and $\tau^2 = \mathrm{Id}$. This group *acts* on the species of two-face plane maps. More precisely, we have a familly of actions: for each finite set U, the function

$$\begin{aligned} <\tau> \times \mathsf{M}[U] &\to \mathsf{M}[U] \\ (g, \mathsf{m}) &\mapsto g \cdot \mathsf{m} \end{aligned} \tag{46}$$

is an action of the group $<\tau>$ on the set $\mathsf{M}[U]$ of all labelled two-face plane maps over U. Also, this action commutes with any relabelling along a bijection $\sigma : U \to V$. Note that it *preserves* the vertex degree distribution and that it *reverses* the face degree distribution.

From this point of view, the two-face *sphere* maps can be seen as *orbits* of the action of $<\tau>$ on the plane maps and the species of two-face sphere maps, which will be denoted by $\mathcal{M}$, is the *quotient* of the species M of two-face plane maps by the group $<\tau>$. This is written as

$$\mathcal{M} = \mathsf{M}/<\tau> . \tag{47}$$

It follows from the Cauchy-Frobenius Theorem (alias Burnside Lemma) that for any finite class C of plane maps (labelled or unlabelled), closed under the action of τ, the cardinality of the corresponding class $\mathcal{C} = \mathsf{C}/<\tau>$ of sphere maps is given by

$$|\mathcal{C}| = |\mathsf{C}/<\tau>\ | = \frac{1}{2}\left(|\mathsf{C}| + |\mathrm{Fix}_{\mathsf{C}}\ \tau|\right), \tag{48}$$

where $|\mathrm{Fix}_{\mathsf{C}}\ \tau|$ is the number of maps in C having an antipodal symmetry.

3.1 Enumeration of labelled two-face sphere maps.

Let $\mathcal{M}_n$, $\mathcal{M}_{\boldsymbol{d}}$, $\mathcal{M}_{\{\alpha,\beta\}}$ and $\mathcal{M}_{\boldsymbol{d},\{\alpha,\beta\}}$ be the sets of labelled two-face *sphere* maps respectively corresponding to the sets M_n, $\mathsf{M}_{\boldsymbol{d}}$, $\mathsf{M}_{(\alpha,\beta)}$ and $\mathsf{M}_{\boldsymbol{d},(\alpha,\beta)}$ of labelled two-face plane maps. By applying equation (48) to these sets, and noting that the only labelled two-face plane maps having an antipodal symmetry are the 1-cycle (1) and the 2-cycle (12), we find:

Proposition 8 Let $\boldsymbol{d}$ satisfy $||\boldsymbol{d}|| = 2|\boldsymbol{d}|$, and $\alpha, \beta > 0$, be two integers having the same parity, and such that $n = |\boldsymbol{d}| = (\alpha+\beta)/2$ and $n \geq 3$. Then

$$|\mathcal{M}_n| = \frac{1}{2}|\mathsf{M}_n|, \tag{49}$$

$$|\mathcal{M}_{\boldsymbol{d}}| = \frac{1}{2}|\mathsf{M}_{\boldsymbol{d}}|, \tag{50}$$

$$|\mathcal{M}_{\{\alpha,\beta\}}| = \begin{cases} |\mathsf{M}_{(\alpha,\beta)}|, & \text{if } \alpha \neq \beta, \\ \dfrac{1}{2}|\mathsf{M}_{(\alpha,\alpha)}|, & \text{if } \alpha = \beta > 2, \end{cases} \tag{51}$$

and

$$|\mathcal{M}_{\boldsymbol{d},\{\alpha,\beta\}}| = \begin{cases} |\mathsf{M}_{\boldsymbol{d},(\alpha,\beta)}|, & \text{if } \alpha \neq \beta, \\ \dfrac{1}{2}|\mathsf{M}_{\boldsymbol{d},(\alpha,\alpha)}|, & \text{otherwise,} \end{cases} \tag{52}$$

where $|\mathsf{M}_n|$, $|\mathsf{M}_{\boldsymbol{d}}|$, $|M_{(\alpha,\beta)}|$ and $|\mathsf{M}_{\boldsymbol{d},(\alpha,\beta)}|$ are respectively given by equations (14), (28), (37) and (44). □

3.2 Enumeration of unlabelled two-face sphere maps.

Let $\widetilde{\mathcal{M}}_n$ denote the set of unlabelled two-face sphere maps with $n \geq 3$ vertices. Formula (48) immediately gives

$$|\widetilde{\mathcal{M}}_n| = \frac{1}{2}(|\widetilde{\mathsf{M}}_n| + |\mathrm{Fix}_{\widetilde{\mathsf{M}}_n}\tau|). \tag{53}$$

Different methods, bijective or algebraic, can be used to compute the term $|\mathrm{Fix}_{\mathcal{M}_n}\tau|$ in (53) and hence the number $|\widetilde{\mathcal{M}}_n|$. See [6], sections 3.2.2 and 3.2.3. The approach presented here uses the method of Liskovets [15,16], for the enumeration of unlabelled (and unrooted) planar (= sphere) maps: we consider unlabelled sphere maps as orbits of labelled maps under vertex relabellings, that is we write $\widetilde{\mathcal{M}}_n = \mathcal{M}_n/\mathsf{S}_n$, and invoke Burnside's Lemma, using the concept of quotient map to enumerate the fixed points. The advantage of this method is that the maps we enumerate are labelled. We have

$$|\widetilde{\mathcal{M}}_n| = \frac{1}{n!}(\mathcal{M}_n + \sum_{\sigma \in \mathcal{S}_n \setminus \mathrm{Id}} |\mathrm{Fix}_{\mathcal{M}_n}\sigma|), \tag{54}$$

where $\mathrm{Fix}_{\mathcal{M}_n}\sigma$ denotes the set of labelled two-face sphere maps for which σ is an automorphism.

It follows from Lemma 1 that any non trivial automorphism of a sphere map can be described as a rotation around an axis which intersects two of its elements. Any two-face sphere map can be drawn on the sphere in such a way that the boundary between the two faces corresponds to the equator. In this case, any non trivial automorphism is in fact a rotation around an axis of one of the four following types:

- axis intersecting the two faces: type FF;
- axis intersecting a vertex and an edge on the equator: type VE;
- axis intersecting two vertices on the equator: type VV;

- axis intersecting two edges on the equator: type EE.

Axes of type FV (face-vertex) or FE (face-edge) are obviously not allowed here since any non trivial automorphism leaving one face fixed must leave the other face fixed as well. A two-face map having an automorphism around an axis of type FF is said to have an *equatorial* symmetry, while a map having an automorphism around an axis of type VE, VV or EE is said to have an *antipodal* symmetry.

For any $\sigma \in \mathcal{S}_n$, the set $\mathrm{Fix}_{\mathcal{M}_n}\sigma$ can then be expressed as the following union

$$\mathrm{Fix}_{\mathcal{M}_n}\sigma = \bigcup_{\Gamma\in\{FF,VE,VV,EE\}} \mathrm{Fix}_{\mathcal{M}_n}(\sigma,\Gamma),$$

where $\mathrm{Fix}_{\mathcal{M}_n}(\sigma,\Gamma)$ denotes the set of maps for which σ is an automorphism of type Γ. This union is disjoint, for $n \geq 3$, and we have

$$|\widetilde{\mathcal{M}}_n| = \frac{1}{n!}(|\mathcal{M}_n| + \sum_{\substack{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}\\ \Gamma\in\{FF,VE,VV,EE\}}} |\mathrm{Fix}_{\mathcal{M}_n}(\sigma,\Gamma)|\,). \tag{55}$$

In this formula, we realize that a part of the sum, namely $\sum_\sigma |\mathrm{Fix}_{\mathcal{M}_n}(\sigma,FF)|$, has essentially been computed, while enumerating two-face *plane* maps. Indeed, the analog of (54) and (55) for unlabelled plane maps is

$$\begin{aligned}|\widetilde{\mathsf{M}}_n| &= \frac{1}{n!}(\mathsf{M}_n + \sum_{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}} |\mathrm{Fix}_{\mathsf{M}_n}\sigma|)\\ &= \frac{1}{n!}(\mathsf{M}_n + \sum_{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}} |\mathrm{Fix}_{\mathsf{M}_n}(\sigma,FF)|)\end{aligned} \tag{56}$$

since any automorphism of a two-face plane map must leave the two faces fixed. Also, for $n \geq 3$, it is clear that

$$|\mathsf{M}_n| = 2\,|\mathcal{M}_n| \quad \text{and} \quad |\mathrm{Fix}_{\mathsf{M}_n}(\sigma,FF)| = 2\,|\mathrm{Fix}_{\mathcal{M}_n}(\sigma,FF)|$$

and we deduce from (55) that

$$|\mathcal{M}_n| = \frac{1}{2}|\widetilde{\mathsf{M}}_n| + \frac{1}{n!}\sum_{\substack{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}\\ \Gamma\in\{VE,VV,EE\}}} |\mathrm{Fix}_{\mathcal{M}_n}(\sigma,\Gamma)| \tag{57}$$

and, comparing with (53), that

$$|\mathrm{Fix}_{\widetilde{\mathsf{M}}_n}\tau| = \frac{2}{n!} \sum_{\substack{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}\\ \Gamma\in\{VE,VV,EE\}}} |\mathrm{Fix}_{\mathcal{M}_n}(\sigma,\Gamma)|. \tag{58}$$

Note that (58) could be proven directly using a standard result on the orbits of two commuting group actions on the same set (see [4], Exercise A.1.9), namely the groups $<\tau>$ and $\mathcal{S}_n$ acting on M_n. Another observation is that the previous reasoning remains valid if we restrict ourselves to maps having a given vertex degree distribution $\boldsymbol{d}$, with $|\boldsymbol{d}| = n \geq 3$, that is

$$|\widetilde{\mathcal{M}}_{\boldsymbol{d}}| = \frac{1}{2}(\widetilde{\mathsf{M}}_d + |\mathrm{Fix}_{\widetilde{\mathsf{M}}_{\boldsymbol{d}}}\tau|), \tag{59}$$

where

$$|\mathrm{Fix}_{\widetilde{\mathsf{M}}_{\boldsymbol{d}}}\tau| = \frac{2}{n!} \sum_{\substack{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}\\ \Gamma\in\{VE,VV,EE\}}} |\mathrm{Fix}_{\mathcal{M}_{\boldsymbol{d}}}(\sigma,\Gamma)|. \tag{60}$$

There remains to compute the various terms of (58) and (60) of the form $\sum_{\sigma\in\mathcal{S}\setminus\mathrm{Id}} |\mathrm{Fix}_{\mathcal{C}}(\sigma,\Gamma)|$, for $\mathcal{C} = \mathcal{M}_n$ or $\mathcal{M}_{\boldsymbol{d}}$ and $\Gamma = VE, VV$ or EE. To do this, we will use the concept of quotient map, following Liskovets [15,16].

Computation of $\sum_{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}} |\mathrm{Fix}_{\mathcal{C}}(\sigma, VE)|$.

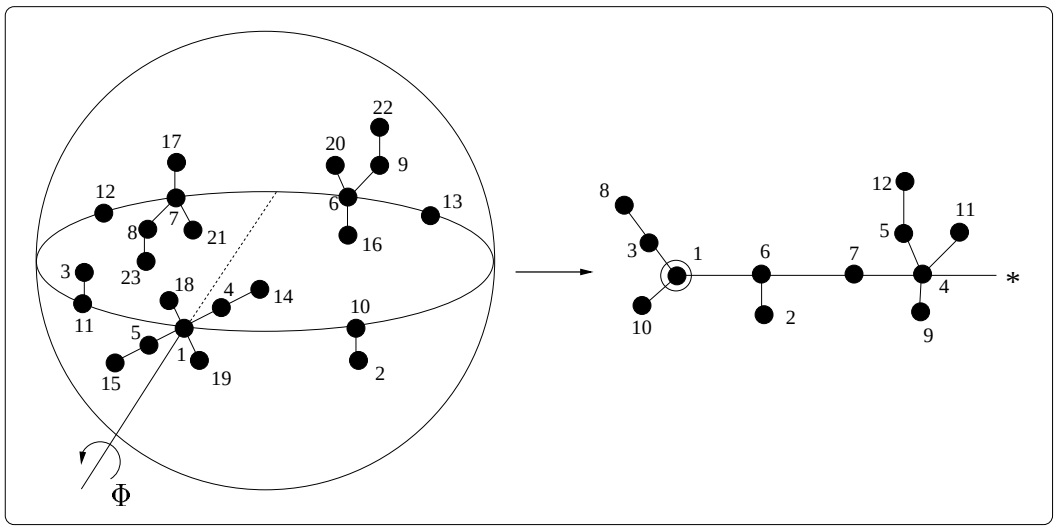

Fig. 5. A map having a symmetry of type VE and its associated quotient.

Consider a two-face sphere map m with $n \geq 3$ vertices and vertex degree distribution $\boldsymbol{d}$, having an automorphism σ of type VE. See Figure 5. In this case, σ corresponds to an antipodal rotation Φ of angle 180° around an axis intersecting one vertex and the opposite edge. This vertex is left fixed while all other vertices are exchanged pairwise. We conclude that the number n of vertices is odd and that σ is of type $\lambda(\sigma) = 1^1 2^{(n-1)/2}$. Since there are

$$\frac{n!}{2^{(n-1)/2}((n-1)/2)!}$$

permutations of cyclic type $1^1 2^{(n-1)/2}$, and $|\mathrm{Fix}_{\mathcal{C}}(\sigma, VE)|$ only depends on this cyclic type, for $\mathcal{C} = \mathcal{M}_n$ or $\mathcal{M}_{\boldsymbol{d}}$, we can write

$$\sum_{\sigma \in \mathcal{S}_n \setminus \{\mathrm{Id}\}} |\mathrm{Fix}_{\mathcal{C}}(\sigma, VE)| = \frac{n!}{2^{(n-1)/2}((n-1)/2)!} |\mathrm{Fix}_{\mathcal{C}}(\sigma_0, VE)|, \qquad (61)$$

where this time, σ_0 is the particular permutation $\sigma_0 = (1)(2,3)\cdots(n-1,n)$.

Consider the action of the subgroup $< \Phi >= \mathbb{Z}_2$ generated by the rotation Φ on the sphere S^2. The quotient space $S^2/\langle\Phi\rangle = \mathbb{Z}_2$ is obtained by identifying points on the sphere lying in the same orbit, and the induced cellular decomposition is called the *quotient map of* m by Φ. To keep track of which elements of the map were originally intersected by the rotation axis, the two corresponding elements in the quotient map are pointed. In the quotient map, the vertices are orbits (cycles) of σ_0 and they are labelled according to the increasing order of the minimum elements of the cycles.

In the present case, the quotient map $\mathsf{m}' = \mathsf{m}/\Phi$ is a labelled plane tree, having $n' = (n+1)/2$ vertices, canonically pointed at vertex 1 and planted at vertex 4 where is attached the half edge corresponding to the edge of m intersecting the rotation axis, as shown in Figure 5. The number $l(\mathsf{m}')$ of liftings of m', that is the number of different labellings of m giving rise to the same quotient is given by

$$l(\mathsf{m}') = 2^{\frac{n-1}{2}-1} = 2^{\frac{n-3}{2}} \qquad (62)$$

since after choosing the vertices $1, 2$ and 3 in a canonical way, there are two choices for each remaining cycles of σ_0. As we know from (2), there are

$$(n'-1)!\binom{2(n'-1)}{n'-1} \qquad (63)$$

labelled planted plane trees on n' vertices. If we express n' in terms of n, we

get

$$|\mathrm{Fix}_{\mathcal{M}_n}(\sigma_0, VE)| = 2^{\frac{n-3}{2}} \left(\frac{n-1}{2}\right)! \binom{n-1}{(n-1)/2}. \tag{64}$$

Now, combining (61) and (64), we find, for $\mathcal{C} = \mathcal{M}_n$ and $\Gamma = VE$,

$$\sum_{\sigma \in \mathcal{S}_n \setminus \mathrm{Id}} |\mathrm{Fix}_{\mathcal{M}_n}(\sigma, VE)| = \frac{n!}{2} \binom{n-1}{(n-1)/2}. \tag{65}$$

For $\mathcal{C} = \mathcal{M}_{\boldsymbol{d}}$, it should be observed that the only fixed point of σ_0 is of even degree, say $2k$, and that the vector $\boldsymbol{d}$ has exactly one odd component, d_{2k}. Let δ_ℓ denote de vector having 1 as its ℓ^{th} component, and 0 as other components. In the quotient map m', the canonically pointed vertex number 1 has degree k and the degree distribution $\boldsymbol{d}'$ of m' is given by

$$\boldsymbol{d}' = (\boldsymbol{d} - \delta_{2k})/2 + \delta_k.$$

Using (7) with $\alpha = 1$, we know that there are $\frac{1}{n'}\binom{n'}{\boldsymbol{d}'}$ unlabelled planted plane trees having vertex degree distribution $\boldsymbol{d}'$. There are d'_k ways to select a vertex of degree k in m' and, after assigning the label 1 to it, there are $(n'-1)!$ ways to label the other vertices.

Taking into account that there are $2^{(n-3)/2}$ possible liftings, we obtain

$$|\mathrm{Fix}_{\mathcal{M}_{\boldsymbol{d}}}(\sigma_0, VE)| = 2^{((n-3)/2)} \frac{d'_k}{|n'|} \binom{n'}{\boldsymbol{d}'} (|n'|-1)! \tag{66}$$

By combining (61) and (66), and expressing $\boldsymbol{d}'$ in terms of $\boldsymbol{d}$, we obtain

$$\sum_{\sigma \in \mathcal{S}_n \setminus \mathrm{Id}} |\mathrm{Fix}_{\mathcal{M}_{\boldsymbol{d}}}(\sigma, VE)| = \frac{n!}{2} \binom{(n-1)/2}{(\boldsymbol{d} - \delta_{2k})/2}. \tag{67}$$

Computation of $\sum_{\sigma \in \mathcal{S}_n \setminus \mathrm{Id}} |\mathrm{Fix}_{\mathcal{C}}(\sigma, VV)|$.

In this case, σ corresponds to an antipodal rotation of angle 180° around an axis intersecting two vertices. These two vertices are left fixed while all other vertices are exchanged pairewise. Therefore the number n of vertices must be even and σ must be of type $\lambda(\sigma) = 1^2 2^{(n-2)/2}$. Since there are

$$\frac{n!}{2! 2^{(n-2)/2} ((n-2)/2)!}$$

permutations of cyclic type $1^2 2^{(n-1)/2}$, and $|\mathrm{Fix}_{\mathcal{C}}(\sigma, VE)|$ only depends on this cyclic type, we can write

$$\sum_{\sigma \in \mathcal{S}_n \setminus \{\mathrm{Id}\}} |\mathrm{Fix}_{\mathcal{C}}(\sigma, VV)| = \frac{n!}{2! 2^{(n-2)/2}\, ((n-2)/2)!} |\mathrm{Fix}_{\mathcal{C}}(\sigma_0, VV)|, \quad (68)$$

where σ_0 is the particular permutation $\sigma_0 = (1)(2)(3,4)\cdots(n-1,n)$. With this particular choice of σ_0, the quotient map is a labelled plane tree having $n' = (n+2)/2$ vertices, and canonically pointed at vertices number 1 and 2, as shown in Figure 6.

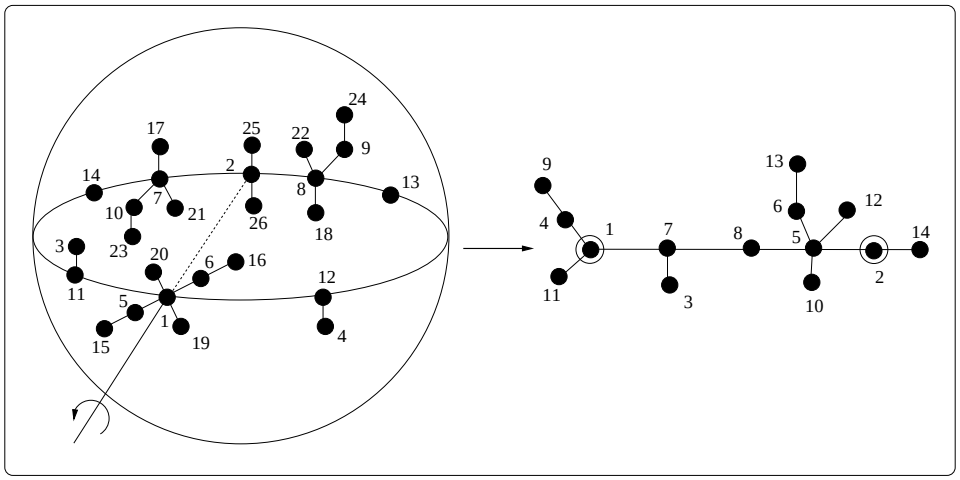

Fig. 6. A map having a symmetry of type VV and its associated quotient.

There are $\frac{(n'-2)!}{2}\binom{2(n'-1)}{n'-1}$ labelled plane trees on n' vertices (use (63) or see [4], example 3.1.17). Also note that the number of liftings, in this case, is given by $2^{(n-4)/2}$. Then, expressing n' in terms of n, we find, for $\mathcal{C} = \mathcal{M}_n$,

$$\sum_{\sigma \in \mathcal{S}_n \setminus \mathrm{Id}} |\mathrm{Fix}_{\mathcal{M}_n}(\sigma, VV)| = \frac{n!}{8}\binom{n}{n/2}. \quad (69)$$

For $\mathcal{C} = \mathcal{M}_{\boldsymbol{d}}$, note that the two fixed points of σ_0 are of even degree, say $2k$ and 2ℓ, and we may assume that $k \le \ell$. There are two subcases to consider: either $k < \ell$ or $k = \ell$.

If $k < \ell$, the vector $\boldsymbol{d}$ has exactly two odd components, namely d_{2k} and $d_{2\ell}$. The quotient map m' is then a labelled plane tree having $\boldsymbol{d}' = (\boldsymbol{d} - \delta_{2k} - \delta_{2\ell})/2 + \delta_k + \delta_\ell$ as vertex degree distribution, and whoses vertices 1 and 2 are of degree k and ℓ, or ℓ and k. There are $(n''-2)!\binom{n'}{\boldsymbol{d}'}$ ways to select a labelled plane tree having this distribution (use (7) or see Tutte [25]). The next step consists in choosing a vertex of degree k and one of degree ℓ. There are $d'_k d'_\ell$

possibillities. This structure can then be unlabelled in $1/n'!$ ways since it is asymmetric.

Now, assign label number 1 (or 2) to the distinguished vertex of degree k. This will determine the label of the distinguished vertex of degree ℓ; there are two choices here. All other vertices are then labelled in $(n'-2)!$ possible ways. Since there are $2^{(n-4)/2}$ possible liftings, we have

$$|\mathrm{Fix}_{\mathcal{M}_{\boldsymbol{d}}}(\sigma_0, VV)| = 2^{(n-4)/2}\frac{2}{n'!}((n'-2)!)^2 d'_k d'_\ell \binom{n'}{\boldsymbol{d}'}. \tag{70}$$

Using (68) and (70), and expressing n' and $\boldsymbol{d}'$ in terms of n and $\boldsymbol{d}$, we finally find, in the case where $\boldsymbol{d}$ has exactly two odd components, d_{2k} and $d_{2\ell}$,

$$\sum_{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}} |\mathrm{Fix}_{\mathcal{M}_{\boldsymbol{d}}}(\sigma, VV)| = \frac{n!}{2}\binom{(n-2)/2}{(\boldsymbol{d}-\delta_{2k}-\delta_{2\ell})/2}. \tag{71}$$

We now consider the case where $\ell = k$. This can happen only if $\boldsymbol{d}$ has no odd components. Fix $2k$ such that $d_{2k} \neq 0$, and suppose that the axis of symmetry intersects two vertices of degre $2k$. The quotient map is then a labelled plane tree having vertex degree distribution

$$\boldsymbol{d}' = \boldsymbol{d}/2 - \delta_{2k} + 2\delta_k,$$

and whose vertices number 1 and 2 are both of degree k. To construct such a map, first select one of the $(n'-2)!\binom{n'}{\boldsymbol{d}'}$ possible labelled plane trees. In this tree, select a first vertex of degree k, then a second vertex of degree k. This is possible since $d'_k \geq 2$. There are $d'_k(d'_k-1)$ possibilities. The structure obtained is now asymmetric, hence there are

$$\frac{d'_k(d'_k-1)}{n'!}(n'-2)!\binom{n'}{\boldsymbol{d}'}$$

corresponding unlabelled structures. Assign label number 1 to the first selected vertex and label 2 to the second one. The rest of the tree can be labelled in $(n'-2)!$ ways. Since there are $2^{(n-4)/2}$ possible liftings, we have, for the case where $\boldsymbol{d}$ has no odd components,

$$|\mathrm{Fix}_{\mathcal{M}_{\boldsymbol{d}}}(\sigma_0, VV)| = \sum_{\substack{k\geq 1\\ d_{2k}\neq 0}} \frac{2^{(n-4)/2}((n'-2)!)^2}{n'!} d'_k(d'_k-1)\binom{n'}{\boldsymbol{d}'} \tag{72}$$

Using (68) and (72), and expressing, n' and $\boldsymbol{d}'$ in terms of n and $\boldsymbol{d}$ we obtain in this case

$$\sum_{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}} |\mathrm{Fix}_{\mathcal{M}_{\boldsymbol{d}}}(\sigma, VV)| = \frac{(n-1)!}{4}\binom{n/2}{\boldsymbol{d}/2}\sum_{k\geq 1} d_{2k}. \tag{73}$$

Computation of $\sum_{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}} |\mathrm{Fix}_{\mathcal{C}}(\sigma, EE)|$.

In this case, σ corresponds to an antipodal rotation of angle 180° around an axis intersecting two edges. All vertices are exchanged pairwise. Therefore the number n of vertices must be even and σ must be of type $\lambda(\sigma) = 2^{n/2}$. Since there are $n!/(2^{n/2}(n/2)!)$ permutations of cyclic type $2^{n/2}$, and $|\mathrm{Fix}_{\mathcal{C}}(\sigma, EE)|$ only depends on this cyclic type, we can write

$$\sum_{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}} |\mathrm{Fix}_{\mathcal{C}}(\sigma, EE)| = \frac{n!}{2^{n/2}(n/2)!}|\mathrm{Fix}_{\mathcal{C}}(\sigma_0, EE)|, \tag{74}$$

where σ_0 is the particular permutation of $(1,2)(3.4)\cdots(n-1,n)$. The quotient map is an (unorderly) biplanted labelled plane tree having $n' = n/2$ vertices, as shown in Figure 7. Let G denote the species of *orderly* biplanted plane trees and $|G_{n'}|$, the number of labelled G-structures on n' vertices. For $\mathcal{C} = \mathcal{M}_n$, the number of quotient structures is then given by $|G_{n'}|/2$. The species G satisfies the combinatorial identity,

$$(G+1)A = A^{\bullet},$$

as shown in Figure 8, where A denotes the species of planted plane trees and $A^{\bullet}$, that of pointed planted plane trees. Therefore we have $G(x) = (A^{\bullet}(x)/A(x)) - 1$. Since

$$A(x) = \frac{1-\sqrt{1-4x}}{2} \quad \text{and} \quad A^{\bullet}(x) = x\frac{d}{dx}A(x) = \frac{x}{\sqrt{1-4x}},$$

we obtain

$$G(x) = \frac{1}{2}\left(\frac{1}{\sqrt{1-4x}} - 1\right).$$

After coefficient extraction, we get

$$|G_{n'}| = \frac{n'!}{2}\binom{2n'}{n'}.$$

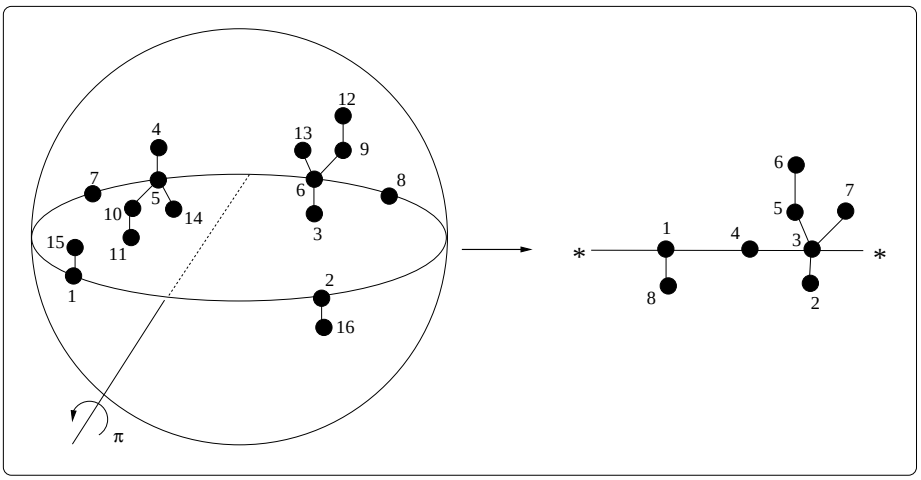

Fig. 7. A map with a symmetry of type EE and its associated quotient.

Using the fact that there are $2^{n-2/2}$ liftings and expressing n' in terms of n, we conclude that

$$\sum_{\sigma\in\mathcal{S}_n\setminus\mathrm{Id}} |\mathrm{Fix}_{\mathcal{M}_n}(\sigma, EE)| = \frac{n!}{8}\binom{n}{n/2}. \tag{75}$$

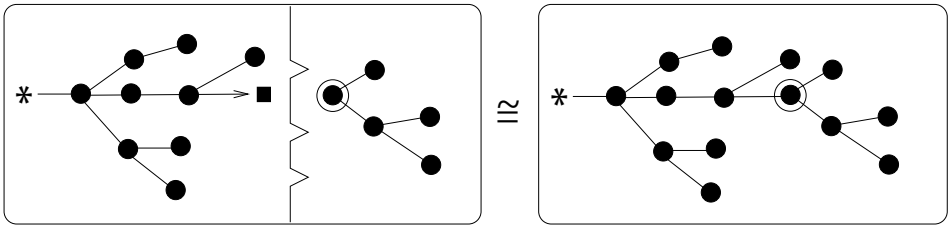

Fig. 8. $(G+1)A = A^\bullet$.

For $\mathcal{C} = \mathcal{M}_{\boldsymbol{d}}$, observe that the quotient map is an unorderly biplanted labelled plane tree having $\boldsymbol{d}' = \boldsymbol{d}/2$ as vertex degree distribution. To construct such a tree, first consider one of the possible $(n''-2)!\binom{n''}{\boldsymbol{d}''}$ labelled plane trees having $\boldsymbol{d}'' = \boldsymbol{d}' + 2\delta_1$ as vertex degree distribution, where $n'' = |\boldsymbol{d}''| = n'+2$. By doing so, the two star vertices in the quotient structure in Figure 7 are temporarily considered as ordinar vertices. In such a tree, select a first vertex of degree one (a leaf), and then a second vertex of degree one. There are $d_1''(d_1''-1)$ possibilities. The structure obtained has become asymmetric, hence we can divide by $n''!$ to obtain the corresponding unlabelled structures. The next step is to label all vertices except the two distinguished ones. We obtain an orderely biplanted labelled plane tree. The result has to be divided by 2 since we are aiming at unorderly biplanted plane trees. Considering the $2^{(n-2)/2}$ possible liftings, it follows that

$$|\mathrm{Fix}_{\mathcal{M}_{\boldsymbol{d}}}(\sigma_0, EE)| = \frac{1}{2}\frac{2^{(n-2)/2}((n''-2)!)^2}{n''!}\binom{n''}{\boldsymbol{d}''}d_1''(d_1''-1). \tag{76}$$

Using the two previous equations, and expressing everything in terms of $\boldsymbol{d}$ and n, we obtain

$$\sum_{\sigma \in \mathcal{S}_n \setminus \mathrm{Id}} |\mathrm{Fix}_{\mathcal{M}_{\boldsymbol{d}}}(\sigma, EE)| = \frac{n!}{4} \binom{n/2}{\boldsymbol{d}/2}. \tag{77}$$

We can now state the following results.

Theorem 9 *The number $|\widetilde{\mathcal{M}}_n|$ of unlabelled two-face sphere maps on $n \geq 3$ vertices is given by*

$$|\widetilde{\mathcal{M}}_n| = \frac{1}{4n} \sum_{s|n} \phi(\frac{n}{s}) \left(2^{2s} - \binom{2s}{s} \right) + \begin{cases} \frac{1}{2}\binom{n-1}{(n-1)/2}, & \text{if } n \text{ is odd,} \\ \frac{1}{4}\binom{n}{n/2}, & \text{otherwise.} \end{cases} \tag{78}$$

PROOF. Formula (57) states that

$$|\widetilde{\mathcal{M}}_n| = \frac{1}{2}|\widetilde{\mathsf{M}}_n| + \frac{1}{n!} \sum_{\substack{\sigma \in \mathcal{S}_n \setminus \mathrm{Id} \\ \Gamma \in \{VE, VV, EE\}}} |\mathrm{Fix}_{\mathcal{M}_n}(\sigma, \Gamma)|.$$

Replacing $|\widetilde{\mathsf{M}}_n|$ by its value, given by (15), yields the first term of (78) while summing formulas (65), where n is odd, and (69) and (75), where n is even, and dividing by $n!$, gives the second term. □

Similarly, we can now use (59) and sum formulas (67), (71), (73), and (77) to obtain the following theorem. Also recall that $|\widetilde{\mathsf{M}}_d|$ is given by (29).

Theorem 10 *Let $\boldsymbol{d}$ be a vector satisfying $||\boldsymbol{d}|| = 2|\boldsymbol{d}|$, with $n = |\boldsymbol{d}| \geq 3$, and let r be the number of odd components in $\boldsymbol{d}$. Then the number $|\widetilde{\mathcal{M}}_{\boldsymbol{d}}|$ of unlabelled two-face sphere maps having $\boldsymbol{d}$ has vertex degree distribution is given by*

$$|\widetilde{\mathcal{M}}_d| = \frac{1}{2}(|\widetilde{\mathsf{M}}_{\boldsymbol{d}}| + |\mathrm{Fix}_{\widetilde{\mathsf{M}}_d} \tau|),$$

where

$$|\mathrm{Fix}_{\widetilde{\mathsf{M}}_{\boldsymbol{d}}}\tau| = \begin{cases} \dfrac{1}{2}\dbinom{n/2}{\boldsymbol{d}/2}\left(1+\dfrac{1}{n}\displaystyle\sum_{k\geq 1} d_{2k}\right), & \text{if } r=0; \\ \dbinom{(n-1)/2}{(\boldsymbol{d}-\delta_{2k})/2}, & \text{if } r=1,\ d_{2k} \text{ odd;} \\ \dbinom{(n-2)/2}{(\boldsymbol{d}-\delta_{2k}-\delta_{2\ell})/2}, & \text{if } r=2,\ d_{2k} \text{ and } d_{2\ell} \text{ odd}; \\ 0, & \text{if } r\geq 3. \end{cases} \tag{79}$$

□

Let $\widetilde{\mathcal{M}}_{\{\alpha,\beta\}}$ denote the set of unlabelled two-face sphere maps having $\{\alpha,\beta\}$ as face degree distribution. If $\alpha \neq \beta$, there is no antipodal symmetry, and we have

$$|\widetilde{\mathcal{M}}_{\{\alpha,\beta\}}| = |\widetilde{\mathsf{M}}_{(\alpha,\beta)}|, \tag{80}$$

since in this case, we can choose the north or inner face to be that of smallest degree. Recall that $|\widetilde{\mathsf{M}}_{(\alpha,\beta)}|$ is given by (38)

If $\alpha = \beta$, the set $\widetilde{\mathsf{M}}_{(\alpha,\alpha)}$ is closed under the action of τ and we can apply (48). We have

$$|\widetilde{\mathcal{M}}_{\{\alpha,\alpha\}}| = \frac{1}{2}\left(|\widetilde{\mathsf{M}}_{(\alpha,\alpha)}| + |\mathrm{Fix}_{\widetilde{\mathsf{M}}_{\{\alpha,\alpha\}}}\tau|\right). \tag{81}$$

Since $\alpha = \beta$, we simply have $\alpha = n$, the number of vertices. Therefore

$$|\mathrm{Fix}_{\widetilde{\mathsf{M}}_{\{\alpha,\alpha\}}}\tau| = |\mathrm{Fix}_{\widetilde{\mathsf{M}}_n}\tau|. \tag{82}$$

The term $|\mathrm{Fix}_{\widetilde{\mathsf{M}}_n}\tau|$ can be easily deduced from (48), (15) and (78), and the next result follows.

Theorem 11 *If $\alpha > 0$ and $\beta > 0$ have the same parity, then the number $|\widetilde{\mathcal{M}}_{\{\alpha,\beta\}}|$ of unlabelled two-face sphere maps having $\{\alpha,\beta\}$ as face degree distribution is given by*

$$|\widetilde{\mathcal{M}}_{\{\alpha,\beta\}}| = \begin{cases} |\widetilde{\mathsf{M}}_{(\alpha,\beta)}|, & \text{if} \alpha \neq \beta, \\ \frac{1}{2}|\widetilde{\mathsf{M}}_{(\alpha,\alpha)}| + \frac{1}{2}\binom{\alpha-1}{(\alpha-1)/2}, & \text{if } \alpha=\beta \text{ is odd}, \\ \frac{1}{2}|\widetilde{\mathsf{M}}_{(\alpha,\alpha)}| + \frac{1}{4}\binom{\alpha}{\alpha/2}, & \text{if } \alpha=\beta \text{ is even}, \end{cases} \tag{83}$$

□

Finally, let $\widetilde{\mathcal{M}}_{\boldsymbol{d},\{\alpha,\beta\}}$ denote the set of all unlabelled two-face sphere maps having joint vertex and face degree distribution given by $\boldsymbol{d}$ and $\{\alpha,\beta\}$. If $\alpha \neq \beta$, we have

$$|\widetilde{\mathcal{M}}_{\boldsymbol{d},\{\alpha,\beta\}}| = |\widetilde{\mathsf{M}}_{\boldsymbol{d},(\alpha,\beta)}|, \tag{84}$$

since in this case, there are no possible antipodal symmetries. Recall that $|\widetilde{\mathsf{M}}_{d,(\alpha,\beta)}|$ is given by (45).

If $\alpha = \beta$, by (48), we have

$$|\widetilde{\mathcal{M}}_{\boldsymbol{d},\{\alpha,\alpha\}}| = \frac{1}{2}|\widetilde{\mathsf{M}}_{\boldsymbol{d},(\alpha,\alpha)}| + \frac{1}{2}|\mathrm{Fix}_{\widetilde{\mathsf{M}}_{\boldsymbol{d},(\alpha,\alpha)}}\tau|, \tag{85}$$

and α is completely determined by $\boldsymbol{d}$: $\alpha = |\boldsymbol{d}|$, hence we have

$$|\mathrm{Fix}_{\widetilde{\mathsf{M}}_{d,(\alpha,\alpha)}}\tau| = |\mathrm{Fix}_{\widetilde{\mathsf{M}}_d}\tau|. \tag{86}$$

Theorem 12 *Let $\boldsymbol{d} \neq \mathbf{0}$ be a vector of nonnegative integers satisfying $||\boldsymbol{d}|| = 2|\boldsymbol{d}|$ and α, β be two positive integers having the same parity and such that $(\alpha+\beta)/2 = |\boldsymbol{d}| = n \geq 3$. Then the number of unlabelled two-face sphere maps having joint vertex and face degree distributions $\boldsymbol{d}$ and $\{\alpha,\beta\}$ is given by*

$$|\widetilde{\mathcal{M}}_{\boldsymbol{d},\{\alpha,\beta\}}| = \begin{cases} |\widetilde{\mathsf{M}}_{\boldsymbol{d},(\alpha,\beta)}|, & \text{if } \alpha \neq \beta, \\ \frac{1}{2}|\widetilde{\mathsf{M}}_{\boldsymbol{d},(\alpha,\alpha)}| + \frac{1}{2}|\mathrm{Fix}_{\widetilde{\mathsf{M}}_{\boldsymbol{d}}}\tau| & \text{if } \alpha = \beta, \end{cases} \tag{87}$$

where $|\mathrm{Fix}_{\widetilde{\mathsf{M}}_{\boldsymbol{d}}}\tau|$, is given by (79). □

ENUMERATION OF SOLID 2-TREES

MICHEL BOUSQUET AND CEDRIC LAMATHE

ABSTRACT. The main goal of this paper is to enumerate solid 2-trees according to the number of edges (or triangles) and also according to the edge degree distribution. We first enumerate oriented solid 2-trees using the general methods of the theory of species. In order to obtain non oriented enumeration formulas we use quotient species which consists in a specialization of Pólya theory.

RÉSUMÉ. Le but de cet article est d'obtenir l'énumération des 2-arbres solides selon le nombre d'arêtes (ou de triangles) ainsi que selon la distribution des degrés des arêtes. Nous obtenons d'abord le dénombrement des 2-arbres solides orientés en utilisant les méthodes de la théorie des espèces. Pour obtenir le dénombrement des 2-arbres solides non orientés, nous utilisons la notion d'espèce quotient qui provient d'une spécialisation de la théorie de Pólya.

1. INTRODUCTION

Definition 1. Let $\mathcal{E}$ be a non-empty finite set of n elements called *edges*. A *2-tree* is either a single edge (if $n = 1$) or a non-empty subset $\mathcal{T} \subseteq \wp_3(\mathcal{E})$ whose elements are called *triangles*, satisfying the following conditions:

1. For every pair $\{a, b\} = \{\{a_1, a_2, a_3\}, \{b_1, b_2, b_3\}\}$ of distinct elements of $\mathcal{T}$, we have $|a \cap b| \leq 1$, which means that two distinct triangles share at most one edge.
2. For every ordered pair $(a, b) = (\{a_1, a_2, a_3\}, \{b_1, b_2, b_3\})$ of distinct elements of $\mathcal{T}$, there is a unique sequence $(t_0 = a, t_1, t_2, \ldots, t_k = b)$ such that for $i = 0, 1, \ldots, k-1$, we have $|t_i \cap t_{i+1}| = 1$, which means that each pair of consecutive triangles in this sequence share exactly one edge.

An edge e and a triangle t are *incident* to each other if $e \in t$. The *degree* of an edge is the number of triangles which are incident to that edge. The *edge degree distribution* of a 2-tree is described by a vector $\vec{n} = (n_1, n_2, \ldots)$, where n_i is the number of edges of degree i. We denote by $\mathrm{Supp}(\vec{n})$, the *support* of $\vec{n}$ which is the set of indices i such that $n_i \neq 0$. Figure 1 shows a 2-tree having 11 edges, 5 triangles and edge degree distribution given by $\vec{n} = (8, 2, 1)$.

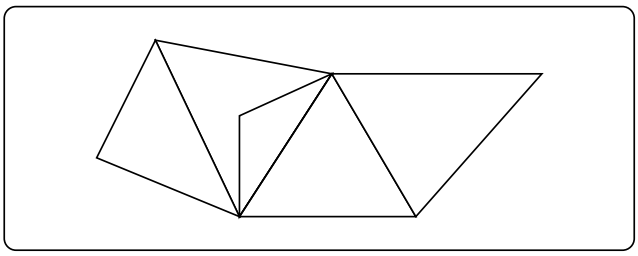

FIGURE 1. A 2-tree.

Several classes of 2-trees have been studied before. Beineke and Pippert enumerate some k-dimensional trees in [1] labelled at vertices. In [7], Harary and Palmer count unlabelled 2-trees. For the enumeration of plane 2-trees see [10], and for a classification of plane and planar 2-trees see [8]. More recently, in [5, 6], Fowler and al. work on general 2-trees and give asymptotical results. Here, we consider a new class of 2-trees, that is, *solid* 2-trees, *i.e.* 2-trees in which there is a cycle structure on the triangles around each edge.

Lemma 1. Let m, n be two nonnegative integers, and $\vec{n} = (n_1, n_2, \dots)$, an infinite vector of nonnegative integers. Then

1. There exists a 2-tree having m triangles and n edges if and only if $n = 2m + 1$.
2. There exists a 2-tree having $\vec{n}$ as edge degree distribution if and only if

$$\sum_i n_i = n \quad \text{and} \quad \sum_i i n_i = 3m. \tag{1}$$

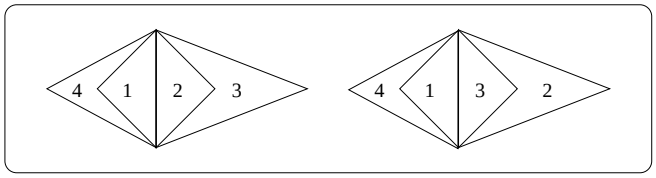

FIGURE 2. Two distinct solid 2-trees but the same 2-tree.

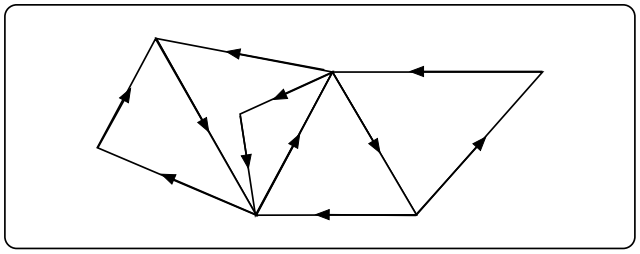

FIGURE 3. A well oriented 2-tree.

A *solid* 2-tree is a 2-tree in which there is a cyclic configuration of triangles around each edge. Figure 2 shows an example of two different solid 2-trees which are in fact the same 2-tree. As we can see, in the case of a solid 2-tree, one has to take into account the cyclic order of the triangles around each edge. A *well oriented* solid 2-tree is obtained from a solid 2-tree in the following way: first, pick any triangle and give a cyclic orientation on its edges. Then each triangle adjacent to the first triangle inherits a circular orientation (see Figure 3). This process is repeated until all edges receive an orientation. By the arborescent nature of the structure, there will be no conflict (the orientation of each edge will always be well defined). Figure 3 shows an example of a well oriented 2-tree. The species of non-oriented and well oriented solid 2-trees will be denoted respectively by $\mathcal{A}$ and $\mathcal{A}_o$. In order to analyze these two species, the following auxiliary species will be used:

- The species of *triangles* X: a single triangle will be denoted by X.
- The species of *edges* Y: a single edge will be denoted by Y.
- The species L of *lists* or *linear orders*.
- The species C and C_3 respectively denoting the species of oriented cycles and of oriented cycles of length 3.
- The species $\mathcal{A}^{-}$ and $\mathcal{A}_o^{\rightarrow}$ respectively denoting the species of non oriented and well oriented solid 2-trees *rooted at an edge*.
- The species $\mathcal{A}^{\Delta}$ and $\mathcal{A}_o^{\Delta}$ respectively denoting the species of non oriented and well oriented solid 2-trees *rooted at a triangle*.
- The species $\mathcal{A}^{\underline{\Delta}}$ and $\mathcal{A}_o^{\underline{\Delta}}$ respectively denoting the species of non oriented and well oriented solid 2-trees *rooted at a triangle having itself one of its edge distinguished*.
- Finally, the species $\mathcal{B}$ which consists of an oriented root edge Y incident to a linear order (L-structure) of triangles X each of which having its two remaining sides being themselves $\mathcal{B}$-structures. Therefore, the species $\mathcal{B}$ satisfies the following combinatorial equation

$$\mathcal{B}(X, Y) = Y L(X\mathcal{B}^2(X, Y)), \tag{2}$$

as illustrated by Figure 4,

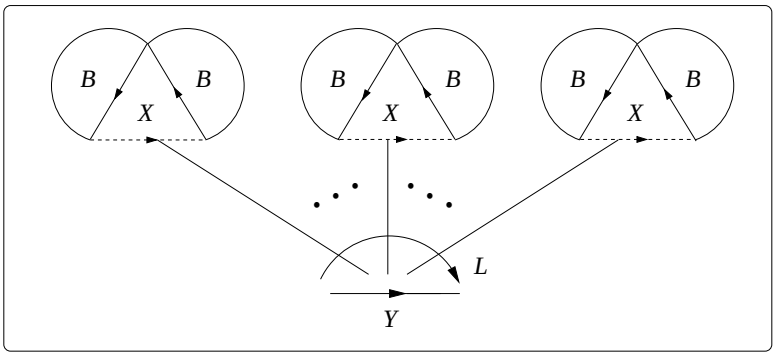

FIGURE 4. A $\mathcal{B}$-structure.

Note that $\mathcal{B}$ has been defined as a *two-sort* species where the sorts are X and Y. Since the numbers of edges n and of triangles m are linked by the relation $n = 2m + 1$, equation (2) above can either be expressed as a one sort species in X alone by setting $Y := 1$, or in Y alone, by setting $X := 1$ respectively, giving the two following equations:

$$\mathcal{B}(X) = L(X\mathcal{B}^2(X)), \tag{3}$$

$$\mathcal{B}(Y) = YL(B^2(Y)). \tag{4}$$

Recall that setting $X := 1$ in a two sort species $F(X, Y)$ essentially means unlabelling the elements of sort X. The second form in equation (4) is more suitable for the use of Lagrange inversion formula. Therefore the species Y of edges will be used as the base singleton species to make our computations. However, the results will be shorter and more elegant when expressed as a function of the number m of triangles.

• Lagrange Inversion Formula

In this paper we make an extensive use of Lagrange inversion formula (see [2]): Let A and R be species satisfying $A(Y) = YR(A)$. If F is another species, then

$$[y^n]F(A(y)) = \frac{1}{n}[y^{n-1}]F'(t)R^n(t), \tag{5}$$

where $[y^n]F(A(y))$ denotes the coefficient of y^n in $F(A(y))$. Another main tool used in this paper is the following dissymmetry theorem which has been proved in [5]. Note that in their paper, the authors made a proof for non solid 2-trees but obviously, the proof is also valid for both well oriented and non oriented solid 2-trees.

Theorem 1. The species $\mathcal{A}_o$ and $\mathcal{A}$ respectively of well oriented and (non oriented) solid 2-trees satisfy the following relations:

$$\mathcal{A}_o^{\rightarrow} + \mathcal{A}_o^{\Delta} = \mathcal{A}_o + \mathcal{A}_o^{\underline{\Delta}}, \tag{6}$$

and

$$\mathcal{A}^{-} + \mathcal{A}^{\Delta} = \mathcal{A} + \mathcal{A}^{\underline{\Delta}}. \tag{7}$$

2. Well oriented solid 2-trees

We begin this section by expressing the species appearing in the dissymmetry theorem (oriented case) in terms of the species $\mathcal{B}$.

Theorem 2. The species $\mathcal{A}_o^{\rightarrow}$, $\mathcal{A}_o^{\Delta}$ and $\mathcal{A}_o^{\overline{\Delta}}$ satisfy the following isomorphisms of species :

$$\mathcal{A}_o^{\rightarrow}(Y) = YC(\mathcal{B}^2(Y)), \tag{8}$$

$$\mathcal{A}_o^{\Delta}(Y) = C_3(\mathcal{B}(Y)), \tag{9}$$

$$\mathcal{A}_o^{\overline{\Delta}}(Y) = \mathcal{B}(Y)^3, \tag{10}$$

where C and C_3 are the species of oriented cycles and of oriented cycles of length 3.

2.1. Enumeration according to the number of edges.

• Labelled case

Let $\mathcal{A}_o[n]$ be the number of edge labelled solid 2-trees over n edges. We similarly define $\mathcal{A}_o^{\rightarrow}[n]$, $\mathcal{A}_o^{\Delta}[n]$ and $\mathcal{A}_o^{\overline{\Delta}}[n]$. Our first task is to determine $\mathcal{A}_o^{\rightarrow}[n]$. By applying Lagrange inversion with $F(t) = C(t^2) = -\log(1-t^2)$ and $R(t) = L(t^2) = (1-t^2)^{-1}$, we find

$$\begin{aligned}[y^n]\mathcal{A}_o^{\rightarrow}(y) &= [y^{n-1}]C(\mathcal{B}^2(y)),\\ &= \frac{2}{3(n-1)}\binom{3(n-1)/2}{n-1}.\end{aligned}$$

Hence, the number $\mathcal{A}_o^{\rightarrow}[n]$ of edge labelled solid 2-trees pointed at an edge over n edges is given by

$$\mathcal{A}_o^{\rightarrow}[n] = n![y^n]\mathcal{A}_o^{\rightarrow}(y) = \frac{2}{3}n(n-2)!\binom{\frac{3(n-1)}{2}}{n-1}. \tag{11}$$

Now, using equation (9) and Lagrange inversion with $F(t) = C_3(t) = t^3/3$ and $R(t) = (1-t^2)^{-1}$, we obtain

$$\mathcal{A}_o^{\Delta}[n] = \frac{1}{3}(n-1)!\binom{\frac{3(n-1)}{2}}{n-1}. \tag{12}$$

To compute $\mathcal{A}_o^{\overline{\Delta}}[n]$, we use equation (10) and Lagrange inversion with $F(t) = t^3$ and $R(t) = (1-t^2)^{-1}$ and we get

$$\mathcal{A}_o^{\overline{\Delta}}[n] = (n-1)!\binom{\frac{3(n-1)}{2}}{n-1}. \tag{13}$$

Using equations (11), (12) and (13) and the dissymmetry theorem, we have:

Proposition 1. The number $\mathcal{A}_o[n]$ of well oriented edge-labelled solid 2-trees over n edges is given by

$$\mathcal{A}_o[n] = \frac{2}{3}(n-2)!\binom{\frac{3(n-1)}{2}}{n-1}, \quad n > 1. \tag{14}$$

Note that if we express equation (14) as a function of m, the number of triangles, we obtain

$$\mathcal{A}_o[m] = \frac{m!}{3}\frac{1}{2m+3}\binom{3m+3}{m+1}, \quad m \geq 1. \tag{15}$$

• Unlabelled case

We first need to compute the generating series $\widetilde{\mathcal{A}_o}^{\rightarrow}(y)$. In order to accomplish this, we use the following property: let F and G be two species, then we have

$$\widetilde{F(G)}(x) = Z_F(\tilde{G}(x), \tilde{G}(x^2), \tilde{G}(x^3), \dots), \tag{16}$$

where the *cycle index series* Z_F of a species is defined by

$$Z_F(x_1, x_2, \dots) = \sum_{k\geq 0}\frac{1}{k!}\sum_{\sigma\in\mathcal{S}_k}\mathrm{fix}F[\sigma]x_1^{\sigma_1}x_2^{\sigma_2}x_3^{\sigma_3}\cdots, \tag{17}$$

where $\mathcal{S}_k$ is the symmetric group of order k and σ_i, the number of cycles of length i in σ and $\mathrm{fix}F[\sigma]$ is the number of F-structures left fixed under the relabelling induced by σ. For example, if $F = C$, the species of oriented cycles, we have

$$Z_C(x_1, x_2, \dots) = \sum_{k\geq 1} \frac{\phi(k)}{k} \log\left(\frac{1}{1-x_k}\right). \tag{18}$$

Now, applying this to the species $\mathcal{A}_o^{\rightarrow} = YC(\mathcal{B}^2)$, we get

$$\begin{aligned} \widetilde{\mathcal{A}_o}^{\rightarrow}(y) &= yZ_C(\tilde{\mathcal{B}}^2(y), \tilde{\mathcal{B}}^2(y^2), \tilde{\mathcal{B}}^2(y^3), \dots), \\ &= y\sum_{k\geq 1} \frac{\phi(k)}{k} \log\left(\frac{1}{1-\tilde{\mathcal{B}}^2(y^k)}\right). \end{aligned}$$

We note that since $\mathcal{B}$ is asymmetric (there are exactly $n!$ labelled structures for each unlabelled structures), we have $\tilde{\mathcal{B}}(y) = \mathcal{B}(y)$, hence

$$\begin{aligned} \widetilde{\mathcal{A}_o}^{\rightarrow}[n] &= [y^n]\widetilde{\mathcal{A}_o}^{\rightarrow}(y), \\ &= [y^{n-1}]\sum_{k\geq 1} \frac{\phi(k)}{k} \log\left(\frac{1}{1-\mathcal{B}^2(y^k)}\right). \end{aligned}$$

But

$$\begin{aligned} [y^{n-1}]\log\left(\frac{1}{1-\mathcal{B}^2(y^k)}\right) &= \frac{2k}{n-1}[t^{\frac{n-1}{k}-2}](1-t^2)^{-\frac{n-1}{k}-1}, \\ &= \frac{2k}{3(n-1)}\binom{3(n-1)/2k}{(n-1)/k}. \end{aligned}$$

Obviously, k must divide $n-1$ and $(n-1)/k$ must be even. Letting $d = (n-1)/k$, we finally get

$$\widetilde{\mathcal{A}_o}^{\rightarrow}[n] = \frac{2}{3(n-1)} \sum_d \phi((n-1)/d)\binom{3d/2}{d}, \tag{19}$$

the sum being taken over all even divisors d of $n-1$. To compute $\widetilde{\mathcal{A}_o}^{\triangle}[n]$, we use equation (9) and the fact that

$$Z_{C_3}(y_1, y_2, \dots) = \frac{1}{3}(y_1^3 + 2y_3).$$

We have

$$[y^n]\mathcal{B}^3(y) = \frac{1}{n}\binom{3(n-1)/2}{n-1},$$

and

$$[y^n]\mathcal{B}(y^3) = [y^{n/3}]\mathcal{B}(y) = \frac{3}{n}\binom{(n-3)/2}{n/3-1},$$

so that

$$\widetilde{\mathcal{A}_o}^{\Delta}[n] = \frac{1}{3n}\binom{\frac{3(n-1)}{2}}{n-1} + \frac{2}{n}\chi(3|n)\binom{\frac{(n-3)}{2}}{\frac{n}{3}-1}, \tag{20}$$

where $\chi(3|n) = 1$ if 3 divides n and 0 otherwise. It can be easily shown, by a very similar way that

$$\widetilde{\mathcal{A}}_o^{\Delta}[n] = \frac{1}{n}\binom{\frac{3(n-1)}{2}}{n-1}. \tag{21}$$

And we get the following result:

Proposition 2. The number of unlabelled well oriented solid 2-trees over n edges is given by

$$\widetilde{\mathcal{A}_o}[n] = \frac{2}{3(n-1)} \sum_d \phi\left(\frac{n-1}{d}\right)\binom{3d/2}{d} + \chi(3|n)\frac{2}{n}\binom{\frac{n-3}{2}}{\frac{n}{3}-1} - \frac{2}{3n}\binom{\frac{3(n-1)}{2}}{n-1}, \tag{22}$$

the first sum being taken over all even divisors d of $n-1$.

We can also write $\widetilde{\mathcal{A}_o}[m]$, in function of the number m of triangles, as follows

$$\widetilde{\mathcal{A}_o}[m] = \frac{1}{3m}\sum_{d|m}\phi\left(\frac{m}{d}\right)\binom{3d}{d} + \chi(3|2m+1)\frac{2}{2m+1}\binom{m-1}{\frac{2m-2}{3}} - \frac{2}{3(2m+1)}\binom{3m}{m}.$$

Note that this expression is also the number of unlabelled 3-gonal cacti on m 3-gones (see [3]). The sequence of these numbers is known as sequence A054423 in the on-line encyclopedia of integers sequences ([11]).

2.2. **Enumeration according to edge degree distribution.**

Let $r = (r_0, r_1, r_2, \dots)$ be an infinite set of formal variables. In order to keep track of the edge degree distribution, we introduce, for a given number n and F, any species, the following weight function:

$$\begin{array}{rccc} w: & F[n] & \longrightarrow & Q[r_1, r_2, \dots] \\ & s & \mapsto & w(s) \end{array} \tag{23}$$

where $Q[r_1, r_2, \dots]$ is the ring of polynomials over Q in the variables $r_1, r_2, \dots$ and where the weight of a given structure s is defined by $w(s) = r_1^{n_1} r_2^{n_2} \cdots$, where n_i is the number of edges of degree i in s. Equations (2), (8), (9) and (10) have the following weighted versions:

$$\mathcal{B}_r = Y L_{r'}(B_r^2), \tag{24}$$

and

$$\mathcal{A}^{\rightarrow}_{o,w}(Y) = Y C_r(\mathcal{B}_r^2), \tag{25}$$

$$\mathcal{A}^{\Delta}_{o,w}(Y) = C_3(B_r), \tag{26}$$

$$\mathcal{A}^{\underline{\Delta}}_{o,w}(Y) = \mathcal{B}_r^3, \tag{27}$$

where C_r is the weighted species of cycles such that a cycle of length i has the weight r_i, and its derivative $L_{r'}$ which is the species of lists where a list of length i has the weight r_{i+1}. These species have the following generating series:

$$C_r(y) = r_1 y + \frac{r_2}{2}y^2 + \frac{r_3}{3}y^3 + \cdots,$$

and

$$L_{r'}(y) = r_1 + r_2 y + r_3 y^2 + \cdots.$$

Let $\vec{n} = (n_1, n_2, n_3, \dots)$ be a vector of nonnegative integers. Recall that there exists a 2-tree having a total of n edges and n_i edges of degree i if and only if the following relation is satisfied:

$$\sum_i n_i = n \quad \text{and} \quad \sum_i i n_i = 3\left(\frac{n-1}{2}\right). \tag{28}$$

• Labelled case

Let $\vec{n}$ be a vector satisfying (28). Then the number $\mathcal{A}_o^{\rightarrow}[\vec{n}]$ of well oriented edge labelled solid 2-trees pointed at an edge, and having $\vec{n}$ as edge degree distribution, is given by

$$\mathcal{A}_o^{\rightarrow}[\vec{n}] = n![y^n][r_1^{n_1} r_2^{n_2} \cdots]\mathcal{A}^{\rightarrow}_{o,w}(y). \tag{29}$$

We have

$$\begin{aligned} [y^n]\mathcal{A}^{\rightarrow}_{o,w}(y) &= \frac{1}{n-1}[t^{n-2}]\frac{d}{dt}(C_r(t^2))\cdot L_{r'}^{n-1}(t^2), \\ &= \frac{2}{n-1}[t^{n-3}](r_1 + r_2 t^2 + r_3 t^4 + \cdots)^n, \\ &= \frac{2}{n-1}[t^{n-3}]\sum_{\ell_1+\ell_2+\cdots=n}\binom{n}{\ell_1, \ell_2, \dots} r_1^{\ell_1} r_2^{\ell_2} \cdots t^{2\ell_2+4\ell_3+6\ell_4+\cdots}. \end{aligned}$$

Finally, we obtain

$$[y^n]\mathcal{A}_o^{\rightarrow}(r,y) = \sum_{\ell_1,\ell_2,\dots} \binom{n}{\ell_1,\ell_2,\dots} r_1^{\ell_1} r_2^{\ell_2} \cdots,$$

the sum being taken over all vectors $(\ell_1,\ell_2,\dots)$ satisfying

$$\sum_i \ell_i = n \quad \text{and} \quad \sum_i 2(i-1)\ell_i = n-3.$$

We note that this condition is the same as in (28). Hence using (29) we have

$$\mathcal{A}_o^{\rightarrow}[\vec{n}] = 2n(n-2)!\binom{n}{n_1,n_2,\dots}. \tag{30}$$

For $\mathcal{A}_o^{\Delta}[\vec{n}]$, we have

$$\mathcal{A}_o^{\Delta}[\vec{n}] = n![y^n][r_1^{n_1} r_2^{n_2}\cdots]\mathcal{A}_{o,w}^{\Delta}(y).$$

But,

$$[y^n]\mathcal{A}_{o,w}^{\Delta}(y) \quad = \quad \frac{1}{n}\sum_{\ell_1,\ell_2,\dots} \binom{n}{\ell_1,\ell_2,\dots} r_1^{\ell_1} r_2^{\ell_2} \cdots,$$

the sum being taken on all vectors $(\ell_1,\ell_2,\dots)$ satisfying $\sum_i \ell_i = n$ and $\sum_i 2(i-1)\ell_i = n-3$, and we obtain

$$\mathcal{A}_o^{\Delta}[\vec{n}] = (n-1)!\binom{n}{n_1,n_2,\dots}. \tag{31}$$

It can be easily shown that $\mathcal{A}_o^{\Delta}[\vec{n}] = 3\mathcal{A}_o^{\Delta}[\vec{n}]$, hence we have

$$\mathcal{A}_o^{\Delta}[\vec{n}] = 3(n-1)!\binom{n}{n_1,n_2,\dots}. \tag{32}$$

Now using (30), (31), (32) and the dissymmetry theorem we find

$$\mathcal{A}_o[\vec{n}] = 2(n-2)!\binom{n}{n_1,n_2,\dots}. \tag{33}$$

• Unlabelled case

Let $\vec{n} = (n_1,n_2,\dots)$ be a coherent edge degree distribution. In order to compute the number $\widetilde{\mathcal{A}_o^{\rightarrow}}[\vec{n}]$ of unlabelled $\mathcal{A}_o^{\rightarrow}$-structures having $\vec{n}$ as edge degree distribution, we use the fact that given two weighted species F_w and G_v, the generating series $\tilde{H}(y)$ of unlabelled H-structures, where $H = F_w(G_v)$, is given by

$$\tilde{H}(y) = Z_{F_w}(\tilde{G}_v(y), \tilde{G}_{v^2}(y^2), \tilde{G}_{v^3}(y^3), \dots). \tag{34}$$

In the present case, we have $\mathcal{A}_{o,w}^{\rightarrow} = YC_r(\mathcal{B}_r^2)$, and since the species $\mathcal{B}$ is asymmetric, $\tilde{\mathcal{B}}_r(y) = \mathcal{B}_r(y)$, hence

$$\widetilde{\mathcal{A}_o^{\rightarrow}}[\vec{n}] = [y^{n-1}][r_1^{n_1} r_2^{n_2}\cdots]Z_{C_r}(\mathcal{B}_r^2(y), \mathcal{B}_{r^2}^2(y^2), \mathcal{B}_{r^3}^2(y^3), \dots). \tag{35}$$

But $Z_{C_r}(y_1,y_2,\dots)$ can be expressed as the following sum:

$$Z_{C_r}(y_1,y_2,\dots) = \sum_{k\geq 1}\frac{r_k}{k}\sum_{d|k}\phi(d)y_d^{k/d}. \tag{36}$$

Combinatorially speaking, the integer k represents the degree of the root edge. Hence, k may only belong to $\mathrm{Supp}(\vec{n})$, the *support* of $\vec{n}$ which is the set of integers i such that $n_i \neq 0$. Hence, we have

$$\widetilde{\mathcal{A}_o^{\rightarrow}}[\vec{n}] = [y^{n-1}][r_1^{n_1} r_2^{n_2}\cdots]\sum_{k\in\mathrm{Supp}(\vec{n})}\frac{r_k}{k}\sum_{d|k}\phi(d)\mathcal{B}_{r^d}^{2k/d}(y^d). \tag{37}$$

First, we compute

$$[y^{n-1}]\mathcal{B}_{r^d}^{2k/d}(y^d) = [y^{(n-1)/d}]\mathcal{B}_{r^d}^{2k/d}(y).$$

From Lagrange inversion, we have

$$\begin{aligned}[y^m]\mathcal{B}^{\ell}_{r^d}(y) &= \frac{1}{m}[t^{m-1}]\frac{d}{dt}\left(t^{\ell}\right) L^m_{r^{\dagger d}}(t^2),\\ &= \frac{\ell}{m}\sum_{\ell_1,\ell_2,\ldots}\binom{m}{\ell_1,\ell_2,\ldots} r_1^{d\ell_1} r_2^{d\ell_2}\cdots, \end{aligned} \tag{38}$$

where the ℓ_i's satisfy $\sum_i \ell_i = m$ and $\sum_i 2(i-1)\ell_i = m-\ell$. Now, letting $m=(n-1)/d$ and $\ell = 2k/d$, we find

$$\widetilde{\mathcal{A}_o}^{\rightarrow}[\vec{n}] = [r_1^{n_1} r_2^{n_2}\cdots]\frac{2}{n-1}\sum_{k\in \mathrm{Supp}(\vec{n})}\sum_{d|k}\phi(d)\sum_{\ell_1,\ell_2,\ldots}\binom{(n-1)/d}{\ell_1,\ell_2,\ldots} r_1^{d\ell_1} r_2^{d\ell_2}\cdots r_k^{d\ell_k+1}\cdots. \tag{39}$$

Finally, we have

Proposition 3. Let $\vec{n}$ be a coherent edge degree distribution, then the number $\widetilde{\mathcal{A}_o}^{\rightarrow}[\vec{n}]$ of unlabelled oriented solid 2-trees pointed at an edge and having $\vec{n}$ as edge degree distribution is given by

$$\widetilde{\mathcal{A}_o}^{\rightarrow}[\vec{n}] = \frac{2}{n-1}\sum_{k\in \mathrm{Supp}(\vec{n})}\sum_{d|\{k,\vec{n}-\delta_k\}}\phi(d)\binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}}, \tag{40}$$

where $\frac{\vec{n}-\delta_k}{d} = (\frac{n_1}{d}, \frac{n_2}{d}, \ldots, \frac{n_k-1}{d}, \ldots)$, for $d\geq 1$ and

$$\binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}} = \binom{\frac{n-1}{d}}{n_1/d, n_2/d, \ldots, (n_k-1)/d, \ldots}.$$

Let $\widetilde{\mathcal{A}}^{\Delta}_o[\vec{n}]$ and $\widetilde{\mathcal{A}}^{\Delta}_{\partial}[n]$ be the numbers of unlabelled oriented solid 2-trees pointed respectively at a triangle and at a triangle pointed itself at one of its edge and having $\vec{n}$ as edge degree distribution. We have

Proposition 4. Let $\vec{n}$ be a coherent edge degree distribution, then the numbers $\widetilde{\mathcal{A}_o}^{\triangle}[\vec{n}]$ and $\widetilde{\mathcal{A}_o}^{\Delta}[\vec{n}]$ are given by

$$\widetilde{\mathcal{A}_o}^{\Delta}[\vec{n}] = \frac{1}{n}\binom{n}{n_1,n_2,\ldots} + \frac{\chi(3|\vec{n})}{n}\binom{n/3}{n_1/3, n_2/3,\ldots}, \tag{41}$$

$$\widetilde{\mathcal{A}_o}^{\Delta}[\vec{n}] = \frac{3}{n}\binom{n}{n_1,n_2,\ldots}, \tag{42}$$

where

$$\chi(3|\vec{n}) = \begin{cases} 1, & \text{if all components of } \vec{n} \text{ are multiples of 3}\\ 0, & \text{otherwise.}\end{cases}$$

Proof. Let us start with $\widetilde{\mathcal{A}_o}^{\Delta}[\vec{n}]$. We have

$$\begin{aligned}\widetilde{\mathcal{A}_o}^{\Delta}[\vec{n}] &= [y^n][r_1^{n_1} r_2^{n_2}\cdots]\widetilde{\mathcal{A}}^{\Delta}_{o,w}(y),\\ &= [y^n][r_1^{n_1} r_2^{n_2}\cdots]Z_{C_3}(\tilde{\mathcal{B}}_r(y), \tilde{\mathcal{B}}_{r^2}(y^2),\ldots),\\ &= [y^n][r_1^{n_1} r_2^{n_2}\cdots]Z_{C_3}(\mathcal{B}_r(y), \mathcal{B}_{r^2}(y^2),\ldots).\end{aligned}$$

Since $Z_{C_3}(y_1,y_2,\ldots) = (y_1^3+2y_3)/3$,

$$\widetilde{\mathcal{A}_o}^{\Delta}[\vec{n}] = \frac{1}{3}[y^n][r_1^{n_1} r_2^{n_2}\cdots]\left(\mathcal{B}^3_r(y) + 2\mathcal{B}_{r^3}(y^3)\right) \tag{43}$$

From equation (38) letting $m=n$, $\ell=3$ and $d=1$, we get

$$[y^n]\mathcal{B}^3_r(y) = \frac{3}{n}\sum_{\ell_1,\ell_2,\ldots}\binom{n}{\ell_1,\ell_2,\ldots} r_1^{\ell_1} r_2^{\ell_2}\cdots, \tag{44}$$

where the ℓ_i's satisfy $\sum_i \ell_i = n$ and $\sum_i 2(i-1)\ell_i = n-3$. Now letting $m = n/3$, $\ell = 1$ and $d = 3$, we get

$$[y^n]\mathcal{B}_{r^3}(y^3) = [y^{n/3}]\mathcal{B}_{r^3}(y) = \frac{3}{n}\sum_{\ell_1,\ell_2,\ldots}\binom{n/3}{\ell_1,\ell_2,\ldots} r_1^{3\ell_1} r_2^{3\ell_2}\cdots, \tag{45}$$

where the ℓ_i's satisfy $\sum_i \ell_i = n$ and $\sum_i 2(i-1)\ell_i = n-1$. Now letting $\ell_i = n_i$ in (44) and $\ell_i = n_i/3$ in (45), we get equation (41). We obtain (42) in a very similar way. □

Finally, using the dissymmetry theorem, we obtain the final result of this section:

Proposition 5. Let $\vec{n}$ be a coherent edge degree distribution, then the number $\widetilde{\mathcal{A}_o}[\vec{n}]$ of unlabelled oriented solid 2-trees having $\vec{n}$ as edge degree distribution is given by

$$\widetilde{\mathcal{A}_o}[\vec{n}] = \frac{2}{n-1}\sum_{k\in \mathrm{Supp}(\vec{n})}\sum_{d\mid\{k,\vec{n}-\delta_k\}}\phi(d)\binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}} + \frac{\chi(3|\vec{n})}{n}\binom{\frac{n}{3}}{\frac{n_1}{3},\frac{n_2}{3},\ldots} - \frac{2}{3n}\binom{n}{n_1,n_2,\ldots}, \tag{46}$$

where

$$\chi(3|\vec{n}) = \begin{cases} 1, & \text{if all components of } \vec{n} \text{ are multiples of 3,}\\ 0, & \text{otherwise,}\end{cases}$$

$$\frac{\vec{n}-\delta_k}{d} = \left(\frac{n_1}{d},\frac{n_2}{d},\ldots,\frac{n_k-1}{d},\ldots\right) \text{ for } d\geq 1,$$

and

$$\binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}} = \binom{\frac{n-1}{d}}{n_1/d, n_2/d,\ldots,(n_k-1)/d,\ldots}.$$

3. Non-oriented solid 2-trees

In order to compute the numbers of labelled and unlabelled solid 2-trees, we use Burnside's Lemma with $\mathbb{Z}_2 = \{Id, \tau\}$, where the action of τ is to reverse the orientation of the structures.

3.1. Enumeration according to the number of edges.

• Labelled case

The labelled case is particularly simple since the only labelled oriented 2-tree which is left fixed under the action of τ is the structure consisting of a single oriented edge. Hence, we have

Proposition 6. The number $\mathcal{A}[n]$ of edge labelled solid 2-trees over n edges is given by

$$\mathcal{A}[n] = \begin{cases} \frac{1}{2}\mathcal{A}_0[n] & \text{if } n>1;\\ 1 & \text{if } n=1.\end{cases} \tag{47}$$

Of course, the same argument will remain valid for all other pointed structures discussed in the previous section.

• Unlabelled case

In the unlabelled case, the action of τ is not so trivial. Figure 5 shows a structure which is left fixed under the action of τ. Let $\mathcal{A}^-$ be the species of unoriented solid 2-trees rooted at an edge. This species can be expressed as the following quotient species (see [4]):

$$\mathcal{A}^- = \frac{\mathcal{A}_o^{\rightarrow}}{\mathbb{Z}_2} = \frac{YC(\mathcal{B}^2(Y))}{\mathbb{Z}_2}, \tag{48}$$

where $\mathbb{Z}_2 = \{\mathrm{Id}, \tau\}$ is the two element group consisting of the identity and τ, whose action is to reverse the orientation of the edges. Hence, an unlabelled $\mathcal{A}^-$-structure is an orbit $\{a, \tau\cdot a\}$ under the action of $\mathbb{Z}_2$ where a is any (oriented) unlabelled $\mathcal{A}_o^{\rightarrow}$-structure.

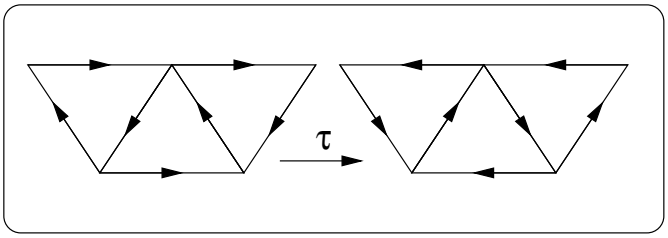

FIGURE 5. An unlabelled 2-tree invariant under the action of τ.

Let us introduce the auxiliary species $\mathcal{B}_{\mathrm{Sym}}$ of τ-symmetric $\mathcal{B}$-structures, *i.e* the species of $\mathcal{B}$-structures left fixed under the edge orientation inversion. Denote by $\mathcal{B}_{\mathrm{Sym}}(y)$ its ordinary generating series. Recall the functional equation verified by the species $\mathcal{B}$:

$$\mathcal{B} = Y\,L(B^2).$$

In order to compute $\mathcal{B}_{\mathrm{Sym}}(y)$, we have to distinguish two cases according to the parity of k, the length of the list of $\mathcal{B}^2$-structures attached to the rooted edge. First consider the case where k is odd (Figure 6 shows an example where $k = 5$). A τ-symmetric $\mathcal{B}$-structure must have a reflective symmetry plane. This plane contains the middle triangle of the list. When an inversion of the orientation of the rooted edge is applied, the two $\mathcal{B}$-structures glued on the two (non root) sides of the middle triangle (structures $\mathcal{B}_5$ and $\mathcal{B}_{5'}$ in Figure 6) are isomorphically exchange. The $k-1$ remaining triangles are exchanged pairwise carrying with them each of their attached $\mathcal{B}$-structures as shown in Figure 6. This gives a factor of $\mathcal{B}^k(y^2)$. We then have to sum the previous expression over all odd values of k. The case where k is even, is very similar except that the symmetry plane must passes between two triangles as shown in Figure 7 and we get the same expression summed over all even values of k. Therefore, we have

$$\mathcal{B}_{\mathrm{Sym}}(y) = y \sum_{k\geq 0} \mathcal{B}^k(y^2) = \frac{y}{1-\mathcal{B}(y^2)}. \tag{49}$$

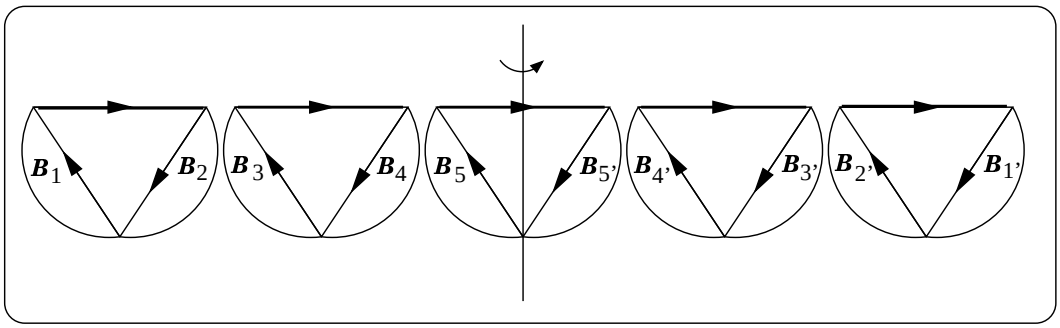

FIGURE 6. A $\mathcal{B}_{\mathrm{Sym}}$-structure, k odd.

From expression (49) and another use of Lagrange inversion, we easily obtain the following result.

Proposition 7. The number $\mathcal{B}_{\mathrm{sym}}[m]$ of τ-symmetric unlabelled oriented $\mathcal{B}$-structures is given by

$$\mathcal{B}_{\mathrm{sym}}[m] = \begin{cases} \dfrac{1}{m+1}\dbinom{3m/2}{m} & \text{if } m \text{ is even,} \\[2ex] \dfrac{1}{m}\dbinom{(3m-1)/2}{m+1} + \dfrac{1}{3m}\dbinom{3(m+1)/2}{m+1} & \text{if } m \text{ is odd,} \end{cases} \tag{50}$$

where $m = (n-1)/2$ is the number of triangles and n, the number of edges.

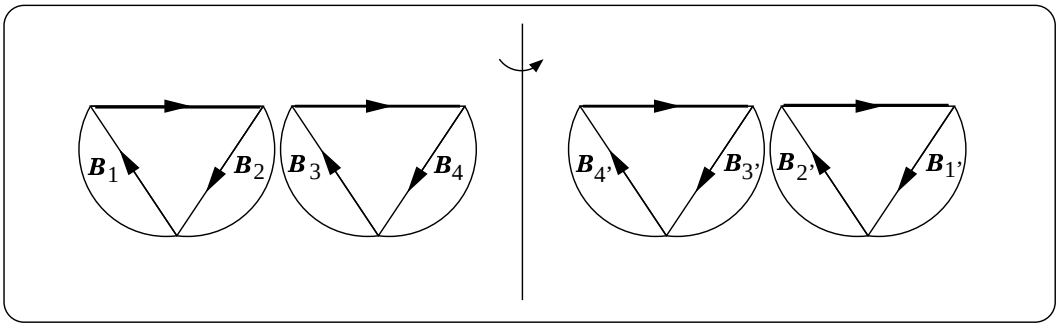

FIGURE 7. A $\mathcal{B}_{\mathrm{Sym}}$-structure, k even.

We now give an expression for the generating function of unlabelled quotient structures, which will allow us to enumerate various kind of unlabelled solid 2-trees (see [4], proposition 2.2.4).

Proposition 8. Let F be any (weighted) species and G, a group acting on F. Then the ordinary generating series of the quotient species F/G is given by

$$(F/G)^{\sim}(y) = \frac{1}{|G|}\sum_{g\in G}\sum_{n\geq 0}|\mathrm{Fix}_{\tilde{F}_n}(g)|_w y^n, \tag{51}$$

where $\mathrm{Fix}_{\tilde{F}_n}(g)$ denotes the set of unlabelled F-structures left fixed under the action of $g \in G$ and $|\mathrm{Fix}_{\tilde{F}_n}(g)|_w$ represents the total weight of this set.

Using an unweighted version of Proposition 8 with $F = \mathcal{A}_o^{\rightarrow}$ and $G = \mathbb{Z}_2$, we obtain

$$\widetilde{\mathcal{A}}^{-}(y) = \frac{1}{2}\sum_{n\geq 0}|\mathrm{Fix}_{\tilde{\mathcal{A}}^{\rightarrow}_{o,n}}(\mathrm{Id})|y^n + \frac{1}{2}\sum_{n\geq 0}|\mathrm{Fix}_{\tilde{\mathcal{A}}^{\rightarrow}_{o,n}}(\tau)|y^n, \tag{52}$$

$$= \frac{1}{2}\widetilde{\mathcal{A}}_o^{\rightarrow}(y) + \frac{1}{2}\mathcal{B}_{\mathrm{sym}}(y), \tag{53}$$

since an oriented $\mathcal{A}^{-}$-structure left fixed under the action of τ is in fact a $\mathcal{B}_{\mathrm{Sym}}$-structure. Then, it becomes easy to extract the coefficient of y^n in relation (53), and we get the number $\mathcal{A}^{-}[n]$ of edge pointed solid 2-trees over n edges

$$\mathcal{A}^{-}[n] = \frac{1}{2}\widetilde{\mathcal{A}}_o^{\rightarrow}[n] + \frac{1}{2}\mathcal{B}_{\mathrm{Sym}}[n]. \tag{54}$$

We now consider the species $\mathcal{A}^{\Delta}$ of triangle rooted solid 2-trees. Since $\mathcal{A}^{\Delta} = \mathcal{A}_o^{\Delta}/\mathbb{Z}_2$, by virtue of Proposition 8, we have

$$\widetilde{\mathcal{A}}^{\Delta}(y) = \frac{1}{2}\sum_{n\geq 0}|\mathrm{Fix}_{\tilde{\mathcal{A}}^{\Delta}_{o,n}}(\mathrm{Id})|y^n + \frac{1}{2}\sum_{n\geq 0}|\mathrm{Fix}_{\tilde{\mathcal{A}}^{\Delta}_{o,n}}(\tau)|y^n, \tag{55}$$

where $|\mathrm{Fix}_{\tilde{\mathcal{A}}^{\Delta}_{o,n}}(\tau)|$, the number of τ-symmetric $\mathcal{A}^{\Delta}$-structures over n edges has to be determined. As shown in Figure 8, such a structure must have an axis of symmetry which coincides with one of the root triangle's medians. Since the structure is already considered up to rotation around the root triangle, the choice among the three possible axes is arbitrary. The base side of the triangle must be a $\mathcal{B}_{\mathrm{Sym}}$-structure while the two other sides must be isomorphic copies of the same $\mathcal{B}$-structure. Therefore,

$$\widetilde{\mathcal{A}}^{\Delta}(y) = \frac{1}{2}\widetilde{\mathcal{A}}_o^{\Delta}(y) + \frac{1}{2}\mathcal{B}_{\mathrm{Sym}}(y)\mathcal{B}(y^2). \tag{56}$$

In a very similar way, since $\mathcal{A}^{\Delta} = \mathcal{A}_o^{\Delta}/\mathbb{Z}_2$, we obtain

$$\widetilde{\mathcal{A}}^{\Delta}(y) = \frac{1}{2}\widetilde{\mathcal{A}}_o^{\Delta}(y) + \frac{1}{2}\mathcal{B}_{\mathrm{Sym}}(y)\mathcal{B}(y^2). \tag{57}$$

Finally, using (53), (56) and (57) and using the dissymetry theorem, we get

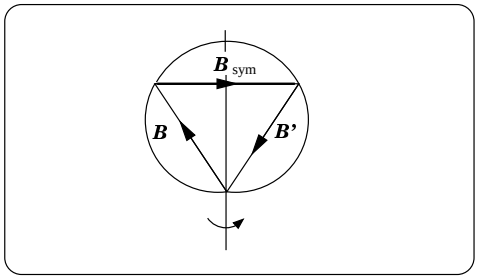

FIGURE 8. A τ-symmetric $\mathcal{A}_o^{\Delta}$-structure.

Proposition 9. The ordinary generating function of solid 2-trees is given by

$$\mathcal{A}(y) = \frac{1}{2}(\mathcal{A}_o(y) + \mathcal{B}_{\mathrm{Sym}}(y)), \tag{58}$$

where $\mathcal{B}_{\mathrm{Sym}}(y)$ is the ordinary generating series of τ-symmetric oriented $\mathcal{B}$-structures. Consequently, the number $\widetilde{\mathcal{A}}[m]$ of unoriented solid 2-trees over m triangles is given by

$$\widetilde{\mathcal{A}}[m] = \frac{1}{2}(\widetilde{\mathcal{A}}_o[m] + \mathcal{B}_{\mathrm{sym}}[m]), \tag{59}$$

where

$$\widetilde{\mathcal{A}_o}[m] = \frac{1}{3m}\sum_{d|m}\phi\left(\frac{m}{d}\right)\binom{3d}{d} + \chi(3|2m+1)\frac{2}{2m+1}\binom{m-1}{\frac{2m-2}{3}} - \frac{2}{3(2m+1)}\binom{3m}{m}.$$

and

$$\mathcal{B}_{\mathrm{sym}}[m] = \begin{cases} \dfrac{1}{m+1}\binom{3m/2}{m} & \text{if } m \text{ is even,} \\[2ex] \dfrac{1}{m}\binom{(3m-1)/2}{m+1} + \dfrac{1}{3m}\binom{3(m+1)/2}{m+1} & \text{if } m \text{ is odd.} \end{cases} \tag{60}$$

To express $\widetilde{\mathcal{A}}[m]$ in term of n the number of edges, we only have to set $m := \frac{n-1}{2}$.

3.2. Enumeration of non oriented solid 2-trees according to the edge degree distribution.

We consider again the weight function defined by

$$\begin{array}{rccc} w: & F[n] & \longrightarrow & Q[r_1, r_2, \dots] \\ & s & \mapsto & w(s), \end{array} \tag{61}$$

where $r = (r_0, r_1, r_2, \dots)$ is an infinite set of formal variables, F is any species and n is any positive integer.

• Labelled case

As mentioned in the previous section, the only labelled solid 2-tree left fixed under the action of τ consists in a single edge. Hence, given a valid edge degree distribution $\vec{n}$ we have

$$\mathcal{A}[\vec{n}] = \begin{cases} \frac{1}{2}\mathcal{A}_0[\vec{n}] & \text{if } n > 1; \\ 1 & \text{if } n = 1, \end{cases} \tag{62}$$

where n is the number of edges and $\mathcal{A}[\vec{n}] = [y^n][r_1^{n_1} r_2^{n_2} \cdots]\mathcal{A}_w^-(y)$.

• Unlabelled case

Using the weighted versions of equations (53), (56) and (57), we get

$$\widetilde{\mathcal{A}}^{-}_{w}(y) = \frac{1}{2}\widetilde{\mathcal{A}}^{\rightarrow}_{o,w}(y) + \frac{1}{2}\mathcal{B}_{\mathrm{sym},w}(y), \tag{63}$$

$$\widetilde{\mathcal{A}}^{\Delta}_{w}(y) = \frac{1}{2}\widetilde{\mathcal{A}}^{\Delta}_{o,w}(y) + \frac{1}{2}\mathcal{B}_{\mathrm{sym},w}(y)\mathcal{B}_{w}(y^2), \tag{64}$$

$$\widetilde{\mathcal{A}}^{\underline{\Delta}}_{w}(y) = \frac{1}{2}\widetilde{\mathcal{A}}^{\underline{\Delta}}_{o,w}(y) + \frac{1}{2}\mathcal{B}_{\mathrm{sym},w}(y)\mathcal{B}_{w}(y^2). \tag{65}$$

Now applying the dissymmetry theorem leads to

$$\widetilde{\mathcal{A}}(y) = \frac{1}{2}\widetilde{\mathcal{A}}_{o,w}(y) + \frac{1}{2}\mathcal{B}_{\mathrm{sym},w}(y). \tag{66}$$

The only unknown term in the above equation is $\mathcal{B}_{\mathrm{sym},w}(y)$. We first establish an additional condition on the vertex degree distribution for an edge rooted oriented solid 2-tree to be τ-symmetric. Since the root edge must remain fixed and all other edges are exchanged pairwise, the edge degree distribution vector $\vec{n}$ must have all its components even except one odd corresponding to the rooted edge.

For an edge degree distribution $\vec{n} = (n_1, n_2, \dots)$ satisfying the previous condition, and using the fact that $\mathcal{B}_{\mathrm{sym,w}}(y) = yr_k\mathcal{B}^k(y^2)$, we have

$$\mathcal{B}_{\mathrm{sym,w}}[\vec{n}] = \frac{2k}{n-1}\binom{\frac{n-1}{2}}{\frac{\vec{n}-\delta_k}{2}}, \tag{67}$$

where k is the root edge degree. We now present the final result of this paper.

Proposition 10. Let $\vec{n}$ be a vector satisfying

$$\sum_i n_i = n \quad \text{and} \quad \sum_i i n_i = 3m.$$

Then, the number $\widetilde{\mathcal{A}}[\vec{n}]$ of (non oriented) unlabelled solid 2-trees having $\vec{n}$ as edge degree distribution is given by

$$\widetilde{\mathcal{A}}[\vec{n}] = \frac{1}{2}\widetilde{\mathcal{A}}_o[\vec{n}] + \frac{1}{2}\widetilde{\mathcal{B}}_{\mathrm{sym}}[\vec{n}], \tag{68}$$

where

$$\widetilde{\mathcal{B}}_{\mathrm{sym}}[\vec{n}] = \begin{cases} \dfrac{2k}{n-1}\binom{\frac{n-1}{2}}{\frac{\vec{n}-\delta_k}{2}}, & \text{if } \vec{n} \text{ has a unique odd component,} \\ 0, & \text{otherwise,} \end{cases}$$

δ_k being the vector having 1 at the k^{th} component and 0 everywhere else, and

$$\widetilde{\mathcal{A}_o}[\vec{n}] = \frac{2}{n-1}\sum_{k\in \mathrm{Supp}(\vec{n})}\sum_{d\mid\{k,\vec{n}-\delta_k\}}\phi(d)\binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}} + \frac{\chi(3|\vec{n})}{n}\binom{n/3}{n_1/3, n_2/3, \dots} - \frac{2}{3n}\binom{n}{n_1, n_2, \dots}.$$

Appendix.

To conclude this paper, we give here two tables giving the numbers of unlabelled solid 2-trees oriented and unoriented as well as the number of unlabelled τ-symmetric $\mathcal{B}$-structures. The first table gives these numbers according to the number n of edges, and the second, according to edge degree distribution. We use the notation $1^{n_1}2^{n_2}\cdots$, where i^{n_i} means n_i edges of degree i.

ENUMERATION OF SOLID 2-TREES ACCORDING TO EDGE NUMBER AND EDGE DEGREE DISTRIBUTION

MICHEL BOUSQUET AND CÉDRIC LAMATHE

Abstract. The goal of this paper is to enumerate solid 2-trees according to the number of edges (or triangles) and also according to the edge degree distribution. We first enumerate oriented solid 2-trees using the general methods of the theory of species. In order to obtain non oriented enumeration formulas, we use quotient species which consists in a specialization of Pólya theory.

Résumé. Le but de cet article est d'obtenir l'énumération des 2-arbres solides selon le nombre d'arêtes (ou de triangles) ainsi que selon la distribution des degrés des arêtes. Nous obtenons d'abord le dénombrement des 2-arbres solides orientés en utilisant les méthodes de la théorie des espèces. Pour obtenir le dénombrement des 2-arbres solides non orientés, nous utilisons la notion d'espèce quotient qui provient d'une spécialisation de la théorie de Pólya.

1. Introduction

Definition 1. Let $\mathcal{E}$ be a non-empty finite set of n elements called *edges*. A *2-tree* is either a single edge (if $n = 1$) or a non-empty subset $\mathcal{T} \subseteq \mathcal{P}_3(\mathcal{E})$ whose elements are called *triangles*, satisfying the following conditions:

1. For every pair $\{a, b\} = \{\{a_1, a_2, a_3\}, \{b_1, b_2, b_3\}\}$ of distinct elements of $\mathcal{T}$, we have $|a \cap b| \leq 1$, which means that two distinct triangles share at most one edge.
2. For every ordered pair $(a, b) = (\{a_1, a_2, a_3\}, \{b_1, b_2, b_3\})$ of distinct elements of $\mathcal{T}$, there is a unique sequence $(t_0 = a, t_1, t_2, \ldots, t_k = b)$ such that for $i = 0, 1, \ldots, k-1$, we have $t_i \in \mathcal{T}$ and $|t_i \cap t_{i+1}| = 1$, which means that each pair of consecutive triangles in this sequence share exactly one edge.

An edge e and a triangle t are *incident* to each other if $e \in t$. The *degree* of an edge is the number of triangles which are incident to that edge. The *edge degree distribution* of a 2-tree is described by a vector $\vec{n} = (n_1, n_2, \ldots)$, where n_i is the number of edges of degree i. Since the case of a 2-tree reduced to a single edge (of degree 0) is obvious, we exclude it of this descritption. We denote by $\mathrm{Supp}(\vec{n})$ the *support* of $\vec{n}$ which is the set of indices i such that $n_i \neq 0$. Figure 1 shows a 2-tree having 11 edges, 5 triangles and edge degree distribution given by $\vec{n} = (8, 2, 1)$.

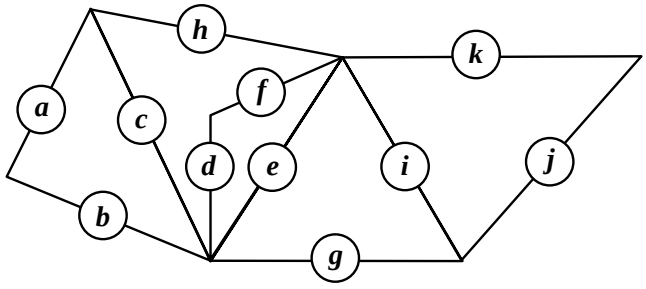

Figure 1. A 2-tree on $\mathcal{E} = \{a, b, c, d, e, f, g, h, i, j, k\}$.

Several classes of 2-trees have been studied before. Beineke and Pippert enumerate some k-dimensional trees in [1] labelled at vertices. In [9], Harary and Palmer count unlabelled 2-trees. For the enumeration of plane 2-trees, see [15], and for a classification according to symmetries of plane and planar 2-trees, see [12]. In [7, 8], Fowler et al. worked on general 2-trees and give asymptotical

results. More recently, in [13], the authors generalize the results of Fowler et al. to the larger familly of k-gonal 2-trees. We also mention the works of Kloks in [10, 11] about partial biconnected 2-trees. Here, we consider a new class of 2-trees, that is, *solid* 2-trees, *i.e.*, 2-trees embedded in three-dimensional space.

The first result gives a sufficient and necessary condition on edges to ensure the existence of a 2-tree.

Lemma 1. Let m, n be two nonnegative integers and $\vec{n} = (n_1, n_2, \ldots)$, an infinite vector of nonnegative integers. Then:

1. There exists a 2-tree having m triangles and n edges if and only if $n = 2m + 1$.
2. There exists a 2-tree having n edges and $\vec{n}$ as edge degree distribution if and only if

$$\sum_i n_i = n \quad \text{and} \quad \sum_i i n_i = 3m. \tag{1}$$

Proof. Item 1 is quite obvious as the reader can check. For item 2, the condition $\sum_i n_i = n$ is straightforward. Concerning the relation $\sum_i i n_i = 3m$, it suffices to observe that the left-hand side counts the total degree of the structure, while, in the right-hand side, each triangle contributes for three units in the total degree. ■

We say that $\vec{n} = (n_1, n_2, \ldots)$ is a *coherent* (or *valid*) edge degree distribution if condition (1) is satisfied.

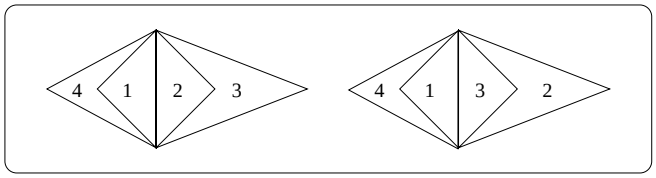

FIGURE 2. Two distinct solid 2-trees but the same 2-tree.

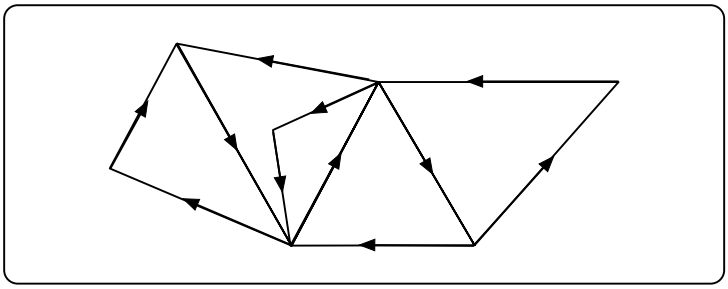

FIGURE 3. A well oriented 2-tree.

A *solid* 2-tree can be viewed topologically as a 2-tree in which the faces of the triangles cannot interpenetrate themselves. As a consequence, there is a cyclic configuration of triangles around each edge. Figure 2 shows an example of two different solid 2-trees which are in fact the same 2-tree. Indeed, the cyclic order on labels 1, 2, 3, 4 given to the triangles for the two 2-trees are different. A *well oriented* solid 2-tree is obtained from a solid 2-tree in the following way: first, pick any triangle and give a cyclic orientation on its edges; then each triangle adjacent to the first triangle inherits a cyclic orientation (see Figure 3). This process is repeated until all edges receive an orientation. By the arborescent nature of the structure, there will be no conflict (the orientation of each edge will always be well defined). Figure 3 shows an example of a well oriented 2-tree. The species of non-oriented and well oriented solid 2-trees will be denoted respectively by $\mathcal{A}$ and $\mathcal{A}_o$. For details

about species, see [2]. In order to analyze these two species, the following auxiliary species will be used:

- The species of *triangles* X: a single triangle will be denoted by X;
- The species of *edges* Y: a single edge will be denoted by Y;
- The species L of *lists* or *linear orders*;
- The species C and C_3, respectively of oriented cycles and of oriented cycles of length 3;
- The species $\mathcal{A}^-$ and $\mathcal{A}_o^-$, respectively of non oriented and well oriented solid 2-trees *rooted at an edge*;
- The species $\mathcal{A}^\Delta$ and $\mathcal{A}_o^\Delta$, respectively of non oriented and well oriented solid 2-trees *rooted at a triangle*;
- The species $\mathcal{A}^{\underline{\Delta}}$ and $\mathcal{A}_o^{\underline{\Delta}}$, respectively of non oriented and well oriented solid 2-trees *rooted at a triangle having itself one of its edges distinguished*;
- Finally, the species $\mathcal{B}$ of *planted* oriented solid 2-trees which consists of an oriented root edge Y incident to a linear order (L-structure) of triangles X each of which having its two remaining sides being themselves $\mathcal{B}$-structures. Therefore, the species $\mathcal{B}$ satisfies the following combinatorial equation

$$\mathcal{B}(X,Y) = YL(X\mathcal{B}^2(X,Y)), \tag{2}$$

as illustrated by Figure 4.

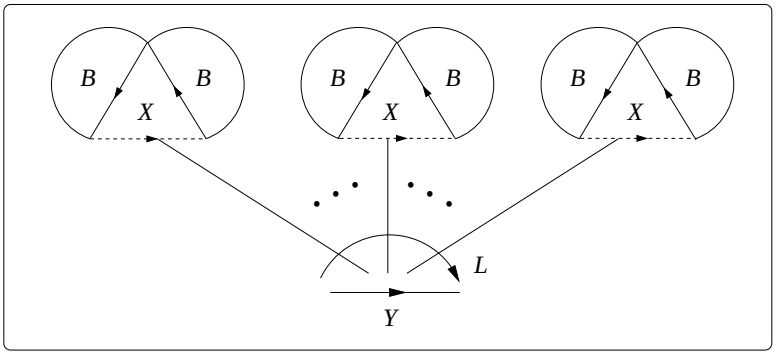

FIGURE 4. A $\mathcal{B}$-structure.

Note that $\mathcal{B}$ has been defined as a *two-sort* species where the sorts are X and Y. Since the numbers of edges n and of triangles m are linked by the relation $n = 2m + 1$, as stated in Lemma 1, equation (2) above can either be expressed as a one sort species in X alone by setting $Y := 1$, or in Y alone, by setting $X := 1$ respectively, giving the two following equations:

$$\mathcal{B}(X,1) = L(X\mathcal{B}^2(X,1)), \tag{3}$$

$$\mathcal{B}(1,Y) = YL(\mathcal{B}^2(1,Y)). \tag{4}$$

Recall that setting $X := 1$ in a two sort species $F(X,Y)$ essentially means unlabelling the elements of sort X. The second form in equation (4) is more suitable for the use of Lagrange inversion formula. Therefore, the species Y of edges will be used as the base singleton species to make our computations and we will rather use the shorter form $\mathcal{B}(Y) = YL(\mathcal{B}^2(Y))$ for (4). Hence, the structures are labelled at edges. However, some results will be more concise when expressed as a function of the number m of triangles.

In this paper, we make an extensive use of Lagrange inversion formula (see [2]). Let $A(y)$ and $R(y)$ be formal series satisfying $A(y) = yR(A(y))$ and $R(0) = 0$. If F is another formal series, then

$$[y^n]F(A(y)) = \frac{1}{n}[t^{n-1}]F'(t)R^n(t), \tag{5}$$

where $[y^n]F(A(y))$ denotes the coefficient of y^n in $F(A(y))$.

Another main tool used in this paper is the following dissymmetry theorem which has been proved in [7, 8]. Note that in their paper, the authors made a proof for general 2-trees but obviously, the proof is also valid for both well oriented and non oriented solid 2-trees.

Theorem 1. The species $\mathcal{A}_o$ and $\mathcal{A}$, respectively of well oriented and (non oriented) solid 2-trees, satisfy the following relations:

$$\mathcal{A}_o^- + \mathcal{A}_o^{\Delta} = \mathcal{A}_o + \mathcal{A}_o^{\underline{\Delta}}, \tag{6}$$

and

$$\mathcal{A}^- + \mathcal{A}^{\Delta} = \mathcal{A} + \mathcal{A}^{\underline{\Delta}}. \tag{7}$$

□

To each species F, we associate two series: the exponential generating series of labelled structures $F(x)$ and the ordinary generating series of unlabelled structures $\widetilde{F}(x)$, as follows:

$$F(x) = \sum_{n\geq 0} |F[n]| \frac{x^n}{n!}, \tag{8}$$

$$\widetilde{F}(x) = \sum_{n\geq 0} |\widetilde{F}[n]|\, x^n, \tag{9}$$

where $|F[n]|$ and $|\widetilde{F}[n]|$ are respectively the numbers of labelled and unlabelled F-structures over n elements.

2. Well oriented solid 2-trees

We begin this section by expressing the species appearing in the dissymmetry theorem (oriented case) in terms of the species $\mathcal{B}$.

Proposition 1. The species $\mathcal{A}_o^-$, $\mathcal{A}_o^{\Delta}$ and $\mathcal{A}_o^{\underline{\Delta}}$ satisfy the following isomorphisms of species:

$$\mathcal{A}_o^-(Y) = Y + YC(\mathcal{B}^2(Y)), \tag{10}$$

$$\mathcal{A}_o^{\Delta}(Y) = C_3(\mathcal{B}(Y)), \tag{11}$$

$$\mathcal{A}_o^{\underline{\Delta}}(Y) = \mathcal{B}(Y)^3. \tag{12}$$

Proof. Let us begin with relation (10). The term Y corresponds to the case of a single rooted edge. In the general case, as illustrated by Figure 5 a), by convention with the right-hand rule, we define a cyclic order over the triangles glued around the oriented root-edge. Next, each triangle in this cyclic configuration, possesses, on its two remaining oriented edges, two $\mathcal{B}$-structures, leading to the expression $YC(\mathcal{B}^2(Y))$. For (11), it suffices to remark that, since the structures are (well) oriented, there is a cyclic order of length three around the edges of the root triangle (see Figure 5 b)). These edges being oriented, we can attach $\mathcal{B}$-structures on them, giving quite directly (11). We obtain (12) in a very similar way (see Figure 5)). ■

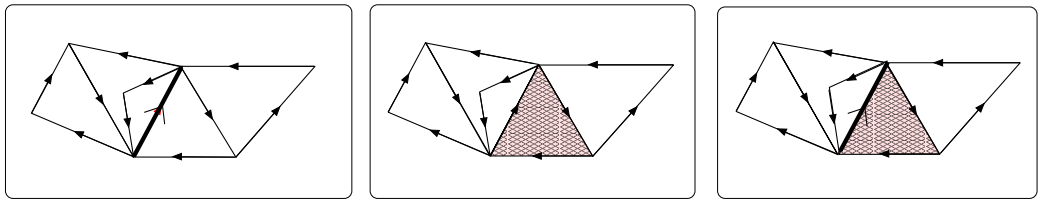

Figure 5. Illustration of equations (10), (11) and (12).

2.1. **Enumeration according to the number of edges.**

In this section, we obtain the labelled and unlabelled enumeration of oriented solid 2-trees according to the number n of edges. We also give formulas in terms of the number m of triangles.

• **Labelled case**

Let $\mathcal{A}_o[n]$ be the set of edge-labelled solid 2-trees over n edges. We similarly define $\mathcal{A}_o^-[n]$, $\mathcal{A}_o^\Delta[n]$ and $\mathcal{A}_o^{\overline{\Delta}}[n]$. Our first task is to determine $|\mathcal{A}_o^-[n]|$, the cardinality of the set $\mathcal{A}_o^-[n]$. By applying Lagrange inversion with $F(t) = C(t^2) = -\ln(1-t^2)$ and $R(t) = L(t^2) = (1-t^2)^{-1}$, we find, for $n > 1$,

$$\begin{aligned}[y^n]\mathcal{A}_o^-(y) &= [y^{n-1}]C(\mathcal{B}^2(y)),\\ &= \frac{2}{3(n-1)}\binom{3(n-1)/2}{n-1}.\end{aligned}$$

Hence, we have

$$|\mathcal{A}_o^-[n]| = n![y^n]\mathcal{A}_o^-(y) = \frac{2}{3}n(n-2)!\binom{\frac{3(n-1)}{2}}{n-1}. \tag{13}$$

Note that, when a solid 2-tree over n edges is labelled, we have n different choices for the root edge. Therefore

$$n|\mathcal{A}_o[n]| = |\mathcal{A}_o^-[n]|,$$

and the next proposition follows.

Proposition 2. The number $|\mathcal{A}_o[n]|$ of well oriented edge-labelled solid 2-trees over n edges is given by

$$|\mathcal{A}_o[n]| = \frac{2}{3}(n-2)!\binom{\frac{3(n-1)}{2}}{n-1}, \quad n > 1. \tag{14}$$

□

Note that if we express equation (14) as a function of m, the number of triangles, we obtain

$$|\mathcal{A}_{o,t}[m]| = \frac{(m-1)!}{3}\frac{1}{2m+1}\binom{3m}{m}, \quad m \geq 2, \tag{15}$$

where the index t in $|\mathcal{A}_{o,t}[m]|$ means that the structures are labelled at triangles instead of edges.

• **Unlabelled case**

We first need to compute the ordinary generating series $\widetilde{\mathcal{A}}_o^-(y)$ of unlabelled $\mathcal{A}_o^-$-structures. In order to accomplish this, we use the following property.

Theorem 2. ([2]) Let F and G be two species. Then, we have

$$(F(G))^\sim(x) = Z_F(\widetilde{G}(x), \widetilde{G}(x^2), \widetilde{G}(x^3), \ldots), \tag{16}$$

where the *cycle index series* Z_F of a species is defined by

$$Z_F(x_1, x_2, \ldots) = \sum_{k\geq 0}\frac{1}{k!}\sum_{\sigma\in\mathcal{S}_k}\mathrm{fix}F[\sigma]x_1^{\sigma_1}x_2^{\sigma_2}x_3^{\sigma_3}\cdots, \tag{17}$$

where $\mathcal{S}_k$ is the symmetric group of order k, σ_i, the number of cycles of length i in the permutation $\sigma \in \mathcal{S}_k$ and $\mathrm{fix}F[\sigma]$, the number of F-structures left fixed under the relabelling induced by σ. □

For example, if $F = C$, the species of oriented cycles, we have

$$Z_C(x_1, x_2, \ldots) = \sum_{k\geq 1}\frac{\phi(k)}{k}\ln\left(\frac{1}{1-x_k}\right), \tag{18}$$

where ϕ is the Euler function. Now, applying this to the species $\mathcal{A}_o^- = Y + YC(\mathcal{B}^2)$, we get

$$\begin{aligned}\widetilde{\mathcal{A}}_o^-(y) &= y + yZ_C(\widetilde{\mathcal{B}}^2(y), \widetilde{\mathcal{B}}^2(y^2), \widetilde{\mathcal{B}}^2(y^3), \dots) \\ &= y + y\sum_{k\geq 1}\frac{\phi(k)}{k}\ln\left(\frac{1}{1-\widetilde{\mathcal{B}}^2(y^k)}\right).\end{aligned}$$

We note that since $\mathcal{B}$ is asymmetric (there are exactly $n!$ labelled structures for each unlabelled structures or equivalently, the stabilizer of each $\mathcal{B}$-structure is trivial), we have $\widetilde{\mathcal{B}}(y) = \mathcal{B}(y)$. Hence, for $n > 1$,

$$\begin{aligned}|\widetilde{\mathcal{A}}_o^-[n]| &= [y^n]\widetilde{\mathcal{A}}_o^-(y), \\ &= [y^{n-1}]\sum_{k\geq 1}\frac{\phi(k)}{k}\ln\left(\frac{1}{1-\mathcal{B}^2(y^k)}\right).\end{aligned}$$

But, using the fact that $[y^n]H(y^k) = [y^{n/k}]H(y)$ and Lagrange inversion,

$$\begin{aligned}[y^{n-1}]\ln\left(\frac{1}{1-\mathcal{B}^2(y^k)}\right) &= \frac{2k}{n-1}[t^{\frac{n-1}{k}-2}](1-t^2)^{-\frac{n-1}{k}-1} \\ &= \frac{2k}{3(n-1)}\binom{3(n-1)/2k}{(n-1)/k}.\end{aligned}$$

Obviously, k must divide $n-1$ and $(n-1)/k$ must be even. Letting $d = (n-1)/k$, we finally get

$$|\widetilde{\mathcal{A}}_o^-[n]| = \frac{2}{3(n-1)}\sum_d \phi\left(\tfrac{n-1}{d}\right)\binom{3d/2}{d}, \tag{19}$$

the sum being taken over all even divisors d of $n-1$. To compute $|\widetilde{\mathcal{A}}_o^{\triangle}[n]|$, we use equation (11) and the fact that

$$Z_{C_3}(y_1, y_2, \dots) = \frac{1}{3}(y_1^3 + 2y_3).$$

We have

$$[y^n]\mathcal{B}^3(y) = \frac{1}{n}\binom{3(n-1)/2}{n-1},$$

and

$$[y^n]\mathcal{B}(y^3) = [y^{n/3}]\mathcal{B}(y) = \frac{3}{n}\binom{(n-3)/2}{n/3-1},$$

so that,

$$|\widetilde{\mathcal{A}}_o^{\Delta}[n]| = \frac{1}{3n}\binom{\frac{3(n-1)}{2}}{n-1} + \frac{2}{n}\chi(3|n)\binom{\frac{(n-3)}{2}}{\frac{n}{3}-1}, \tag{20}$$

where $\chi(3|n) = 1$ if 3 divides n and 0 otherwise. It can be easily shown, by a very similar way, that

$$|\widetilde{\mathcal{A}}_o^{\Delta}[n]| = \frac{1}{n}\binom{\frac{3(n-1)}{2}}{n-1}. \tag{21}$$

So, by virtue of the dissymmetry theorem (6), we get the following result:

Proposition 3. The number of unlabelled well oriented solid 2-trees over n edges is given by

$$|\widetilde{\mathcal{A}}_o[n]| = \frac{2}{3(n-1)}\sum_d \phi\left(\frac{n-1}{d}\right)\binom{3d/2}{d} + \chi(3|n)\frac{2}{n}\binom{\frac{n-3}{2}}{\frac{n}{3}-1} - \frac{2}{3n}\binom{\frac{3(n-1)}{2}}{n-1}, \tag{22}$$

the sum being taken over all even divisors d of $n-1$. □

We can also write $|\widetilde{\mathcal{A}}_{o,t}[m]|$, in function of the number m of triangles, as follows

$$|\widetilde{\mathcal{A}}_{o,t}[m]| = \frac{1}{3m}\sum_{d|m}\phi\left(\frac{m}{d}\right)\binom{3d}{d} + \chi(3|2m+1)\frac{2}{2m+1}\binom{m-1}{\frac{2m-2}{3}} - \frac{2}{3(2m+1)}\binom{3m}{m}.$$

Note that this expression also counts the number of unlabelled 3-gonal cacti on m triangles (see [3]). There is an quite direct bijection between these objects and solid 2-trees. The sequence of these numbers is known as sequence A054423 in the on-line encyclopedia of integers sequences ([16]). To

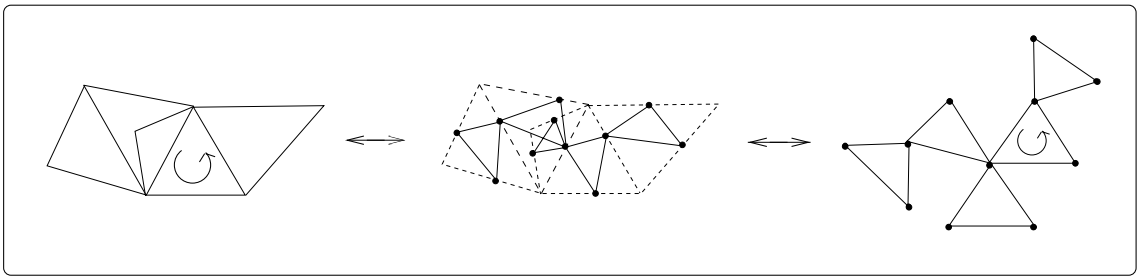

FIGURE 6. Bijection between solid 2-trees and cacti

obtain a (uncolored) 3-gonal cactus from a solid 2-tree, construct the dual of each triangle by putting vertices on edges of each triangle, and join vertices belonging to the same triangle (see Figure 6). Preserving the cyclic order gives a 3-gonal cactus. This construction closely resembles the one of the edge-graph of a solid 2-tree.

2.2. **Enumeration according to edge degree distribution.**

For enumeration according to edge degree distribution, we follow the approach of Labelle and Leroux [14] for plane trees. Consider $r = (r_1, r_2, r_3, \dots)$ an infinite vector of formal variables. Recall that $\mathcal{A}[n]$ is the set of solid 2-trees over n edges. In order to keep track of the edge degree distribution, we introduce, for a given integer n, the following weight function (see [14]):

$$\begin{array}{rccc} w: & \mathcal{A}[n] & \longrightarrow & \mathbb{Q}[r_1, r_2, \dots] \\ & s & \longmapsto & w(s) \end{array} \tag{23}$$

where $\mathbb{Q}[r_1, r_2, \dots]$ is the ring of polynomials over the field of rational numbers $\mathbb{Q}$ in the variables $r_1, r_2, \dots$, and where the weight of a given $\mathcal{A}$-structure s is defined by $w(s) = r_1^{n_1} r_2^{n_2} \cdots$, where n_i is the number of edges of degree i in the structure s. Equations (2), (10), (11) and (12) have the following weighted versions:

$$\mathcal{B}_r = Y L_{r'}(\mathcal{B}_r^2), \tag{24}$$

and

$$\mathcal{A}^{-}_{o,w}(Y) = Y + Y C_r(\mathcal{B}_r^2), \tag{25}$$

$$\mathcal{A}^{\Delta}_{o,w}(Y) = C_3(\mathcal{B}_r), \tag{26}$$

$$\mathcal{A}^{\underline{\Delta}}_{o,w}(Y) = \mathcal{B}_r^3, \tag{27}$$

where C_r is the weighted species of cycles such that a cycle of length i has the weight r_i, and its derivative $L_{r'}$ which is the species of lists where a list of length i has the weight r_{i+1}. It is well known that these species have the following generating series of labelled structures (see [2, 14]):

$$C_r(y) = r_1 y + \frac{r_2}{2}y^2 + \frac{r_3}{3}y^3 + \cdots$$

and

$$L_{r'}(y) = (C_r(y))' = r_1 + r_2 y + r_3 y^2 + \cdots.$$

Let $\vec{n} = (n_1, n_2, n_3, \ldots)$ be a vector of nonnegative integers. Recall that, from Lemma 1, there exists a 2-tree having a total of n edges and n_i edges of degree i, $i \geq 1$, if and only if the following relations are satisfied:

$$\sum_i n_i = n \quad \text{and} \quad \sum_i i n_i = 3\left(\frac{n-1}{2}\right). \tag{28}$$

Let us begin the weighted enumeration by the labelled case.

• **Labelled case**

Let $\vec{n}$ be a coherent vector in the sense of Lemma 1 (satisfying (28)). Then, the number $|\mathcal{A}_o^-[\vec{n}]|$ of well oriented edge-rooted labelled solid 2-trees having $\vec{n}$ as edge degree distribution, is given by

$$|\mathcal{A}_o^-[\vec{n}]| = n![r_1^{n_1} r_2^{n_2} \cdots][y^n]\mathcal{A}_{o,w}^-(y). \tag{29}$$

We have

$$\begin{aligned}
[y^n]\mathcal{A}_{o,w}^-(y) &= \frac{1}{n-1}[t^{n-2}]\frac{d}{dt}(C_r(t^2)) \cdot L_{r'}^{n-1}(t^2) \\
&= \frac{2}{n-1}[t^{n-3}](r_1 + r_2 t^2 + r_3 t^4 + \cdots)^n \\
&= \frac{2}{n-1}[t^{n-3}] \sum_{\ell_1+\ell_2+\cdots=n} \binom{n}{\ell_1, \ell_2, \ldots} r_1^{\ell_1} r_2^{\ell_2} \cdots t^{2\ell_2+4\ell_3+6\ell_4+\cdots}.
\end{aligned}$$

Finally, we obtain

$$[y^n]\mathcal{A}_{o,w}^-(y) = \sum_{\ell_1,\ell_2,\ldots} \binom{n}{\ell_1, \ell_2, \ldots} r_1^{\ell_1} r_2^{\ell_2} \cdots,$$

the sum being taken over all vectors $(\ell_1, \ell_2, \ldots)$ satisfying

$$\sum_i \ell_i = n \quad \text{and} \quad \sum_i 2(i-1)\ell_i = n-3.$$

We note that this condition is equivalent to relation (28). Hence, using (29), we have

$$|\mathcal{A}_o^-[\vec{n}]| = 2n(n-2)!\binom{n}{n_1, n_2, \ldots}. \tag{30}$$

As in the unweighted case, we have

$$|\mathcal{A}_o^-[\vec{n}]| = n|\mathcal{A}_o[\vec{n}]|,$$

and we get the following result.

Proposition 4. Let $\vec{n}$ be a coherent edge degree distribution. Then, the number of oriented solid 2-trees having $\vec{n}$ as edge degree distribution, $|\mathcal{A}_o[\vec{n}]|$, is given by

$$|\mathcal{A}_o[\vec{n}]| = 2(n-2)!\binom{n}{n_1, n_2, \ldots}. \tag{31}$$

□

We now give the unlabelled weighted enumeration.

• **Unlabelled case**

Let $\vec{n} = (n_1, n_2, \ldots)$ be a coherent edge degree distribution. In order to compute the number $|\widetilde{\mathcal{A}}_o^-[\vec{n}]|$ of unlabelled $\mathcal{A}_o^-$-structures having $\vec{n}$ as edge degree distribution, we use the weighted version of Theorem 2.

Theorem 3. ([2]) Given two weighted species F_w and G_v, the generating series $\widetilde{H}(y)$ of unlabelled H-structures, where $H = F_w(G_v)$, is given by

$$\widetilde{H}(y) = Z_{F_w}(\widetilde{G}_v(y), \widetilde{G}_{v^2}(y^2), \widetilde{G}_{v^3}(y^3), \dots), \tag{32}$$

with $G_{v^k}(y^k) = p_k \circ G_v(y)$ where p_k denotes the k^{th} power sum and for all structure s, $v^k(s) = (v(s))^k$. □

In the present case, we have $\mathcal{A}^-_{o,w} = Y + YC_r(\mathcal{B}^2_r)$, and since the species $\mathcal{B}$ is asymmetric, that is $\widetilde{\mathcal{B}}_r(y) = \mathcal{B}_r(y)$,

$$|\widetilde{\mathcal{A}}^-_o[\vec{n}]| = [r_1^{n_1} r_2^{n_2} \cdots][y^{n-1}]\, Z_{C_r}(\mathcal{B}^2_r(y), \mathcal{B}^2_{r^2}(y^2), \mathcal{B}^2_{r^3}(y^3), \dots). \tag{33}$$

But, the cycle index series of the weighted species C_r, $Z_{C_r}(y_1, y_2, \dots)$, can be expressed as the following sum:

$$Z_{C_r}(y_1, y_2, \dots) = \sum_{k\geq 1} \frac{r_k}{k} \sum_{d|k} \phi(d) y_d^{k/d}. \tag{34}$$

Roughly speaking, the integer k represents the degree of the root edge in the $\mathcal{A}^-_o$-structure. Hence, k may only belong to $\mathrm{Supp}(\vec{n})$, the *support* of $\vec{n}$, which consists in the set of integers $i \geq 1$ such that $n_i \neq 0$. So, we have

$$|\widetilde{\mathcal{A}}^-_o[\vec{n}]| = [r_1^{n_1} r_2^{n_2} \cdots][y^{n-1}] \sum_{k\in \mathrm{Supp}(\vec{n})} \frac{r_k}{k} \sum_{d|k} \phi(d) \mathcal{B}^{2k/d}_{r^d}(y^d). \tag{35}$$

First, we compute

$$[y^{n-1}]\mathcal{B}^{2k/d}_{r^d}(y^d) = [y^{(n-1)/d}]\mathcal{B}^{2k/d}_{r^d}(y).$$

Using Lagrange inversion, we get the following result, which will be usefull during computations:

Lemma 2. We have,

$$[y^m]\mathcal{B}^\ell_{r^d}(y) = \frac{\ell}{m} \sum_{\ell_1,\ell_2,\dots} \binom{m}{\ell_1, \ell_2, \dots} r_1^{d\ell_1} r_2^{d\ell_2} \cdots, \tag{36}$$

where the ℓ_i's satisfy $\sum_i \ell_i = m$ and $\sum_i 2(i-1)\ell_i = m - \ell$. □

Now, letting $m = (n-1)/d$ and $\ell = 2k/d$ in the previous lemma, we find

$$|\widetilde{\mathcal{A}}^-_o[\vec{n}]| = [r_1^{n_1} r_2^{n_2} \cdots]\frac{2}{n-1} \sum_{k\in \mathrm{Supp}(\vec{n})} \sum_{d|k} \phi(d) \sum_{\ell_1,\ell_2,\dots} \binom{(n-1)/d}{\ell_1, \ell_2, \dots} r_1^{d\ell_1} r_2^{d\ell_2} \cdots r_k^{d\ell_k+1} \cdots. \tag{37}$$

Finally, we have:

Proposition 5. Let $\vec{n}$ be a coherent edge degree distribution. Then, the number $|\widetilde{\mathcal{A}}^-_o[\vec{n}]|$ of unlabelled oriented solid 2-trees pointed at an edge and having $\vec{n}$ as edge degree distribution is given by

$$|\widetilde{\mathcal{A}}^-_o[\vec{n}]| = \frac{2}{n-1} \sum_{k\in \mathrm{Supp}(\vec{n})} \sum_{d|\{k,\vec{n}-\delta_k\}} \phi(d) \binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}}, \tag{38}$$

where $\frac{\vec{n}-\delta_k}{d} = (\frac{n_1}{d}, \frac{n_2}{d}, \dots, \frac{n_k-1}{d}, \dots)$, for $d \geq 1$,

$$\binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}} = \binom{\frac{n-1}{d}}{n_1/d, n_2/d, \dots, (n_k-1)/d, \dots},$$

and $d|\{k, \vec{n}-\delta_k\}$ means that the integer d must divide k and all components of the vector $\vec{n}-\delta_k$. □

Let $|\widetilde{\mathcal{A}}^{\Delta}_o[\vec{n}]|$ and $|\widetilde{\mathcal{A}}^{\blacktriangle}_o[\vec{n}]|$ be the numbers of unlabelled oriented solid 2-trees pointed respectively at a triangle and at a triangle rooted itself at one of its edges and having $\vec{n}$ as edge degree distribution. Next proposition gives explicit formulas for these numbers.

Proposition 6. Let $\vec{n}$ be a coherent edge degree distribution, then the numbers $|\widetilde{\mathcal{A}}_o^{\Delta}[\vec{n}]|$ and $|\widetilde{\mathcal{A}}_o^{\Delta}[\vec{n}]|$ are given by

$$|\widetilde{\mathcal{A}}_o^{\Delta}[\vec{n}]| = \frac{1}{n}\binom{n}{n_1, n_2, \ldots} + \frac{\chi(3|\vec{n})}{n}\binom{n/3}{n_1/3, n_2/3, \ldots}, \tag{39}$$

$$|\widetilde{\mathcal{A}}_o^{\Delta}[\vec{n}]| = \frac{3}{n}\binom{n}{n_1, n_2, \ldots}, \tag{40}$$

where

$$\chi(3|\vec{n}) = \begin{cases} 1, & \text{if all components of } \vec{n} \text{ are multiples of 3,} \\ 0, & \text{otherwise.} \end{cases}$$

Proof. Let us start with $|\widetilde{\mathcal{A}}_o^{\Delta}[\vec{n}]|$. We have

$$\begin{aligned} |\widetilde{\mathcal{A}}_o^{\Delta}[\vec{n}]| &= [r_1^{n_1} r_2^{n_2} \cdots][y^n]\widetilde{\mathcal{A}}_{o,w}^{\Delta}(y) \\ &= [r_1^{n_1} r_2^{n_2} \cdots][y^n] Z_{C_3}(\widetilde{\mathcal{B}}_r(y)\widetilde{\mathcal{B}}_{r^2}(y^2), \ldots). \end{aligned}$$

Since $Z_{C_3}(y_1, y_2, \ldots) = (y_1^3 + 2y_3)/3$, and $\widetilde{\mathcal{B}}_r(y) = \mathcal{B}_r(y)$,

$$|\widetilde{\mathcal{A}}_o^{\Delta}[\vec{n}]| = \frac{1}{3}[r_1^{n_1} r_2^{n_2} \cdots][y^n]\left(\mathcal{B}_r^3(y) + 2\mathcal{B}_{r^3}(y^3)\right). \tag{41}$$

From equation (36) in Lemma 2, letting $m = n$, $\ell = 3$ and $d = 1$, we get

$$[y^n]\mathcal{B}_r^3(y) = \frac{3}{n}\sum_{\ell_1, \ell_2, \ldots}\binom{n}{\ell_1, \ell_2, \ldots} r_1^{\ell_1} r_2^{\ell_2} \cdots, \tag{42}$$

where the ℓ_i's satisfy $\sum_i \ell_i = n$ and $\sum_i 2(i-1)\ell_i = n - 3$. Now letting $m = n/3$, $\ell = 1$ and $d = 3$ in (36), we obtain

$$[y^n]\mathcal{B}_{r^3}(y^3) = [y^{n/3}]\mathcal{B}_{r^3}(y) = \frac{3}{n}\sum_{\ell_1, \ell_2, \ldots}\binom{n/3}{\ell_1, \ell_2, \ldots} r_1^{3\ell_1} r_2^{3\ell_2} \cdots, \tag{43}$$

where the ℓ_i's satisfy $\sum_i \ell_i = n$ and $\sum_i 2(i-1)\ell_i = n - 1$. Now letting $\ell_i = n_i$ in (42) and $\ell_i = n_i/3$ in (43), we get equation (39). We obtain (40) in a very similar way, details are left to the reader. ■

Finally, using the dissymmetry theorem (6), we obtain the final result of this section:

Proposition 7. Let $\vec{n}$ be a coherent edge degree distribution. Then the number $|\widetilde{\mathcal{A}}_o[\vec{n}]|$ of unlabelled oriented solid 2-trees having $\vec{n}$ as edge degree distribution is given by

$$|\widetilde{\mathcal{A}}_o[\vec{n}]| = \frac{2}{n-1}\sum_{k \in \mathrm{Supp}(\vec{n})}\sum_{d | \{k, \vec{n}-\delta_k\}} \phi(d)\binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}} + \frac{\chi(3|\vec{n})}{n}\binom{\frac{n}{3}}{\frac{n_1}{3}, \frac{n_2}{3}, \ldots} - \frac{2}{3n}\binom{n}{n_1, n_2, \ldots}, \tag{44}$$

where

$$\chi(3|\vec{n}) = \begin{cases} 1, & \text{if all components of } \vec{n} \text{ are multiples of 3,} \\ 0, & \text{otherwise,} \end{cases}$$

$$\frac{\vec{n} - \delta_k}{d} = \left(\frac{n_1}{d}, \frac{n_2}{d}, \ldots, \frac{n_k - 1}{d}, \ldots\right) \text{ for } d \geq 1,$$

and

$$\binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}} = \binom{\frac{n-1}{d}}{\frac{n_1}{d}, \frac{n_2}{d}, \ldots, \frac{n_k-1}{d}, \ldots}.$$

□

3. Non-oriented solid 2-trees

In order to compute the numbers of labelled and unlabelled solid 2-trees, we use Burnside's Lemma with the group $\mathbb{Z}_2 = \{Id, \tau\}$, where the action of τ is to reverse the orientation of the structures. This involves the notion of quotient species (see [4]).

3.1. **Enumeration according to the number of edges.**

As in the unweighted case, we begin with the labelled and unlabelled enumeration according to the number of edges.

• Labelled case

The labelled case is particularly simple since every labelled oriented 2-tree has exactly two possible orientations except the structure consisting of a single oriented edge. Hence, we have:

Proposition 8. The number $|\mathcal{A}[n]|$ of edge-labelled solid 2-trees over n edges is given by

$$|\mathcal{A}[n]| = \begin{cases} \frac{1}{2}|\mathcal{A}_o[n]|, & \text{if } n > 1, \\ 1, & \text{if } n = 1. \end{cases} \tag{45}$$

□

Of course, the same argument remains valid for all other pointed structures discussed in the previous section.

• Unlabelled case

In the unlabelled case, the action of τ is not so trivial. Figure 7 shows an oriented 2-tree which is left fixed under the action of τ. Let $\mathcal{A}^-$ be the species of (unoriented) solid 2-trees rooted at an edge. This species can be expressed as the following quotient species (see [7, 8, 13] for quotient species related to 2-trees):

$$\mathcal{A}^- = \frac{\mathcal{A}_o^-}{\mathbb{Z}_2} = \frac{Y + YC(\mathcal{B}^2(Y))}{\mathbb{Z}_2}, \tag{46}$$

where $\mathbb{Z}_2 = \{\mathrm{Id}, \tau\}$ is the two-element group consisting of the identity and τ, whose action is to reverse the orientation of the edges. Hence, an unlabelled $\mathcal{A}^-$-structure is an orbit $\{a, \tau \cdot a\}$ under the action of $\mathbb{Z}_2$, where a is any (oriented) unlabelled $\mathcal{A}_o^-$-structure. Roughly speaking, quotient by $\mathbb{Z}_2$ corresponds to forget the orientation in the structures.

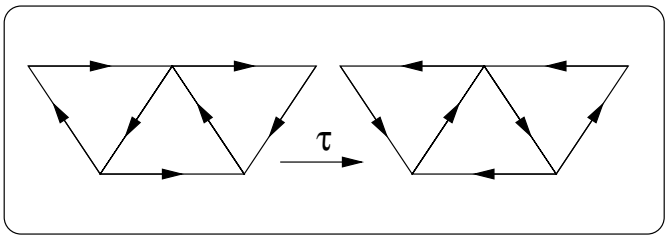

Figure 7. An unlabelled 2-tree invariant under the action of τ.

Let us introduce the auxiliary species $\mathcal{B}_{\mathrm{Sym}}$ of τ-symmetric $\mathcal{B}$-structures, *i.e*, the species of $\mathcal{B}$-structures left fixed under the edge orientation inversion. Denote by $\widetilde{\mathcal{B}}_{\mathrm{Sym}}(y)$ its ordinary generating series of unlabelled structures. Recall the functional equation verified by the species $\mathcal{B}$:

$$\mathcal{B} = YL(\mathcal{B}^2).$$

In order to compute $\widetilde{\mathcal{B}}_{\mathrm{Sym}}(y)$, we have to distinguish two cases according to the parity of k, the length of the list of $\mathcal{B}^2$-structures attached to the rooted edge. First consider the case where k is

odd (Figure 8 shows an example where $k = 5$). A $\mathcal{B}$-structure is τ-symmetric if it can be embedded in space in such a way that the action of reversing the orientation of all edges corresponds to flip the whole structure back to itself by reversing the end points of the root edge. When an inversion of the orientation of the rooted edge is applied, the two $\mathcal{B}$-structures glued on the two (non root) sides of the middle triangle (structures $\mathcal{B}_5$ and $\mathcal{B}_{5'}$ in Figure 8) are isomorphically exchanged. The $k-1$ remaining triangles are exchanged pairwise carrying with them each of their attached $\mathcal{B}$-structures as shown in Figure 8, where $\mathcal{B}_i \stackrel{\sim}{=} \mathcal{B}_{i'}$. This gives a factor of $\mathcal{B}^k(y^2)$. We then have to sum the previous expression over all odd values of k. The case where k is even is very similar except that there is no middle triangle, as shown in Figure 9 and we get the same expression summed over all even values of k. It leads us to

$$\widetilde{\mathcal{B}}_{\mathrm{Sym}}(y) = y \sum_{k \geq 0} \mathcal{B}^k(y^2) = \frac{y}{1 - \mathcal{B}(y^2)}. \tag{47}$$

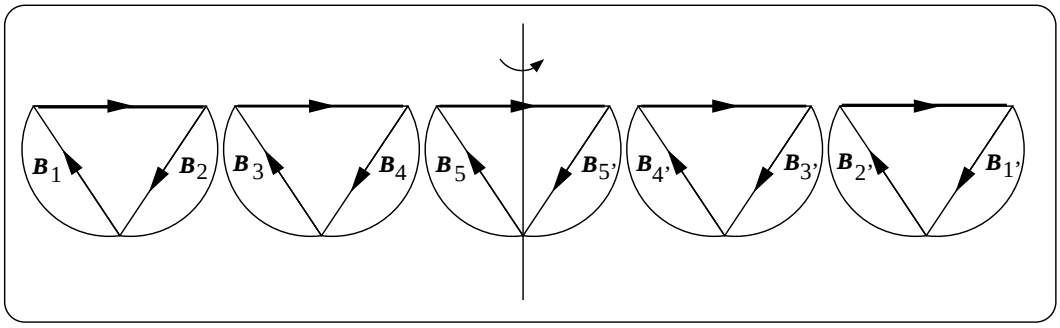

FIGURE 8. A $\mathcal{B}_{\mathrm{Sym}}$-structure, k odd.

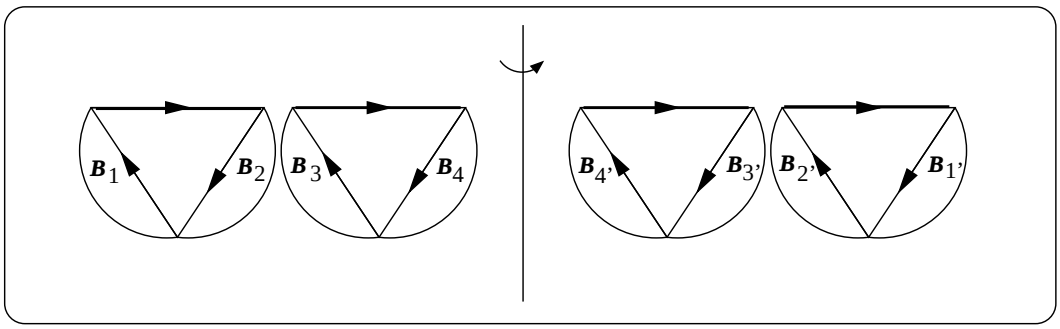

FIGURE 9. A $\mathcal{B}_{\mathrm{Sym}}$-structure, k even.

From expression (47) and another use of Lagrange inversion, we easily obtain the following result.

Proposition 9. The number $|\widetilde{\mathcal{B}}_{\mathrm{sym}}[m]|$ of τ-symmetric unlabelled oriented $\mathcal{B}$-structures over m triangles is given by

$$|\widetilde{\mathcal{B}}_{\mathrm{sym}}[m]| = \begin{cases} \dfrac{1}{m+1}\binom{3m/2}{m}, & \text{if } m \text{ is even,} \\ \dfrac{1}{m}\binom{(3m-1)/2}{m+1} + \dfrac{1}{3m}\binom{3(m+1)/2}{m+1}, & \text{if } m \text{ is odd.} \end{cases} \tag{48}$$

□

We can also express $|\widetilde{\mathcal{B}}_{\mathrm{sym}}[m]|$ as follows:

$$|\widetilde{\mathcal{B}}_{\mathrm{sym}}[m]| = \begin{cases} \dfrac{1}{2k+1}\binom{3k}{k}, & \text{if } m = 2k, \\ \\ \dfrac{1}{2k+1}\binom{3k+1}{k+1}, & \text{if } m = 2k+1. \end{cases} \tag{49}$$

Note that, the numbers $|\widetilde{\mathcal{B}}_{\mathrm{sym}}[m]|$ also enumerate several classes of symmetric objects (in some sense), in particular symmetric diagonally convex directed polyominoes, or symmetric non-crossing trees, ... (see [5, 6]). These numbers are indexed in the on-line Encyclopedia of integer sequences [16] as the sequence A047749.

We now give an expression for the generating function of unlabelled quotient structures, which will allow us to enumerate various kind of unlabelled solid 2-trees.

Proposition 10. ([4]) Let F be any (weighted) species and G, a group acting on F. Then the ordinary generating series of the quotient species F/G is given by

$$(F/G)^{\sim}(y) = \frac{1}{|G|}\sum_{g\in G}\sum_{n\geq 0}|\mathrm{Fix}_{\widetilde{F}_n}(g)|_w\, y^n, \tag{50}$$

where $\mathrm{Fix}_{\widetilde{F}_n}(g)$ denotes the set of unlabelled F-structures over n edges left fixed under the action of the element $g \in G$ and $|\mathrm{Fix}_{\widetilde{F}_n}(g)|_w$ represents the total weight of this set. □

Using an unweighted version of Proposition 10, with $F = \mathcal{A}_o^-$ and $G = \mathbb{Z}_2 = \{\mathrm{Id}, \tau\}$, we obtain

$$\widetilde{\mathcal{A}}^-(y) = \frac{1}{2}\sum_{n\geq 0}|\mathrm{Fix}_{\widetilde{\mathcal{A}}^-_{o,n}}(\mathrm{Id})|y^n + \frac{1}{2}\sum_{n\geq 0}|\mathrm{Fix}_{\widetilde{\mathcal{A}}^-_{o,n}}(\tau)|y^n, \tag{51}$$

$$= \frac{1}{2}\widetilde{\mathcal{A}}^-_o(y) + \frac{1}{2}\widetilde{\mathcal{B}}_{\mathrm{sym}}(y), \tag{52}$$

since the oriented $\mathcal{A}^-$-structures left fixed under the action of τ have the same generating series as the $\mathcal{B}_{\mathrm{Sym}}$-structures. Hence, it becomes easy to extract the coefficient of y^n in relation (52), and we get the number $|\mathcal{A}^-[n]|$ of edge-pointed solid 2-trees over n edges,

$$|\mathcal{A}^-[n]| = \frac{1}{2}|\widetilde{\mathcal{A}}^-_o[n]| + \frac{1}{2}|\widetilde{\mathcal{B}}_{\mathrm{Sym}}[n]|. \tag{53}$$

We now consider the species $\mathcal{A}^{\Delta}$ of triangle rooted solid 2-trees. Since $\mathcal{A}^{\Delta} = \mathcal{A}^{\Delta}_o/\mathbb{Z}_2$, by virtue of Proposition 10, we have

$$\widetilde{\mathcal{A}}^{\Delta}(y) = \frac{1}{2}\sum_{n\geq 0}|\mathrm{Fix}_{\widetilde{\mathcal{A}}^{\Delta}_{o,n}}(\mathrm{Id})|y^n + \frac{1}{2}\sum_{n\geq 0}|\mathrm{Fix}_{\widetilde{\mathcal{A}}^{\Delta}_{o,n}}(\tau)|y^n, \tag{54}$$

where $|\mathrm{Fix}_{\widetilde{\mathcal{A}}^{\Delta}_{o,n}}(\tau)|$, the number of τ-symmetric $\mathcal{A}^{\Delta}$-structures over n edges has to be determined. As shown in Figure 10, such a structure must have an axis of symmetry which coincides with one of the root triangle's medians. Since the structure is already considered up to rotation around the root triangle, the choice among the three possible axes is arbitrary. The base side of the triangle must be a $\mathcal{B}_{\mathrm{Sym}}$-structure while the two other sides must be isomorphic copies of the same $\mathcal{B}$-structure ($\mathcal{B} \cong \mathcal{B}'$). Therefore,

$$\widetilde{\mathcal{A}}^{\Delta}(y) = \frac{1}{2}\widetilde{\mathcal{A}}^{\Delta}_o(y) + \frac{1}{2}\widetilde{\mathcal{B}}_{\mathrm{Sym}}(y)\mathcal{B}(y^2). \tag{55}$$

In a very similar way, since $\mathcal{A}^{\underline{\Delta}} = \mathcal{A}^{\underline{\Delta}}_o/\mathbb{Z}_2$, we obtain

$$\widetilde{\mathcal{A}}^{\underline{\Delta}}(y) = \frac{1}{2}\widetilde{\mathcal{A}}^{\underline{\Delta}}_o(y) + \frac{1}{2}\widetilde{\mathcal{B}}_{\mathrm{Sym}}(y)\mathcal{B}(y^2). \tag{56}$$

Finally, combining equations (52), (55), (56) and the dissymmetry theorem, we get:

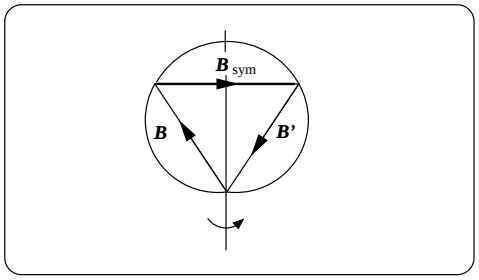

FIGURE 10. A τ-symmetric $\mathcal{A}_o^{\Delta}$-structure.

Proposition 11. The ordinary generating function of unlabelled solid 2-trees is given by

$$\widetilde{\mathcal{A}}(y) = \frac{1}{2}(\widetilde{\mathcal{A}}_o(y) + \widetilde{\mathcal{B}}_{\mathrm{Sym}}(y)), \tag{57}$$

where $\widetilde{\mathcal{B}}_{\mathrm{Sym}}(y)$ is the ordinary generating series of τ-symmetric $\mathcal{B}$-structures. Consequently, the number $|\widetilde{\mathcal{A}}_t[m]|$ of unoriented solid 2-trees over m triangles is given by

$$|\widetilde{\mathcal{A}}_t[m]| = \frac{1}{2}(|\widetilde{\mathcal{A}}_{o,t}[m]| + |\widetilde{\mathcal{B}}_{\mathrm{sym}}[m]|), \tag{58}$$

where

$$|\widetilde{\mathcal{A}}_{o,t}[m]| = \frac{1}{3m}\sum_{d|m}\phi\left(\frac{m}{d}\right)\binom{3d}{d} + \chi(3|2m+1)\frac{2}{2m+1}\binom{m-1}{\frac{2m-2}{3}} - \frac{2}{3(2m+1)}\binom{3m}{m},$$

and

$$|\widetilde{\mathcal{B}}_{\mathrm{sym}}[m]| = \begin{cases} \dfrac{1}{m+1}\binom{3m/2}{m}, & \text{if } m \text{ is even,} \\ \dfrac{1}{m}\binom{(3m-1)/2}{m+1} + \dfrac{1}{3m}\binom{3(m+1)/2}{m+1}, & \text{if } m \text{ is odd.} \end{cases} \tag{59}$$

□

Note that, to express $|\widetilde{\mathcal{A}}_t[m]|$ in terms of n the number of edges, we only have to set $n := 2m+1$ in the previous expressions.

3.2. **Enumeration of solid 2-trees according to the edge degree distribution.**

We consider again the weight function defined by

$$\begin{array}{rccc} w: & \mathcal{A}[n] & \longrightarrow & \mathbb{Q}[r_1, r_2, \ldots] \\ & s & \mapsto & w(s), \end{array} \tag{60}$$

where $r = (r_1, r_2, r_3, \ldots)$ is an infinite set of formal variables and n is any positive integer.

• **Labelled case**

Using the same argument as in the unweighted case, we have

$$|\mathcal{A}[\vec{n}]| = \begin{cases} \frac{1}{2}|\mathcal{A}_o[\vec{n}]|, & \text{if } n > 1, \\ 1, & \text{if } n = 1, \end{cases} \tag{61}$$

where $\vec{n}$ is a valid edge degree distribution, n is the number of edges and $|\mathcal{A}[\vec{n}]| = [r_1^{n_1} r_2^{n_2} \cdots][y^n]\mathcal{A}_w(y)$.

• **Unlabelled case**

Using the weighted versions of equations (52), (55) and (56), we easily get

$$\widetilde{\mathcal{A}}^{-}_{w}(y) = \frac{1}{2}\widetilde{\mathcal{A}}^{-}_{o,w}(y) + \frac{1}{2}\widetilde{\mathcal{B}}_{\mathrm{sym},w}(y), \tag{62}$$

$$\widetilde{\mathcal{A}}^{\Delta}_{w}(y) = \frac{1}{2}\widetilde{\mathcal{A}}^{\Delta}_{o,w}(y) + \frac{1}{2}\widetilde{\mathcal{B}}_{\mathrm{sym},w}(y)\mathcal{B}_{w}(y^2), \tag{63}$$

$$\widetilde{\mathcal{A}}^{\Delta}_{w}(y) = \frac{1}{2}\widetilde{\mathcal{A}}^{\Delta}_{o,w}(y) + \frac{1}{2}\widetilde{\mathcal{B}}_{\mathrm{sym},w}(y)\mathcal{B}_{w}(y^2), \tag{64}$$

where $\widetilde{\mathcal{B}}_{\mathrm{sym},w}(y)$ is the ordinary generating series of unlabelled weighted τ-symmetric $\mathcal{B}$-structures. Now, applying the dissymmetry theorem, leads to

$$\widetilde{\mathcal{A}}(y) = \frac{1}{2}\widetilde{\mathcal{A}}_{o,w}(y) + \frac{1}{2}\widetilde{\mathcal{B}}_{\mathrm{sym},w}(y). \tag{65}$$

The only unknown term in the above equation is $\widetilde{\mathcal{B}}_{\mathrm{sym},w}(y)$. We first establish an additional condition on the edge degree distribution for an edge-rooted oriented solid 2-tree to be τ-symmetric. Since the root edge must remain fixed and all other edges are exchanged pairwise, the edge degree distribution vector $\vec{n}$ must have all its components even except one odd corresponding to the degree of the rooted edge.

For an edge degree distribution $\vec{n} = (n_1, n_2, \ldots)$ satisfying the previous condition, and using the fact that $\widetilde{\mathcal{B}}_{\mathrm{sym},w}(y) = yr_k\mathcal{B}^k(y^2)$, we have

$$|\widetilde{\mathcal{B}}_{\mathrm{sym}}[\vec{n}]| = \frac{2k}{n-1}\binom{\frac{n-1}{2}}{\frac{\vec{n}-\delta_k}{2}}, \tag{66}$$

where k corresponds to the root edge degree. We now present the final result of this paper.

Proposition 12. Let $\vec{n}$ be a vector satisfying

$$\sum_i n_i = n \quad \text{and} \quad \sum_i i n_i = 3m.$$

Then, the number $|\widetilde{\mathcal{A}}[\vec{n}]|$ of (non oriented) unlabelled solid 2-trees having $\vec{n}$ as edge degree distribution is given by

$$|\widetilde{\mathcal{A}}[\vec{n}]| = \frac{1}{2}|\widetilde{\mathcal{A}}_o[\vec{n}]| + \frac{1}{2}|\widetilde{\mathcal{B}}_{\mathrm{sym}}[\vec{n}]|, \tag{67}$$

where

$$|\widetilde{\mathcal{B}}_{\mathrm{sym}}[\vec{n}]| = \begin{cases} \dfrac{2k}{n-1}\binom{\frac{n-1}{2}}{\frac{\vec{n}-\delta_k}{2}}, & \text{if } \vec{n} \textit{ has a unique odd component,} \\ 0, & \text{otherwise,} \end{cases}$$

δ_k being the vector having 1 at the k^{th} component and 0 everywhere else, and

$$|\widetilde{\mathcal{A}}_o[\vec{n}]| = \frac{2}{n-1}\sum_{k\in\mathrm{Supp}(\vec{n})}\sum_{d|\{k,\vec{n}-\delta_k\}}\phi(d)\binom{\frac{n-1}{d}}{\frac{\vec{n}-\delta_k}{d}} + \frac{\chi(3|\vec{n})}{n}\binom{n/3}{n_1/3, n_2/3, \ldots} - \frac{2}{3n}\binom{n}{n_1, n_2, \ldots}.$$

Appendix.

To conclude this paper, we give here two tables giving the numbers of unlabelled solid 2-trees oriented and unoriented as well as the number of unlabelled τ-symmetric $\mathcal{B}$-structures. The first table gives these numbers according to the number n of edges for odd values of n from 1 up to 21, and the second, according to edge degree distribution for a few vectors $\vec{n}$. We use the notation $1^{n_1}2^{n_2}\cdots$, where i^{n_i} means n_i edges of degree i.

ABSTRACT

This paper presents Korat, a novel framework for automated testing of Java programs. Given a formal specification for a method, Korat uses the method precondition to automatically generate all (nonisomorphic) test cases up to a given small size. Korat then executes the method on each test case, and uses the method postcondition as a test oracle to check the correctness of each output.

To generate test cases for a method, Korat constructs a Java predicate (i.e., a method that returns a boolean) from the method's precondition. The heart of Korat is a technique for automatic test case generation: given a predicate and a bound on the size of its inputs, Korat generates all (nonisomorphic) inputs for which the predicate returns true. Korat exhaustively explores the bounded input space of the predicate but does so efficiently by monitoring the predicate's executions and pruning large portions of the search space.

This paper illustrates the use of Korat for testing several data structures, including some from the Java Collections Framework. The experimental results show that it is feasible to generate test cases from Java predicates, even when the search space for inputs is very large. This paper also compares Korat with a testing framework based on declarative specifications. Contrary to our initial expectation, the experiments show that Korat generates test cases much faster than the declarative framework.

1. INTRODUCTION

Manual software testing, in general, and test data generation, in particular, are labor-intensive processes. Automated testing can significantly reduce the cost of software development and maintenance [4]. This paper presents Korat, a novel framework for automated testing of Java programs. Korat uses specification-based testing [5, 13, 15, 25]. Given a formal specification for a method, Korat uses the method precondition to automatically generate all nonisomorphic test cases up to a given small size. Korat then executes the method on each test case, and uses the method postcondition as a test oracle to check the correctness of each output.

To generate test cases for a method, Korat constructs a Java predicate (i.e., a method that returns a boolean) from the method's precondition. One of the key contributions of Korat is a technique for automatic test case generation: given a predicate, and a bound on the size of its inputs, Korat generates all nonisomorphic inputs for which the predicate returns `true`. Korat uses backtracking to systematically explore the bounded input space of the predicate. Korat generates *candidate* inputs and checks their validity by invoking the predicate on them. Korat monitors accesses that the predicate makes to all the fields of the candidate input. If the predicate returns without reading some fields of the candidate, then the validity of the candidate must be independent of the values of those fields—Korat uses this observation to prune large portions of the search space. Korat also uses an optimization to generate only nonisomorphic test cases. (Section 3.4 gives a precise definition of nonisomorphism.) This optimization reduces the search time without compromising the exhaustive nature of the search.

Korat lets programmers write specifications in any language as long as the specifications can be automatically translated into Java predicates. We have implemented a prototype of Korat that uses the Java Modeling Language (JML) [20] for specifications. Programmers can use JML to write method preconditions and postconditions, as well as class invariants. JML uses Java syntax and semantics for expressions, and contains some extensions such as quantifiers. A large subset of JML can be automatically translated into Java predicates. Programmers can thus use Korat without having to learn a specification language much different than Java. Moreover, since JML specifications can call Java methods, programmers can use the full expressiveness of the Java language to write specifications.

To see an illustration of the use of Korat, consider a method that removes the minimum element from a balanced binary tree. The (implicit) precondition for this method requires the input to satisfy its class invariant: the input must be a binary tree and the tree must be balanced. Korat uses the code that checks the class invariant as the predicate for generating all nonisomorphic balanced binary trees bounded by a given size. Good programming practice [21] suggests that implementations of abstract data types provide predicates (known as the `repOk` or `checkRep` methods) that check class invariants—Korat then generates test cases almost for free. Korat invokes the method on each of the generated trees and checks the postcondition in each case. If a method postcondition is not (explicitly) specified, Korat can still be used to test partial correctness of the method. In the binary tree example, Korat can be used to check the class invariant at the end of the remove method, to see that the tree remains a balanced binary tree after removing the minimum element from it.

```
import java.util.*;
class BinaryTree {
    private Node root; // root node
    private int size;  // number of nodes in the tree
    static class Node {
        private Node left;  // left child
        private Node right; // right child

    }
    public  boolean repOk() {
        // checks that empty tree has size zero
        if (root == null) return size == 0;
        Set visited = new HashSet();
        visited.add(root);
        LinkedList workList = new LinkedList();
        workList.add(root);
        while (!workList.isEmpty()) {
            Node current = (Node)workList.removeFirst();
            if (current.left != null) {
                // checks that tree has no cycle
                if (!visited.add(current.left))
                    return false;
                workList.add(current.left);
            }
            if (current.right != null) {
                // checks that tree has no cycle
                if (!visited.add(current.right))
                    return false;
                workList.add(current.right);
            }
        }
        // checks that size is consistent
        if (visited.size() != size) return false;
        return true;
    }
}
```

Figure 1: `BinaryTree` example

We have used Korat to test several data structures, including some from the Java Collections Framework. The experimental results show that it is feasible to generate test cases from Java predicates, even when the search space for inputs is very large. In particular, our experiments indicate that it is practical to generate inputs to achieve complete statement coverage, even for intricate methods that manipulate complex data structures. This paper also compares Korat with the Alloy Analyzer [16], which can be used to generate test cases [22] from declarative predicates. Contrary to our initial expectation, the experiments show that Korat generates test cases much faster than the Alloy Analyzer.

The rest of this paper is organized as follows. Section 2 illustrates the use of Korat on two examples. Section 3 presents the algorithm that Korat uses to explore the search space. Section 4 describes how Korat checks method correctness. Section 5 presents the experimental results. Section 6 reviews related work, and Section 7 concludes.

2. EXAMPLES

This section presents two examples to illustrate how programmers can use Korat to test their programs. These examples, a binary tree data structure and a heap[1] data structure, illustrate methods that manipulate linked data structures and array-based data structures, respectively.

2.1 Binary tree

This section illustrates the generation and testing of linked data structures using simple binary trees. The Java code in Figure 1 declares a binary tree and defines its `repOk` method, i.e., a Java

[1]The term "heap" refers to the data structure (priority queues) and not to the garbage-collected memory.

```
public static Finitization finBinaryTree(int NUM_Node) {
  Finitization f = new Finitization(BinaryTree.class);
  ObjSet nodes = f.createObjects("Node", NUM_Node);
                                // #Node = NUM_Node
  nodes.add(null);
  f.set("root", nodes);       // root in null + Node
  f.set("size", NUM_Node);    // size = NUM_Node
  f.set("Node.left", nodes);  // Node.left in null + Node
  f.set("Node.right", nodes); // Node.right in null+ Node
  return f;
}
```

Figure 2: Finitization description for the `BinaryTree` example

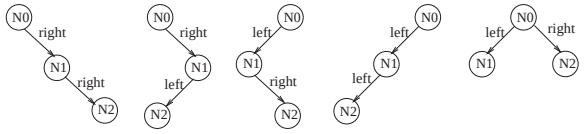

Figure 3: Trees generated for `finBinaryTree(3)`

predicate that checks the representation invariant (or class invariant) of the corresponding data structure [21]. In this case, `repOk` checks if the input is a tree with the correct `size`.

Each object of the class `BinaryTree` represents a tree. The `size` field contains the number of nodes in the tree. Objects of the inner class `Node` represent nodes of the trees. The method `repOk` first checks if the tree is empty. If not, `repOk` traverses all nodes reachable from `root`, keeping track of the visited nodes to detect cycles. (The method `add` from `java.util.Set` returns `false` if the argument already exists in the set.)

To generate trees that have a given number of nodes, the Korat search algorithm uses the *finitization* description shown in Figure 2. The statements in the finitization description specify bounds on the number of objects to be used to construct instances of the data structure, as well as possible values stored in the fields of those objects. Most of the finitization description shown in the figure is automatically generated from the type declarations in the Java code. In Figure 2, the parameter `NUM_Node` specifies the bound on number of nodes in the tree. Each reference field in the tree is either `null` or points to one of the `Node` objects. Note that the identity of these objects is irrelevant—two trees are *isomorphic* if they have the same branching structure, irrespective of the actual nodes in the trees.

Korat automatically generates all nonisomorphic trees with a given number of nodes. For example, for `finBinaryTree(3)`, Korat generates the five trees shown in Figure 3. As another example, for `finBinaryTree(7)`, Korat generates 429 trees in less than one second.

We next illustrate how programmers can use Korat to check correctness of methods. The JML annotations in Figure 4 specify partial correctness for the example `remove` method that removes from a `BinaryTree` a node that is in the tree. The `normal_behavior` annotation specifies that if the precondition (`requires`) is satisfied at the beginning of the method, then the postcondition (`ensures`) is satisfied at the end of the method and the method returns without throwing an exception. (The helper method `has` checks that the tree contains the given node.) Implicitly, the class `invariant` is added to the precondition and the postcondition. Korat uses the JML tool-set to translate annotations into runtime Java assertions.

```
//@ public invariant repOk(); // class invariant
                              //   for BinaryTree
/*@ public normal_behavior    // specification for remove
  @     requires has(n);      //     precondition
  @     ensures !has(n);      //     postcondition
  @*/
public void remove(Node n) {
    // ... method body
}
```

Figure 4: Partial specification for `BinaryTree.remove`

```
public class HeapArray {
    private int size; // number of elements in the heap
    private Comparable[] array; // heap elements
    //@ public invariant repOk();
    public boolean repOk() {
        // checks that array is non-null
        if (array == null) return false;
        // checks that size is within array bounds
        if (size < 0 || size > array.length)
            return false;
        for (int i = 0; i < size; i++) {
            // checks that elements are non-null
            if (array[i] == null) return false;
            // checks that array is heapified
            if (i > 0 &&
                array[i].compareTo(array[(i-1)/2]) > 0)
                return false;
        }
        // checks that non-heap elements are null
        for (int i = size; i < array.length; i++)
            if (array[i] != null) return false;
        return true;
    }
}
```

Figure 5: `HeapArray` example

To test a method, Korat first generates test inputs. For `remove`, each input is a pair of a tree and a node. The precondition defines valid inputs for the method: the tree must be valid and the node must be in the tree. Given a finitization for inputs (which can be written reusing the finitization description for trees presented in Figure 2), Korat generates all nonisomorphic inputs. For `remove`, the number of input pairs is the product of the number of trees and the number of nodes in the trees. After generating the inputs, Korat invokes the method (with runtime assertions for postconditions) on each input and reports a counterexample if the method fails to satisfy the correctness criteria.

2.2 Heap array

This section illustrates the generation and checking of array-based data structures, using the heap data structure [8]. The (binary) *heap* data structure can be viewed as a complete binary tree—the tree is completely filled on all levels except possibly the lowest, which is filled from the left up to some point. Heaps also satisfy the *heap property*—for every node n other than the root, the value of n's parent is greater than or equal to the value of n. The Java code in Figure 5 declares an array-based heap and defines the corresponding `repOk` method that checks if the input is a valid `HeapArray`.

The elements of the heap are stored in `array`. The elements implement the interface `Comparable`, providing the method `compareTo` for comparisons. The method `repOk` first checks for the special case when `array` is `null`. If not, `repOk` checks that the `size` of the heap is within the bounds of the `array`. Then, `repOk` checks that the array elements that belong to the heap are not `null` and that they satisfy the heap property. Finally, `repOk` checks that the array elements that do not belong to the heap are `null`.

```
public static Finitization finHeapArray(int MAX_size,
                                        int MAX_length,
                                        int MAX_elem) {
    Finitization f = new Finitization(HeapArray.class);
    // size in [0..MAX_size]
    f.set("size", new IntSet(0, MAX_size));
    f.set("array",
          // array.length in [0..MAX_length]
          new IntSet(0, MAX_length),
          // array[] in null + Integer([0..MAX_elem])
          new IntegerSet(0, MAX_elem).add(null));
    return f;
}
```

Figure 6: Finitization description for the `HeapArray` example

```
size = 0, array = []
size = 0, array = [null]
size = 1, array = [Integer(0)]
size = 1, array = [Integer(1)]
```

Figure 7: Heaps generated for `finHeapArray(1,1,1)`

To generate heaps, the Korat search algorithm uses the finitization description shown in Figure 6. Again, most of the finitization description shown in the figure is automatically generated from the type declarations in the Java code. In Figure 6, the parameters `MAX_size`, `MAX_length`, and `MAX_elem` bound the size of the heap, the length of the array, and the elements of the array, respectively. The elements of the array can either be `null` or contain `Integer` objects where the integers can range from 0 to `MAX_elem`.

Given values for the finitization parameters, Korat automatically generates all heaps. For example, for `finHeapArray(1,1,1)`, Korat generates the four heaps shown in Figure 7. As another example, in less than one second, for `finHeapArray(5,5,5)`, Korat generates 1919 heaps. Note that Korat requires only the `repOk` method (which can use the full Java language) and finitization to generate all heaps. Writing a dedicated generator for complex data structures [2] is much more involved than writing `repOk`.

We next illustrate how programmers can use Korat to check partial correctness of the `extractMax` method that removes and returns the largest element from a `HeapArray`. The JML annotations in Figure 8 specify partial correctness for the `extractMax` method. The `normal_behavior` specifies that if the input heap is valid and non-empty, then the method returns the largest element in the original heap and the resulting heap after execution of the method is valid. The JML keywords `\result` and `\old` denote, respectively, the object returned by the method and the expressions that should be evaluated in the pre-state. JML annotations can also express exceptional behavior of methods. The example `exceptional_behavior` specifies that if the input heap is empty, the method throws an `IllegalArgumentException`.

To check the method `extractMax`, Korat first uses a finitization to generate all nonisomorphic heaps that satisfy either the `normal_behavior` precondition or the `exceptional_behavior` precondition. Next, Korat invokes the method (with runtime assertions for postconditions) on each input and reports a counterexample if any invocation fails to satisfy the correctness criteria.

3. TEST CASE GENERATION

The heart of Korat is a technique for test case generation: given a Java predicate and a finitization for its input, Korat automatically generates all nonisomorphic inputs for which the predicate

```
/*@ public normal_behavior
  @     requires size > 0;
  @     ensures \result == \old(array[0]);
  @ also public exceptional_behavior
  @     requires size == 0;
  @     signals (IllegalArgumentException e) true;
  @*/
public Comparable extractMax() {
    // ... method body
}
```

Figure 8: Partial specification for `HeapArray.extractMax`

```
void koratSearch(Predicate p, Finitization f) {
    intialize(f);
    while (hasNextCandidate()) {
        Object candidate = nextCandidate();
        try {
            if (p.invoke(candidate))
                output(candidate);
        } catch (Throwable t) {}
        backtrack();
    }
}
```

Figure 9: Pseudo-code of the Korat search algorithm

returns `true`. Figure 9 gives an overview of the Korat search algorithm. The algorithm uses a *finitization* (described in Section 3.1) to bound the *state space* (Section 3.2) of predicate inputs. Korat uses backtracking (Section 3.3) to exhaustively explore the state space. Korat generates *candidate* inputs and checks their validity by invoking the predicate on them. Korat monitors accesses that the predicate makes to all the fields of the candidate input. To monitor the accesses, Korat instruments the predicate and all the methods that the predicate transitively invokes (Section 3.5). If the predicate returns without reading some fields of the candidate, the validity of the candidate must be independent of the values of those fields—Korat uses this observation to prune the search. Korat also uses an optimization that generates only nonisomorphic test cases (Section 3.4).

This section first illustrates how Korat generates valid inputs for predicate methods that take only the implicit `this` argument. Section 3.6 shows how Korat generates valid inputs for Java predicates that take multiple arguments.

3.1 Finitization

To generate a finite state space of a predicate's inputs, the search algorithm needs a *finitization*, i.e., a set of bounds that limits the size of the inputs. Since the inputs can consist of objects from several classes, the finitization specifies the number of objects for each of those classes. A set of objects from one class forms a *class domain*. The finitization also specifies for each field the set of classes whose objects the field can point to. The set of values a field can take forms its *field domain*. Note that a field domain is a union of some class domains.

In the spirit of using the implementation language (which programmers are familiar with) for specification and testing, Korat provides a `Finitization` class that allows finitizations to be written in Java.[2] Korat automatically generates a finitization *skeleton* from the type declarations in the Java code. For the `BinaryTree` example presented in Figure 1, Korat automatically generates the skeleton shown in Figure 10.

[2]The initial version of Korat provided a special-purpose language for more compact descriptions of finitizations, sketched in the comments in the examples in Figures 2 and 6.

```
public static Finitization finBinaryTree(int NUM_Node,
                                         int MIN_size,
                                         int MAX_size) {
  Finitization f = new Finitization(BinaryTree.class);
  ObjSet nodes = f.createObjects("Node", NUM_Node);
  nodes.add(null);
  f.set("root", nodes);
  f.set("size", new IntSet(MIN_size, MAX_size));
  f.set("Node.left", nodes);
  f.set("Node.right", nodes);
  return f;
}
```

Figure 10: Generated finitization description for `BinaryTree`

In Figure 10, the `createObjects` method specifies that the input contains at most `NUM_Node` objects from the `Node`. The `set` method specifies the field domain for each field. In the skeleton, the fields `root`, `left`, and `right` are specified to contain either `null` or a `Node` object. The `size` field is specified to range between `MIN_size` and `MAX_size` using the utility class `IntSet`. The Korat package provides several additional classes for easy construction of class domains and field domains.

Once Korat generates a finitization skeleton, programmers can further specialize or generalize it. For example, the skeleton shown in Figure 10 can be specialized by setting `MIN_size` to 0 and `MAX_size` to `NUM_Node`. We presented another specialized finitization in Figure 2. Note that programmers can use the full expressive power of the Java language for writing finitization descriptions.

3.2 State space

We continue with the `BinaryTree` example to illustrate how Korat constructs the state space for the input to `repOk` using the finitization presented in Figure 2. Consider the case when Korat is invoked for `finBinaryTree(3)`, i.e., `NUM_Node = 3`. Korat first allocates the specified objects: one `BinaryTree` object and three `Node` objects. The three `Node` objects form the `Node` class domain. Korat then assigns a field domain and a unique identifier to each field. The identifier is the index into the *candidate vector*. In this example, the vector has eight elements; there are total of eight fields: the single `BinaryTree` object has two fields, `root` and `size`, and the three `Node` objects have two fields each, `left` and `right`.

For this example, a *candidate* `BinaryTree` input is a sample valuation of those eight fields. The state space of inputs consists of all possible assignments to those fields, where each field gets a value from its corresponding field domain. Since the domain for fields `root`, `left`, and `right` has four elements (`null` and three `Node`s from the `Node` class domain), the state space has $4 * 1 * (4 * 4)^3 = 2^{14}$ potential candidates. For `NUM_Node`$= n$, the state space has $(n + 1)^{2n+1}$ potential candidates. Figure 11 shows an example candidate that is a valid binary tree on three nodes. Not all valuations are valid binary trees. Figure 12 shows an example candidate that is not a tree; `repOk` returns `false` for this input.

3.3 Search

To systematically explore the state space, Korat orders all the elements in every class domain and every field domain (which is a union of class domains). The ordering in each field domain is consistent with the orderings in the class domains, and all the values that belong to the same class domain occur consecutively in the ordering of each field domain.

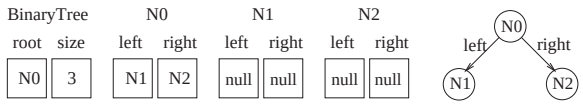

Figure 11: Candidate input that is a valid `BinaryTree`.

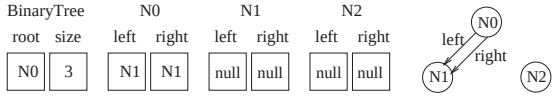

Figure 12: Candidate input that is not a valid `BinaryTree`.

Each candidate input is a vector of *field domain indices* into the corresponding field domains. For our running example with `NUM_Node = 3`, assume that the `Node` class domain is ordered as [N_0,N_1,N_2], and the field domains for `root`, `left`, and `right` are ordered as [`null`,N_0,N_1,N_2]. (`null` by itself forms a class domains.) The domain of the `size` field has a single element, 3. According to this ordering, the candidate inputs in Figures 11 and 12 have candidate vectors $[1, 0, 2, 3, 0, 0, 0, 0]$ and $[1, 0, 2, 2, 0, 0, 0, 0]$, respectively.

The search starts with the candidate vector set to all zeros. For each candidate, Korat sets fields in the objects according to the values in the vector. Korat then invokes `repOk` to check the validity of the current candidate. During the execution of `repOk`, Korat monitors the fields that `repOk` accesses. Specifically, Korat builds a *field-ordering*: a list of the field identifiers ordered by the first time `repOk` accesses the corresponding field. Consider the invocation of `repOk` from Figure 1 on the candidate shown in Figure 12. In this case, `repOk` accesses only the fields [`root`,N_0`.left`,N_0`.right`] (in that order) before returning `false`. Hence, the field-ordering that Korat builds is `[0,2,3]`.

After `repOk` returns, Korat generates the next candidate vector backtracking on the fields accessed by `repOk`. Korat first increments the field domain index for the field that is last in the field-ordering. If the domain index exceeds the domain size, Korat resets that index to zero, and increments the domain index of the previous field in the field-ordering, and so on. (The next section presents how Korat generates only nonisomorphic candidates by resetting a domain index for a field to zero even when the index does not exceed the size of the field domain.)

Continuing with our example, the next candidate takes the next value for N_0`.right`, which is N_2 by the above order, whereas the other fields do not change. This prunes from the search all 4^4 candidate vectors of the form `[1,_,2,2,_,_,_,_]` that have the (partial) valuation: `root=`N_0, N_0`.left=`N_1, N_0`.right=`N_1. This pruning does not rule out any valid data structure because `repOk` did not read the other fields, and it could have returned `false` irrespective of the values of those fields.

Continuing further with our example, the next candidate is the valid tree shown in Figure 11. Before executing `repOk` on this candidate, Korat also initializes the field-ordering to `[0,2,3]`. Note that, if `repOk` accesses fields in a deterministic order, this is consistent with the first three fields that `repOk` is going to access, because the values of the first two fields in the field-ordering were not changed when constructing this candidate from the previous candidate. When `repOk` executes on this candidate, `repOk` returns `true` and the field-ordering that Korat builds is `[0,2,3,4,5,6,7,1]`. If `repOk` returns `true`, Korat outputs all (nonisomorphic) candidates that have the same values for the accessed fields as the current candidate. (Note that `repOk` may not access all reachable fields before returning `true`.) The search then backtracks to the next candidate.

Recall that Korat orders the values in the class and field domains. Additionally, each execution of `repOk` on a candidate imposes an order on the fields in the field-ordering. Together, these orders induce a lexicographic order on the candidates. The search algorithm described here generates inputs in the lexicographical order. Moreover, for non-deterministic `repOk` methods, our algorithm provides the following guarantee: all candidates for which `repOk` always returns `true` are generated; candidates for which `repOk` always returns `false` are never generated; and candidates for which `repOk` sometimes returns `true` and sometimes `false` may or may not be generated.

In practice, our search algorithm prunes large portions of the search space, and thus enables Korat to explore very large state spaces. The efficiency of the pruning depends on the `repOk` method. An ill-written `repOk`, for example, might always read the entire input before returning, thereby forcing Korat to explore almost every candidate. However, our experience indicates that naturally written `repOk` methods, which return `false` as soon as the first invariant violation is detected, induce very effective pruning.

3.4 Nonisomorphism

To further optimize the search, Korat avoids generating multiple candidates that are isomorphic to one another. Our optimization is based on the following definition of isomorphism.

Definition: Let $O_1, \ldots, O_n$ be some sets of objects from n classes. Let $O = O_1 \cup \ldots \cup O_n$, and suppose that candidates consist only of objects from O. (Pointer fields of objects in O can either be `null` or point to other objects in O.) Let P be the set consisting of `null` and all values of primitive types (such as `int`) that the fields of objects in O can contain. Further, let $r \in O$ be a special root object, and let O_C be the set of all objects reachable from r in C. Two candidates, C and C', are *isomorphic* iff there is a permutation π on O, mapping objects from O_i to objects from O_i for all $1 \leq i \leq n$, such that:

$\forall o, o' \in O_C.\ \forall f \in fields(o).\ \forall p \in P.$
$o.f$==o' in C iff $\pi(o).f$==$\pi(o')$ in C' and
$o.f$==p in C iff $\pi(o).f$==p in C'.

The operator == is Java's comparison by object identity. Note that isomorphism is defined with respect to a root object. Two candidates are defined to be isomorphic if the parts of their object graphs reachable from the root object are isomorphic. In case of `repOk`, the root object is the `this` object that is passed as an implicit argument to `repOk`.

Isomorphism between candidates partitions the state space into *isomorphism partitions*. Recall the lexicographic ordering induced by the ordering on the values in the field domains and the field-orderings built by `repOk` executions. For each isomorphism partition, Korat generates only the lexicographically smallest candidate in that partition.

Conceptually, Korat avoids generating multiple candidates from the same isomorphism partition by incrementing field domain indices

```
class SomeClass {
    boolean somePredicate(X x, Y y) {...}
    ...
}
```

Figure 13: Predicate method with multiple arguments

by more than one: while backtracking on a field f in the field-ordering, Korat checks for how much to increment the field domain index of f as follows. Suppose that f contains a pointer to an object o_f that belongs to a class domain c_f. Recall that all objects in a class domain are ordered. Let i_f be the index of o_f in c_f. For instance, in the example ordering used above for `finBinaryTree(3)`, field domain index `2` for `right` corresponds to the class domain `Node` and class domain index `1`.

Further, Korat finds all fields f' such that f' occurs before f in the field-ordering and f' contains a pointer to an object o'_f of the same class domain c_f. Let i'_f be the index of o'_f in c_f, and let m_f be the maximum of all such indices i'_f. (If there is no such field f' before f in the field-ordering, $m_f =$`-1`.) In the example candidate for Figure 12, backtracking on $f =$`N`$_0$`.right` gives $m_f =$`1`.

Then, during backtracking on f, Korat checks if i_f is greater than m_f. If $i_f \leq m_f$, Korat increments the field domain index of f by one. If $i_f > m_f$, Korat increments the field domain index of f so that it contains a pointer to an object of the class domain after c_f. If no such domain exists, i.e., c_f is the last domain for the field f, Korat resets the field domain index of f to zero and continues backtracking on the previous field in the field-ordering. The actual Korat implementation uses caching to speed up the computation of m_f.

For example, Korat for `finBinaryTree(3)` generates only the five trees shown in Figure 3. Each tree is a representative from an isomorphism partition that has six distinct trees, one for each of 3! permutations of nodes.

3.5 Instrumentation

To monitor `repOk`'s executions, Korat instruments all classes whose objects appear in finitizations by doing a source to source translation. For each of the classes, Korat adds a special constructor. For each field of those classes, Korat adds an identifier field and special `get` and `set` methods. In the code for `repOk` and all the methods that `repOk` transitively invokes, Korat replaces each field access with an invocation of the corresponding `get` or `set` method. Arrays are similarly instrumented, essentially treating each array element as a field.

To monitor the field accesses and build a field-ordering, Korat uses an approach similar to the *observer* pattern [11]. Korat uses the special constructors to initialize all objects in a finitization with an observer. The search algorithm initializes each of the identifier fields to a unique index into the candidate vector. Special `get` and `set` methods first notify the observer of the field access using the field's identifier and then perform the field access (return the field's value or assign to the field).

3.6 Predicates with multiple arguments

The discussion so far described how Korat generates inputs that satisfy a `repOk` method. This section describes how Korat generalizes this technique to generate inputs that satisfy any Java predicate, including predicates that take multiple arguments. Figure 13 shows

```
class SomeClass_somePredicate {
    SomeClass This;
    X x;
    Y y;
    boolean repOk() {
        return This.somePredicate(x, y);
    }
}
```

Figure 14: Equivalent `repOk` method

a Java predicate that takes two arguments (besides `this`). In order to generate inputs for this predicate, Korat generates an equivalent `repOk` method shown in Figure 14. Korat then generates inputs to the `repOk` method using the technique described earlier.

4. TESTING METHODS

The previous section focused on automatic test case generation from a Java predicate and a finitization description. This section presents how Korat builds on this technique to check correctness of methods. Korat uses specification-based testing: to test a method, Korat first generates test inputs from the method's precondition, then invokes the method on each of those inputs, and finally checks the correctness of the output using the method's postcondition.

The current Korat implementation uses the Java Modeling Language (JML) [20] for specifications. Programmers can use JML annotations to express method preconditions and postconditions, as well as class invariants; these annotations use JML keywords `requires`, `ensures`, and `invariant`, respectively. Each annotation contains a boolean expression; JML uses Java syntax and semantics for expressions, and contains some extensions such as quantifiers. Korat uses a large subset of JML that can be automatically translated into Java predicates.

JML specifications can express several *normal* and *exceptional behaviors* for a method. Each behavior has a precondition and a postcondition: if the method is invoked with the precondition being satisfied, the behavior requires that the method terminate with the postcondition being satisfied. Additionally, normal behaviors require that the method return without an exception, whereas exceptional behaviors require that the method return with an exception. Korat generates inputs for all method behaviors using the *complete* method precondition that is a conjunction of: 1) the class invariant for all objects reachable from the input parameters and 2) a disjunction of the preconditions for all behaviors. In the text that follows, we refer to complete precondition simply as precondition.

4.1 Generating test cases

Valid test cases for a method must satisfy its precondition. To generate valid test cases, Korat uses a class that represents method's inputs. This class has one field for each parameter of the method (including the implicit `this` parameter) and a `repOk` predicate that uses the precondition to check the validity of method's inputs. Given a finitization, Korat then generates all inputs for which this `repOk` returns `true`; each of these inputs is a valid input to the original method.

We illustrate generation of test cases using the `remove` method for `BinaryTree` from Section 2. For this method, each input consists of a pair of `BinaryTree this` and a `Node n`, and the precondition is `this.has(n)`. Figure 15 shows the class that Korat uses for the method's inputs. For this class, Korat creates the finitization skeleton that reuses the finitization for `BinaryTree`, as shown in

```
class BinaryTree_remove {
    BinaryTree This;   // the implicit "this" parameter
    BinaryTree.Node n; // the Node parameter
    //@ invariant repOk();
    public boolean repOk() {
        return This.has(n);
    }
}
```

Figure 15: Class representing `BinaryTree.remove`

```
public static Finitization
        finBinaryTree_remove(int NUM_Node) {
    Finitization f =
        new Finitization(BinaryTree_remove.class);
    Finitization g = BinaryTree.finBinaryTree(NUM_Node);
    f.includeFinitization(g);
    f.set("This", g.getObjects(BinaryTree.class));
    f.set("n", /***/);
    return f;
}
```

Figure 16: Finitization skeleton for `BinaryTree_remove`

Figure 16. The comment `/***/` indicates that Korat cannot automatically determine an appropriate field domain for `n`.

To create finitization for `BinaryTree_remove`, the programmer modifies the skeleton, e.g., by replacing `/***/` with `g.get("root")` or `g.getObjects(BinaryTree.Node.class)` to set the domain for the parameter `n` to the domain for the field `root` or to the set of nodes from the finitization `g`, respectively. Given a value for `NUM_Node`, Korat then generates all valid test cases, each of which is a pair of a tree (with the given number of nodes) and a node from that tree.

4.1.1 Dependent and independent parameters

For the `remove` method, the precondition makes the parameters `This` and `n` explicitly dependent. When the parameters are independent, programmers can instruct Korat to generate all test cases by separately generating all possibilities for each parameter and creating all valid test cases as the Cartesian product of these possibilities.

We next compare Korat with another approach for generating all valid (nonisomorphic) test cases, which uses the Cartesian product even for dependent parameters. Consider a method `m`, with n parameters and precondition $\mathtt{m}_{pre}$. Suppose that a set of possibilities S_i, $1 \leq i \leq n$, is given for each of the parameters. All valid test cases from $S_1 \times \ldots \times S_n$ can be then generated by creating *all* n-tuples from the product, followed by filtering each of them through $\mathtt{m}_{pre}$. (This approach is used in the JML+JUnit testing framework [6] that combines JML [20] and JUnit [3].) Note that this approach requires manually constructing possibilities for all parameters, some of which can be complex data structures.

Korat, on the other hand, constructs data structures from a simple description of the fields in the structures. Further, in terms of Korat's search of `repOk`'s state space, the presented approach would correspond to the search that tries every candidate input. Korat improves on this approach by: 1) pruning the search based on the accessed fields and 2) generating only one representative from each isomorphism partition.

4.2 Checking correctness

To check a method, Korat first generates all valid inputs for the method using the process explained above. Korat then invokes the method on each of the inputs and checks each output with a *test oracle*. To check partial correctness of a method, a simple test oracle could just invoke `repOk` in the *post-state* (i.e., the state immediately after the method's invocation) to check if the method preserves its class invariant. If the result is `false`, the method under test is incorrect, and the input provides a concrete counterexample. Programmers could also manually develop more elaborate test oracles. Programmers can also check for properties that relate the post-state with the *pre-state* (i.e., the state just before the method's invocation).

	Testing framework		
testing activity	JUnit	JML+JUnit	Korat
generating test cases			√
generating test oracle		√	√
running tests	√	√	√

Table 1: Comparison of several testing frameworks for Java. Automated testing activities are indicated with "√".

The current Korat implementation uses the JML tool-set to automatically generate test oracles from method postconditions, as in the JML+JUnit framework [6]. The JML tool-set translates JML postconditions into runtime Java assertions. If an execution of a method violates such an assertion, an exception is thrown to indicate a violated postcondition. Test oracle catches these exceptions and reports correctness violations. These exceptions are different from the exceptions that the method specification allows, and Korat leverages on JML to check both normal and exceptional behavior of methods. More details of the JML tool-set and translation can be found in [20].

Korat also uses JML+JUnit to combine JML test oracles with JUnit [3], a popular framework for unit testing of Java modules. JUnit automates test execution and error reporting, but requires programmers to provide test inputs and test oracles. JML+JUnit, thus, automates both test execution and correctness checking. However, JML+JUnit requires programmers to provide sets of possibilities for all method parameters: it generates all valid inputs by generating the Cartesian product of possibilities and filtering the tuples using preconditions. Korat additionally automates generation of test cases, thus automating the entire testing process. Table 1 summarizes the comparison of these testing frameworks.

5. EXPERIMENTAL RESULTS

This section presents the performance results of the Korat prototype. We used Java to implement the search for valid nonisomorphic `repOk` inputs. For automatic instrumentation of `repOk` (and transitively invoked methods), we modified the sources of the Sun's `javac` compiler. We also modified `javac` to automatically generate finitization skeletons. For checking method correctness, we slightly modified the JML tool-set, building on the existing JML+JUnit framework [6].

We first present Korat's performance for test case generation, then compare Korat with the test generation that uses Alloy Analyzer [16], and finally present Korat's performance for checking method correctness. We performed all experiments on a Linux machine with a Pentium III 800 MHz processor using Sun's Java 2 SDK1.3.1 JVM.

benchmark	package	finitization parameters
BinaryTree	korat.examples	NUM_Node
HeapArray	korat.examples	MAX_size, MAX_length, MAX_elem
LinkedList	java.util	MIN_size, MAX_size, NUM_Entry, NUM_Object
TreeMap	java.util	MIN_size, NUM_Entry, MAX_key, MAX_value
HashSet	java.util	MAX_capacity, MAX_count, MAX_hash, loadFactor
AVTree	ins.namespace	NUM_AVPair, MAX_child, NUM_String

Table 2: Benchmarks and finitization parameters. Each benchmark is named after the class for which data structures are generated; the structures also contain objects from other classes.

5.1 Benchmarks

Table 2 lists the benchmarks for which we show Korat's performance. `BinaryTree` and `HeapArray` are presented in Section 2. (Additionally, `HeapArray`s are similar to array-based stacks and queues, as well as `java.util.Vector`s.) `LinkedList` is the implementation of linked lists in the Java Collections Framework, a part of the standard Java libraries. This implementation uses doubly-linked, circular lists that have a `size` field and a `header` node as a sentinel node. (Linked lists also provide methods that allow them to be used as stacks and queues.) `TreeMap` implements the `Map` interface using red-black trees [8]. This implementation uses binary trees with `parent` fields. Each node (implemented with inner class `Entry`) also has a `key` and a `value`. (Setting all `value` fields to `null` corresponds to the set implementation in `java.util.TreeSet`.) `HashSet` implements the `Set` interface, backed by a hash table [8]. This implementation builds collision lists for buckets with the same hash code. The `loadFactor` parameter determines when to increase the size of the hash table and rehash the elements.

`AVTree` implements the *intentional name* trees that describe properties of services in the Intentional Naming System (INS) [1], an architecture for service location in dynamic networks. Each node in an intentional name has an `attribute`, a `value`, and a set of child nodes. INS uses attributes and values to classify services based on their properties. The names of these properties are implemented with arbitrary `String`s except that `"*"` is a wildcard that matches all other values. The finitization bounds the number of `AVPair` objects that implement nodes, the number of children for each node, and the total number of `String`s (including the wildcard).

5.2 Korat's test case generation

Table 3 presents the results for generating valid structures with our Korat implementation. For each benchmark, all finitization parameters are set to the same (size) value (except the `loadFactor` parameter for `HashSet`, which is set to default 0.75). For a range of size values, we tabulate the time that Korat takes to generate all valid structures, the number of structures generated, the number of candidate structures checked by `repOk`, and the size of the state space.

Korat can generate all structures even for very large state spaces because the search pruning allows Korat to explore only a tiny fraction of the state space. The ratios of the number of candidate structures considered and the size of the state spaces show that the key to effective pruning is backtracking based on fields accessed during `repOk`'s executions. Without backtracking, and even with isomorphism optimization, Korat would generate infeasibly many candidates. Isomorphism optimization further reduces the number of candidates, but it mainly reduces the number of valid structures.

benchmark	size	time (sec)	structures generated	candidates considered	state space
BinaryTree	8	1.53	1430	54418	2^{53}
	9	3.97	4862	210444	2^{63}
	10	14.41	16796	815100	2^{72}
	11	56.21	58786	3162018	2^{82}
	12	233.59	208012	12284830	2^{92}
HeapArray	6	1.21	13139	64533	2^{20}
	7	5.21	117562	519968	2^{25}
	8	42.61	1005075	5231385	2^{29}
LinkedList	8	1.32	4140	5455	2^{91}
	9	3.58	21147	26635	2^{105}
	10	16.73	115975	142646	2^{120}
	11	101.75	678570	821255	2^{135}
	12	690.00	4213597	5034894	2^{150}
TreeMap	7	8.81	35	256763	2^{92}
	8	90.93	64	2479398	2^{111}
	9	2148.50	122	50209400	2^{130}
HashSet	7	3.71	2386	193200	2^{119}
	8	16.68	9355	908568	2^{142}
	9	56.71	26687	3004597	2^{166}
	10	208.86	79451	10029045	2^{190}
	11	926.71	277387	39075006	2^{215}
AVTree	5	62.05	598358	1330628	2^{50}

Table 3: Korat's performance on several benchmarks. All finitization parameters are set to the size value. Time is the elapsed real time in seconds for the entire generation. State size is rounded to the nearest smaller exponent of two.

For `BinaryTree`, `LinkedList`, `TreeMap`, and `HashSet` (with the `loadFactor` parameter of 1), the numbers of nonisomorphic structures appear in the Sloane's On-Line Encyclopedia of Integer Sequences [30]. For all these benchmarks, Korat generates exactly the actual number of structures.

5.2.1 Comparison with Alloy Analyzer

We next compare Korat's test case generation with that of the Alloy Analyzer (AA) [16], an automatic tool for analyzing Alloy *models*. Alloy [17] is a first-order, declarative language based on relations. Alloy is suitable for modeling structural properties of software. Alloy models of several data structures can be found in [22]. These models specify class invariants in Alloy, which correspond to `repOk` methods in Korat, and also declare field types, which corresponds to setting field domains in Korat finitizations.

Given a model of a data structure and a *scope*—a bound on the number of atoms in the universe of discourse—AA can generate all (mostly nonisomorphic) *instances* of the model. An instance valuates the relations in the model such that all constraints of the model are satisfied. Setting the scope in Alloy corresponds to setting the finitization parameters in Korat. AA translates the input Alloy model into a boolean formula and uses an off-the-shelf SAT solver to find a satisfying assignment to the formula. Each such assignment is translated back to an instance of the input model. AA adds symmetry-breaking predicates [29] to the boolean formula so that different satisfying assignments to the formula represent (mostly) nonisomorphic instances of the input model.

benchmark	size	Korat			Alloy Analyzer		
		struc. gen.	total time	first struc.	inst. gen.	total time	first inst.
BinaryTree	3	5	0.56	0.62	6	2.63	2.63
	4	14	0.58	0.62	28	3.91	2.78
	5	42	0.69	0.67	127	24.42	4.21
	6	132	0.79	0.66	643	269.99	6.78
	7	429	0.97	0.62	3469	3322.13	12.86
HeapArray	3	66	0.53	0.58	78	11.99	6.20
	4	320	0.57	0.59	889	171.03	16.13
	5	1919	0.73	0.63	1919	473.51	39.58
LinkedList	3	5	0.58	0.60	10	2.61	2.39
	4	15	0.55	0.65	46	3.47	2.77
	5	52	0.57	0.65	324	14.09	3.51
	6	203	0.73	0.61	2777	148.73	5.74
	7	877	0.87	0.61	27719	2176.44	10.51
TreeMap	4	8	0.75	0.69	16	12.10	6.35
	5	14	0.87	0.88	42	98.09	18.08
	6	20	1.49	0.98	152	1351.50	50.87
AVTree	2	2	0.55	0.65	2	2.35	2.43
	3	84	0.65	0.61	132	4.25	2.76
	4	5923	1.41	0.61	20701	504.12	3.06

Table 4: Performance comparison. For each benchmark, performances of Korat and AA are compared for a range of finitization values. For values larger than presented, AA does not complete its generation within 1 hour. Korat's performance for larger values is given in Table 3.

Table 4 summarizes the performance comparison. Since AA cannot handle arbitrary arithmetic, we do not generate `HashSets` with AA. For all other benchmarks, we compare the total number of structures/instances and the time to generate them for a range of parameter values. We also compare the time to generate the first structure/instance.

Time presented is the total elapsed real time (in seconds) that each experiment took from the beginning to the end, including start-up.[3] Start-up time for Korat is approximately 0.5 sec. (That is why in some cases it seems that generating all structures is faster than generating the first structure or that generating all structures for a larger input is faster than generating all structures for a smaller input.) Start-up time for AA is somewhat higher, approximately 2 sec, as AA needs to translate the model and to start a SAT solver. AA uses precompiled binaries for SAT solvers.

In all cases, Korat outperforms AA; Korat is not only faster for smaller inputs, but it also completes generation for larger inputs than AA. There are two reasons that could account for this difference. Since AA translates Alloy models into boolean formulas, it could be that the current (implementation of the) translation generates unnecessarily large boolean formulas. Another reason is that often AA generates a much greater number of instances than Korat, which takes a greater amount of time by itself. One way to reduce the number of instances generated by AA is to add more symmetry-breaking predicates.

Our main argument for developing Korat was simple: for Java programmers not familiar with Alloy, it is easier to write a `repOk` method than an Alloy model. (From our experience, for researchers familiar with Alloy, it is sometimes easier to write an Alloy model than a `repOk` method.) Before conducting the above experiments, we expected that Korat would generate structures slower than AA.

[3]We include start-up time, because AA does not provide generation time only for generating all instances. We eliminate the effect of cold start by executing each test twice and taking the smaller time.

benchmark	method	max. size	test cases generated	gen. time	test time
BinaryTree	remove	3	15	0.64	0.73
HeapArray	extractMax	6	13139	0.87	1.39
LinkedList	reverse	2	8	0.67	0.76
TreeMap	put	8	19912	136.19	2.70
HashSet	add	7	13106	3.90	1.72
AVTree	lookup	4	27734	4.33	14.63

Table 5: Korat's performance on several methods. All upper-limiting finitization parameters for method inputs are set to the given maximum size. These sizes give complete statement coverage. Times are the elapsed real times in seconds for the entire generation of all valid test cases and testing of methods for all those inputs. These times include writing and reading of files with test cases.

Our intuition was that Korat depends on the executions of `repOk` to "learn" the invariants of the structures, whereas AA uses a SAT solver that can "inspect" the entire formula (representing invariants) to decide how to search for an assignment. The experimental results show that our assumption was incorrect—Korat generates structures much faster than AA. We are now exploring a translation of Alloy models into Java (or even C) and the use of Korat (or a similar search) to generate instances.

5.3 Checking correctness

Table 5 presents the results for checking methods with Korat. For each benchmark, a representative method is chosen; the results are similar for other methods. Methods `remove` and `extractMax` are presented in Section 2. Method `reverse`, from `java.util.Collections`, uses list iterators to reverse the order of list elements; this method is static. Method `put`, from `java.util.TreeMap`, inserts a key-value pair into the map; this method has three parameters (`this`, `key`, and `value`) and invokes several helper methods that rebalance the tree after insertion. Method `add` inserts an element into the set. Method `lookup`, from INS, searches a `database` of intentional names for a given `query` intentional name. The correctness specifications for all methods specify simple containment properties (beside preservation of class invariants).

For each method, the `MIN` finitization parameters are set to zero and the `MAX` and `NUM` parameters to the same size value. Thus, the methods are checked for all valid inputs up to the maximum size, not only for the maximum size. The results show that it is practical to use Korat to exhaustively check correctness of intricate methods that manipulate complex data structures.

AA can also be used to check correctness of Java methods by writing method specifications as Alloy models and defining appropriate translations between Alloy instances and Java objects, as demonstrated in the TestEra framework [22]. However, the large number of instances generated by AA makes TestEra less practical to use than Korat. For example, maximum sizes six and eight for `extractMax` and `put` methods, respectively, are the smallest that give complete statement coverage. As shown in Table 4, for these sizes, AA cannot in a reasonable time even generate data structures that are parts of the inputs for these methods.

6. RELATED WORK

6.1 Specification-based testing

There is a large body of research on specification-based testing. An early paper by Goodenough and Gerhart [13] emphasizes its impor-

tance. Many projects automate test case generation from specifications, such as Z specifications [15, 31], UML statecharts [25, 26], or ADL specifications [5, 28]. These specifications typically do not consider linked data structures, and the tools do not generate Java test cases.

The TestEra framework [22] generates Java test cases from Alloy [17] specifications of linked data structures. TestEra uses the Alloy Analyzer (AA) [16] to automatically generate method inputs and check correctness of outputs, but it requires programmers to learn a specification language much different than Java. Korat generates inputs directly from Java predicates and uses the Java Modeling Language (JML) [20] for specifications. The experimental results also show that Korat generates test cases faster and for larger scopes than AA.

Cheon and Leavens [6] describe automatic translation of JML specifications into test oracles for JUnit [3]. This framework automates execution and checking of methods. However, the burden of test case generation is still on programmers: they have to provide sets of possibilities for all method parameters. Korat builds on this framework by automating test case generation.

6.2 Static analysis

Several projects aim at developing static analyses for verifying program properties. The Extended Static Checker (ESC) [10] uses a theorem prover to verify partial correctness of classes annotated with JML specifications. ESC has been used to verify absence of such errors as null pointer dereferences, array bounds violations, and division by zero. However, tools like ESC cannot verify properties of complex linked data structures.

There are some recent research projects that attempt to address this issue. The Three-Valued-Logic Analyzer (TVLA) [27] is the first static analysis system to verify that the list structure is preserved in programs that perform list reversals via destructive updating of the input list. TVLA has been used to analyze programs that manipulate doubly linked lists and circular lists, as well as some sorting programs. The pointer assertion logic engine (PALE) [24] can verify a large class of data structures that can be represented by a spanning tree backbone, with possibly additional pointers that do not add extra information. These data structures include doubly linked lists, trees with parent pointers, and threaded trees. While TVLA and PALE are primarily intraprocedural, Role Analysis [19] supports compositional interprocedural analysis and verifies similar properties.

While static analysis of program properties is a promising approach for ensuring program correctness in the long run, the current static analysis techniques can only verify limited program properties. For example, none of the above techniques can verify correctness of implementations of balanced trees, such as red-black trees. Testing, on the other hand, is very general and can verify any decidable program property, but for inputs bounded by a given size.

Jackson and Vaziri propose an approach [18] for analyzing methods that manipulate linked data structures. Their approach is to first build an Alloy model of bounded initial segments of computation sequences and then check the model exhaustively with AA. This approach provides static analysis, but it is unsound with respect to both the size of input and the length of computation. Korat not only checks the entire computation, but also handles larger inputs and more complex data structures than those in [18]. Further, Korat does not require Alloy, but JML specifications, and more importantly, unlike [18], Korat does not require specifications for all (helper) methods.

6.3 Software model checking

There has been a lot of recent interest in applying model checking to software. JavaPathFinder [32] and VeriSoft [12] operate directly on a Java, respectively C, program and systematically explore its state to check correctness. Other projects, such as Bandera [7] and JCAT [9], translate Java programs into the input language of existing model checkers like SPIN [14] and SMV [23]. They handle a significant portion of Java, including dynamic allocation, object references, exceptions, inheritance, and threads. They also provide automated support for reducing program's state space through program slicing and data abstraction.

However, most of the work on applying model checking to software has focused on checking event sequences and not linked data structures. Where data structures have been considered, the purpose has been to reduce the state space to be explored and not to check the data structures themselves. Korat, on the other hand, checks correctness of methods that manipulate linked data structures.

7. CONCLUSIONS

This paper presented Korat, a novel framework for automated testing of Java programs. Given a formal specification for a method, Korat uses the method precondition to automatically generate all nonisomorphic test cases up to a given small size. Korat then executes the method on each test case, and uses the method postcondition as a test oracle to check the correctness of each output.

To generate test cases for a method, Korat constructs a Java predicate (i.e., a method that returns a boolean) from the method's precondition. The heart of Korat is a technique for automatic test case generation: given a predicate and a finitization for its inputs, Korat generates all nonisomorphic inputs for which the predicate returns `true`. Korat exhaustively explores the input space of the predicate, but does so efficiently by: 1) monitoring the predicate's executions to prune large portions of the search space and 2) generating only nonisomorphic inputs.

The Korat prototype uses the Java Modeling Language (JML) for specifications, i.e., class invariants and method preconditions and postconditions. Good programming practice suggests that implementations of abstract data types should already provide methods for checking class invariants—Korat then generates test cases almost for free.

This paper illustrated the use of Korat for testing several data structures, including some from the Java Collections Framework. The experimental results show that it is feasible to generate test cases from Java predicates, even when the search space for inputs is very large. This paper also compared Korat with the Alloy Analyzer, which can be used to generate test cases from declarative predicates. Contrary to our initial expectation, the experiments show that Korat generates test cases much faster than the Alloy Analyzer.

Acknowledgements

We would like to thank Michael Ernst, Daniel Jackson, Alexandru Sălcianu, and the anonymous referees for their comments on this paper. We are also grateful to Viktor Kuncak for helpful discussions on Korat and Alexandr Andoni for helping us with experiments. This work was funded in part by NSF grant CCR00-86154.

ANISOTROPIC STEP, SURFACE CONTACT, AND AREA WEIGHTED DIRECTED WALKS ON THE TRIANGULAR LATTICE

A. C. OPPENHEIM, R. BRAK and A. L. OWCZAREK*

Department of Mathematics and Statistics,

Received 2 January 2002

We present results for the generating functions of single fully-directed walks on the triangular lattice, enumerated according to each type of step and weighted proportional to the area between the walk and the surface of a half-plane (wall), and the number of contacts made with the wall. We also give explicit formulae for total area generating functions, that is when the area is summed over all configurations with a given perimeter, and the generating function of the moments of heights above the wall (the first of which is the total area). These results generalise and summarise nearly all known results on the square lattice: all the square lattice results can be obtaining by setting one of the step weights to zero. Our results also contain as special cases those that already exist for the triangular lattice. In deriving some of the new results we utilise the Enumerating Combinatorial Objects (ECO) and marked area methods of combinatorics for obtaining functional equations in the most general cases. In several cases we give our results both in terms of ratios of infinite q-series and as continued fractions.

Keywords: Directed lattice walks; triangular lattice; Enumerating Combinatorial Objects method; marked area.

1. Introduction

The study of directed lattice walks have been of increasing interest for the past two decades, since the article of Fisher[1] demonstrating the many modelling uses for these lattice objects as simple polymer models[2] and as domain walls between phases in various systems. Because of their intrinsic interest as a basic type of lattice object, and their many relations to other types of combinatorial objects such as lattice trees and partitions of integers,[3,4] they have been studied in the combinatorics literature for more than a century. Recently the connections between combinatorics and physics have been strengthened through their appearance in a range of exactly solvable lattice models and in relation to various q-series identities that arise in these studies. The study of a single walk is usually the basis for studying arbitrary numbers of walks in that the solution of many walk generating

functions can often be written in terms of one walk generating functions. Hence the single walk is the starting place for many studies of directed walk systems, and so it is important to have a compendium of one walk results from which to consult. Directed walks often appear in physics as weighted configurations and so it is of some importance to study single lattice walks with a variety of key properties distinguished by different weights.

Single walks on various lattices under several different boundary conditions were studied in now little-known papers about paths on a chessboard,[5–8] and some cases were treated as lattice permutations in Ref. 9. On the square lattice, denoted $\mathbb{S}$, many problems concerning one and more directed walks have been solved exactly, and so this task has essentially been accomplished.[10–15] However, a less complete set of problems have also been solved on the triangular lattice, denoted $\mathbb{T}$. The literature pertinent to $\mathbb{T}$ directed lattice walks is still fairly large;[16–26] more references are listed in Refs. 27 and 28. The triangular lattice is interesting in the combinatorial sense as the regular planar lattice other than the square where each site is topologically equivalent. Also, by considering weighted paths the square lattice can be treated as a special case. Triangular lattice results are of interest in statistical mechanics because they allow one to test the hypothesis of universality for various quantities, in particular in regard to the study of different corrections to scaling. Mathematically, the triangular lattice can force one to approach the solution of problems a little differently and so lead one to introduce new techniques. Here we take the opportunity to make contact with the combinatorial literature on the subject of directed walks and survey most of the physically useful results and related methods. Hence, while many sub-cases of the results appearing here have appeared previously in the combinatorics literature our most general results containing the contact weights as well as area and step weights have not appeared. This paper then provides a review of the most physically interesting triangular lattice results by providing a compendium of general formula for those results already known. Our work also generalises those results by the inclusion of two types of surface contact weight. Additionally, we introduce methods from the combinatorics literature that may prove useful in future work.[29]

As stated above we consider directed walks on the triangular lattice. Our triangular lattice is a tiling of isosceles right-angled triangles so that two adjacent triangles meeting along their hypotenuses form a square. Let us refer to those bonds as diagonal bonds as they form diagonals of squares. In this way the square lattice, rather than any arbitrary parallelogram lattice, can be obtained by the removal of a subset of bonds. This is simply an aesthetic consideration here because we consider walks with general step weights. We shall refer to this lattice as the "*squared*-triangular" lattice to distinguish it from the normal isotropic triangular lattice made from equilateral triangles.

We consider a "wall" parallel to some diagonal edge so that steps of the walk are allowed only on one side of the wall or on the wall. It is more convenient visually to display such single walk configurations by rotating the lattice through 45° (see

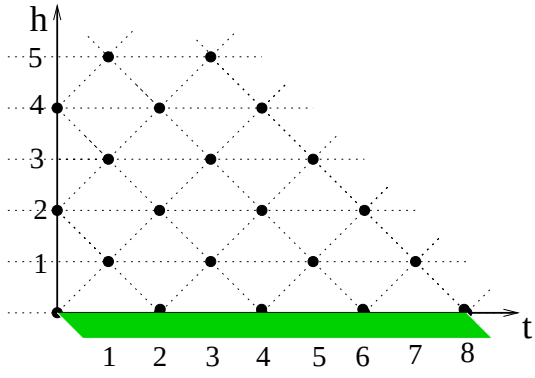

Fig. 1. The half-plane of the squared-triangular lattice considered here with the coordinate system displayed. Sites are coincident with each axis at only even integer values of the coordinates. The shaded region represents the wall with the t axis (*direction* axis) lying along the wall.

Fig. 1). We consider single walks in the half-plane on one side of (or on) the wall with one end of the walk on (touching) the wall. We use the site of attachment of the walk to the wall (i.e. left-most such touching) as the origin of a coordinate system. We use a coordinate system (t, h) where the t coordinate measures distance along the wall (along a *direction* axis) and the h coordinate height above the wall, both scaled so that the first site beyond the origin that is on an axis is at distance 2. By considering orienting the walks away from the origin in the first quadrant they are directed so that every step in the path has non-negative projection on the axis parallel to the wall (direction axis). For convenience we consider the direction axis to be on the wall.

In this paper, two classes of single walks most interesting to physics and fundamental in combinatorics are studied in particular. These classes are shown on the $\mathbb{T}$ lattice in Fig. 2. The classes of walk studied are types of single walks in the half-plane described above that have starting sites on the wall but can finish on or above the wall. In general these walks are called *ballot walks*. The two related classes of ballot walks considered here are

- A *return walk* is a ballot walk that, in addition, ends on the wall.
- An *elevated walk* is a return walk that touches the wall only at its starting and ending sites.

We will demonstrate later how to obtain results for general ballot walks from results concerning return walks.

The paper has the following structure. We begin in the next section by considering only step weights. This allows us to introduce the forms of the generating function solution and provide some fundamental formulae required in later sections. We then add contact weights in Sec. 3. In Sec. 4 we consider the added complication of counting area and introduce the Enumerating Combinatorial Objects (ECO)

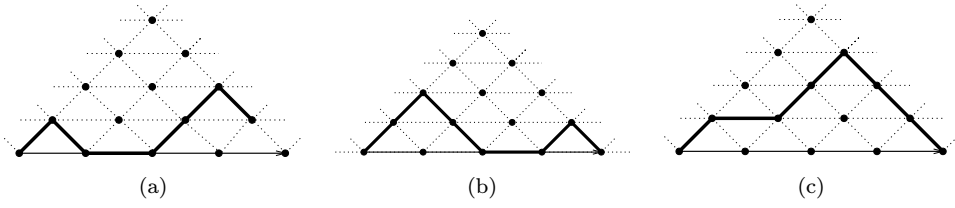

Fig. 2. Single walks with a wall on the $\mathbb{T}$ lattice: (a) a ballot walk (b) a return walk (c) an elevated walk.

method from combinatorics. First area-moment and height moments generating functions are then tackled in the following two sections, allowing us to introduce another combinatorial method known as marked area.

2. Return Walks with Step Weights

The walks that start and end at the wall in a one-wall system have been studied by various authors and go by many names: they have been called positive paths or walks,[10,30,31] zero paths,[32] return paths,[33] restricted walks[34] or under-diagonal walks,[35] amongst other names. On the $\mathbb{S}$ lattice, the walks are often referred to as Dyck paths, since when represented as words of x's and y's they are Dyck words.[a] Here, walks that start and end at the wall are always referred to as *return walks*. The empty or zero-step walk that is the site at the origin is classed as a return walk.

We introduce variables x, y and d associated with down, up and horizontal steps of a walk respectively.

Example 2.1. There are six return walks on the $\mathbb{T}$ lattice that consist of an up step, a down step and two horizontal steps. Each of the six walks contribute an xyd^2 term to an anisotropic length generating function for return walks. The walks are shown in Fig. 3; the walk labelled as (e) in Fig. 3 is an elevated walk.

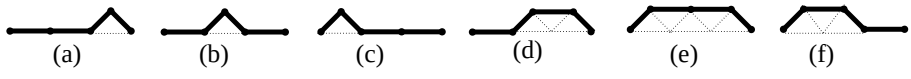

Fig. 3. Return walks of weight xyd^2.

Because a return walk finishes at the wall, it has the same number of down steps and up steps, and so the x and y variables have been coalesced in this case without loss of generality into a variable $v = xy$ that counts the number of up-down step pairs.

[a]Dyck words (and the Dyck language) are named after Walther Franz Anton (von) Dyck 1856–1934, a German mathematician.

Thus, with $\mathcal{W}$ denoting the set of return walks on the $\mathbb{T}$ lattice, let $L(v,d)$ be a generating function

$$L(v,d) = \sum_{w\in\mathcal{W}} v^{a(w)} d^{c(w)} \tag{2.1}$$

that enumerates return walks on the $\mathbb{T}$ lattice by types of steps, so that a walk w with $a(w)$ up (and so down) steps and $c(w)$ horizontal steps contributes a $v^{a(w)}d^{c(w)}$ term to $L(v,d)$.

Two equivalent representations for $L(v,d)$ are derived in this section. While $L(v,d)$ is relatively simple, it is a building block of the more complex generating functions and allows us to introduce some of the methods used to calculate such generating functions. The first is as an algebraic function derived as the solution to a quadratic equation, whilst the second is as an infinite continued fraction. Corresponding functions for elevated walks are then deduced.

Both derivations of $L(v,d)$ begin by partitioning the set of return walks in the following manner. The set $\mathcal{W}$ of return walks can be partitioned by splitting each walk in the set (other than the zero-step walk) into two parts at its first return to the wall. The section before this first return is either (i) a horizontal step, or (ii) an elevated walk. The section after the first return is a (possibly empty) return walk. If the zero-step walk is included as a separate category, the set of return walks has the partition shown schematically in Fig. 4, taken from, for example.[36,37]

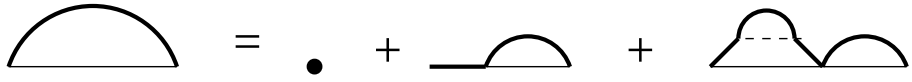

Fig. 4. Partition of return walks on the $\mathbb{T}$ lattice by first return to the wall.

From the decomposition of each walk leading to the partition of the set of walks one can deduce

$$L(v,d) = 1 + dL(v,d) + vL(v,d)^2\,. \tag{2.2}$$

2.1. *Deriving $L(v,d)$ as an algebraic function*

An algebraic function representation of $L(v,d)$ is found by solving the quadratic of Eq. (2.2). The equation has two roots,

$$L_\pm = \frac{1-d\pm\sqrt{(1-d)^2-4v}}{2v}\,, \tag{2.3}$$

only one of which can be the solution unless the discriminant is zero. A generating function enumerating walks by number of steps via the variable z is $L(z^2,z)$. An examination of the first few terms in the Laurent expansions of $L_\pm$ show that L_- is the only allowed candidate. Hence,

$$L(v,d) = \frac{1-d-\sqrt{(1-d)^2-4v}}{2v}\,, \tag{2.4}$$

where the generating function for the return walks in the variables x, y, d is given by $L(xy, d)$.

2.2. *Deriving $L(v, d)$ as a continued fraction*

A continued fraction representation for functions similar to $L(v, d)$ is often used in the literature, for example in Refs. 10, 32 and 38, and can be easily derived for $L(v, d)$. Indeed, Eq. (2.2) can be rearranged as

$$L(v, d) = \frac{1}{1 - d - vL(v, d)}, \tag{2.5}$$

which by iteration gives the infinite continued fraction representation

$$L(v, d) = \frac{1}{1 - d - \frac{v}{1 - d - \frac{v}{1 - d - \cdots}}}, \tag{2.6}$$

or, in more compact notation,

$$L(v, d) = \frac{1}{1 - d -} \quad \frac{v}{1 - d -} \quad \frac{v}{1 - d - \cdots}. \tag{2.7}$$

This representation of $L(v, d)$ may be further specified by including the height coordinate of the site at the start of each step. Indeed, from the partition of the set of return walks in Fig. 4 and the relation in Eq. (2.5) for $L(v, d)$, the first denominator of the fraction in Eq. (2.7), i.e. $1 - d - v$, represents steps (or step pairs xy in the case of v) that start and end at height 0. Continuing, the second denominator represents steps (or step pairs) that start and end at height 1 and so on. If d_i denotes a horizontal step at height i and v_i an up-down step pair that starts and ends at height i (see Fig. 5 for examples), then from Ref. 10, a generating function that enumerates return walks by types of steps and in addition specifies the height of each step is the infinite continued fraction

$$L^{\#} = \frac{1}{1 - d_0 -} \quad \frac{v_0}{1 - d_1 -} \quad \frac{v_1}{1 - d_2 -} \quad \cdots \quad \frac{v_h}{1 - d_{h+1} - \cdots}. \tag{2.8}$$

2.3. *Elevated walks*

Elevated walks, i.e. return walks that do not touch the wall between their starting and ending sites, have also been called prime paths,[36] lead paths,[39] elevated paths[40]

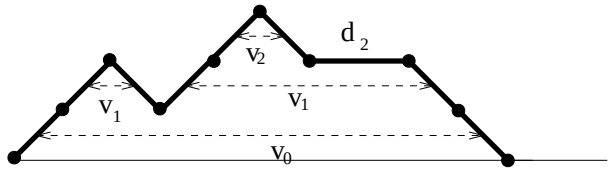

Fig. 5. A return walk with step heights specified.

and excursions (from the wall),[41] among other names. The zero-step walk does not leave the wall and so is not considered an elevated walk. Elevated walks are a subset of return walks, and their anisotropic length generating functions can be obtained from the corresponding functions for return walks. An elevated walk begins with an up step and ends with a down step, and in between these two steps is a return walk that starts and ends at height 1. Thus elevated walks can be constructed by "expanding" return walks away from the wall. A generating function, $\widehat{L}(v,d)$, enumerating elevated walks by its types of steps is then

$$\hat{L}(v,d) = vL(v,d) \tag{2.9}$$

2.4. *Length metrics*

Before we consider some special cases of the results above let us define a *length metric* on the $\mathbb{T}$ lattice to facilitate the discussions. The results with arbitrary weights x, y and d can be used to consider those cases where a *length* alone is assigned to each configuration. If we let the (α, β, γ) "metric" to be such that

$$x = z^{\alpha}, \qquad y = z^{\beta}, \qquad d = z^{\gamma}\,, \tag{2.10}$$

then α, β and γ assign *length* multiples to each type of step so that a length generating function for walks is

$$G(z^{\alpha}, z^{\beta}, z^{\gamma}) = \sum_{n\geq 0} l_n z^n\,, \tag{2.11}$$

where l_n is the number of walks of "length" $n = a(\alpha+\beta) + c\gamma$ with a being the number of up-down pairs of steps and c being the number of horizontal steps. It is given that α, β, γ are usually all non-negative integers. There is one exception to allow for cases where, say $d = 0$, we use the convention that a metric can have the "value" $-$, e.g. $\gamma = -$. Under metrics with $\gamma = -$ walks that have steps counted by d do not contribute to the generating functions, and so such cases consider the square lattice with $n = a(\alpha+\beta)$, where a is the number of up-down step pairs.

2.5. *Special cases*

Case 2.1. An early application of a one-wall lattice system for an enumerative problem appears in Ref. 5. The problem can be described as finding the number of 2-row Young tableaux[42] in which each row had n entries. These tableaux can be represented as return walks on the $\mathbb{S}$ lattice from the origin to the site at $(t,h) = (2n, 0)$, i.e. Dyck paths. The $\mathbb{S}$ lattice scaled so that each step has unit length is the same as the $\mathbb{T}$ lattice under the $(1, 1, -)$ metric. Thus the length generating function enumerating return walks by steps on the $\mathbb{S}$ lattice, or by number of configurations to $(2n, 0)$, is

$$L(z^2, 0) = \frac{1-\sqrt{1-4z^2}}{2z^2} = C(z^2)\,, \tag{2.12}$$

where $C(z) = \sum_{n\geq 0} c_n z^n$ is the generating function for Catalan numbers.[b] The coefficients of $L(z^2, 0)$ are often referred to as aerated Catalan numbers because of the zero term in between each successive Catalan number (see Refs. 40 and 46 for example).

Case 2.2. The $(1, 1, 2)$ metric is a natural metric of the lattice under the (t, h) coordinate system since it implies that whether a walk takes an up and then a down step to traverse across the diagonal of a square or simply takes a diagonal "step" both are counted as 2 steps. Hence using this metric is equivalent to considering walks enumerated by length on the *squared*-triangular lattice. The generating function for the return walk configurations ending at successive sites along a wall on the $\mathbb{T}$ lattice under a $(1, 1, 2)$ metric, given by evaluating $L(v, d)$ at $v = z^2, d = z^2$, is

$$L(z^2, z^2) = \frac{1 - z^2 - \sqrt{1 - 6z^2 + z^4}}{2z^2} = R(z^2)\,, \tag{2.13}$$

where $R(z^2) = \sum_{n\geq 0} r_n z^{2n}$ is the generating function for the (aerated) large Schröder numbers.[c] Here diagonal (horizontal) steps are treated as twice the length of up or down steps. This case is interesting since it is a case where all return walks of equal length end at the same lattice site. This condition fails when the isotropic lattice is considered.

As just mentioned, the two previous examples are exceptional in that all return walks of length n end at the one site, $(t, h) = (n, 0)$. The final two examples do not have this property; nonetheless a generating function enumerating return walks by length can be calculated for each.

Case 2.3. Walks on a lattice of unit step length equilateral triangles can be counted using the results above on the $\mathbb{T}$ lattice under the $(1, 1, 1)$ metric. Return walks under this metric have the length generating function

$$L(z^2, z) = \frac{1 - z - \sqrt{1 - 2z - 3z^2}}{2z^2} = M(z)\,, \tag{2.14}$$

where $M(z)$ is the generating function for Motzkin numbers.[d]

[b]The sequence of terms $\{\frac{1}{n+1}\binom{2n}{n}\}$ for $n \geq 0$, now commonly referred to as the sequence of Catalan numbers c_n, has a long and often misrepresented history starting in the middle of the eighteenth century;[4,43] see also Refs. 44 and 45.

[c]The Schröder number sequences are named after the author of a paper concerning bracketing problems[47] in which the small Schröder numbers s_n (related linearly to r_n via $s_0 = 1, s_n = \frac{1}{2}r_n$) were mentioned. The sequence $\{s_n\}$ also has a curious history, beginning apparently in ancient Greece [Refs. 48 (mark 732)], 49 [mark 1047], for which see Refs. 50 and 51. Schröder numbers also occur often in combinatorics; see Refs. 4, 22 and 52, for example.

[d]The Motzkin number sequence m_n was first introduced in another area of combinatorics in Ref. 53. Further details of the many classes of combinatorial objects counted by Motzkin numbers can be found in Refs. 4, 46 and 54–56. The "standard" walks enumerated by Motzkin numbers are walks not on a lattice of equilateral triangles, but on a graph that is a different generalisation of the $\mathbb{S}$ lattice.[10,30,40,57]

Case 2.4. Return walks under the $(1, 2, 2)$ metric have the length generating function

$$L(z^3, z^2) = \frac{1 - z^2 - \sqrt{1 - 2z^2 - 4z^3 + z^4}}{2z^3}\,. \tag{2.15}$$

This is essentially the generating function of Sequence A025250 in the Sloane encyclopaedia,[58] and so there is now a lattice derivation of the terms of that sequence.

3. Single Walks with Return Contact Weights

We now assign a weight κ to a site on the wall arrived at by a down step, and assign a weight μ to a site on the wall arrived at by a horizontal step along the wall (see Fig. 6). These weights describe the *return contacts* of the walk with the wall. Walks have been counted by their number of returns to the wall in combinatorics also; examples are found in Refs. 33, 37 and 59–61.

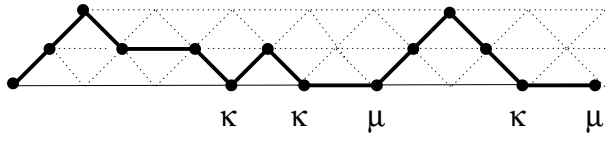

Fig. 6. Weights of (return) contacts representing the interaction between the walk and the wall. The weight κ is associated with sites that are on the wall having incident steps that are down steps, while the weight μ is associated with sites that are on the wall having incident steps that are horizontal steps.

Let $\mathbf{L}(v, d; \kappa, \mu)$ be a generating function

$$\mathbf{L}(v, d; \kappa, \mu) = \sum_{w \in \mathcal{W}} v^{a(w)} d^{c(w)} \kappa^{m(w)} \mu^{n(w)} \tag{3.16}$$

that enumerates return walks by types of steps and also by number of return contacts with the wall. A return walk w of $a(w)$ up (and so down) steps and $c(w)$ horizontal steps that has $m(w)$ down steps incident on the wall and $n(w)$ horizontal steps along the wall then contributes a unit $v^{a(w)} d^{c(w)} \kappa^{m(w)} \mu^{n(w)}$ term to $\mathbf{L}(v, d; \kappa, \mu)$.

The function $\mathbf{L}(v, d; \kappa, \mu)$ is simple to derive using the decomposition of return walks introduced in Sec. 2. Here, though, as a method which generalises to walk pairs it is derived by splitting a return walk into components by each return to the wall. The length generating function of return walks on the $\mathbb{S}$ lattice was derived using different terminology in Ref. 9 (p. 128) by separating a return walk into its elevated components, i.e.

$$L(v, 0) = \frac{1}{1 - \hat{L}(v, 0)}\,. \tag{3.17}$$

In general, on the $\mathbb{T}$ lattice, where in addition to elevated walk components, a return walk may also have single horizontal step components along the wall,

$$L(v,d) = \frac{1}{1-d-\hat{L}(v,d)}\,, \tag{3.18}$$

which, since $L(v,d) = v\hat{L}(v,d)$, is then the same as Eq. (2.5), thus the concatenation of elevated components provides a direct combinatorial interpretation of Eq. (2.5).

An elevated walk has a single return contact with the wall from the down step to its ending site (that is weighted by κ). A horizontal step along the wall has a single *return* contact at its ending site (that is weighted by μ). By incorporating these two weights of return contact to Eq. (3.18), one obtains

$$\mathbf{L}(v,d;\kappa,\mu) = \frac{1}{1-\mu d-\kappa\hat{L}(v,d)} = \frac{2}{2-\kappa+d(\kappa-2\mu)+\kappa\sqrt{(1-d)^2-4v}}\,. \tag{3.19}$$

Cases of $\mathbf{L}(v,d;\kappa,\mu)$ for various values of the contact weights are given below.

3.1. *Special cases*

Case 3.1 (Vanishing wall). If $(\kappa,\mu) = (2,1)$, then

$$\mathbf{L}(v,d;2,1) = \frac{1}{\sqrt{(1-d)^2-4v}}\,, \tag{3.20}$$

which is a generating function for bilateral walks on $\mathbb{T}$, i.e. for walks not in the half-plane but in the infinite plane that end at height 0 ($h=0$). In other words, setting κ to 2 is the same as removing the wall and counting all walks that traverse the plane (in directed manner) freely so long as they end at height 0. This can be thought of as having two choices for each elevated walk component returning to the wall, one above the wall, and the other its reflection below the wall. This behaviour for $\kappa = 2$ was first noted for the $\mathbb{S}$ lattice in Ref. 2, where it represents the behaviour of a system at its critical point.

Case 3.2 ($\boldsymbol{\mu} = 0$ or bouncy walks). The return walks that have weights (κ,μ) set to $(1,0)$ can touch the wall at sites other than their starting and ending sites but do not include steps along the wall. Thus such walks are concatenations of elevated walks. The single site (zero-step walk) is from these definitions included in this set.

A generating function enumerating walks that "bounce" off the wall (*bouncy* walks) is then

$$\check{L}(v,d) = \mathbf{L}(v,d;1,0) = \frac{1}{1-vL(v,d)} \tag{3.21}$$

$$= \frac{1}{1-\hat{L}(v,d)} = \frac{2}{1+d+\sqrt{(1-d)^2-4v}}\,. \tag{3.22}$$

On any parallelogram lattice, i.e. the $\mathbb{T}$ lattice under an $(\alpha,\beta,-)$ metric, $\check{L}(v,d) = L(v,d)$ since no horizontal steps (represented by the variable d) are allowed along

the wall or elsewhere in a walk. On triangular lattices, however, $\check{L}(v,d) \neq L(v,d)$. Two specific subcases for which the numbers of bouncy walks of length n are well-known sequences are given below.

Subcase 3.2.1. Under the $(1,1,2)$ metric, the isotropic length generating function for bouncy walks is

$$\check{L}(z^2,z^2) = \frac{1+z^2-\sqrt{1-6z^2+z^4}}{4z^2} = S(z^2)\,, \tag{3.23}$$

where $S(z^2)$ is the generating function for (aerated) small Schröder numbers s_n. The first lattice derivation of a generating function for the sequence $\{s_n\}$ apparently is in Ref. 22, but this was in another context. From Eq. (3.21), the small and large Schröder numbers can be related using

$$S(z^2) = \frac{1}{1-z^2R(z^2)}\,. \tag{3.24}$$

Subcase 3.2.2. Under the $(1,1,1)$ metric, i.e. on the isotropic triangular lattice, the perimeter generating function for bouncy walks is

$$\check{L}(z^2,z) = \frac{1}{2z}\left(1-\sqrt{\frac{1-3z}{1+z}}\right)\,. \tag{3.25}$$

The sequence of coefficients $\{[z^n]\check{L}(z^2,z)\}$ was first considered in the context of rooted trees in Ref. 39, where it was referred to as $\{\gamma_n\}$. The numbers γ_n count the number of bouncy walks of length n on the $\mathbb{T}$ lattice under the $(1,1,1)$ metric.[e] One example of their relationship to Motzkin numbers (that counted return walks under the same metric), is, from Eq. (3.21),

$$\check{L}(z^2,z) = \frac{1}{1-z^2M(z)}\,. \tag{3.26}$$

This relation was shown algebraically in Ref. 54 (p. 277).

3.2. *Ballot walks*

A ballot walk, in the literature often called a ballot path or a left factor, is a walk that starts on the wall remains in the half-plane on or above the wall, and finishes at an arbitrary (integer) height above the wall. On the $\mathbb{S}$ lattice, such a walk is a representation of a ballot between two candidates A and B, where at any point in the counting, A always has at least as many votes as B. Ballot problems have been generalised to include various kinds of winning margins, further candidates and in other ways. One summary of their early history is found in Ref. 62.

A ballot walk can be decomposed into sections, called "terraces", by considering the last site at which the walk is at each height value less than the final height.[61]

[e]More recently, the coefficients have been called the ring numbers, and also Riordan numbers.[56] Further properties of the sequence γ_n are found in Refs. 46 and 54 and in particular in Ref. 56.

The section of a ballot walk that is after the last step that leaves a height $h = i$, and before the last step that leaves height $h = i+1$, is a (sub)-walk that starts and ends at height $h+1$, and does not drop below height $h+1$. This is shown in Fig. 7. Thus ballot walks can be described in terms of return walks.

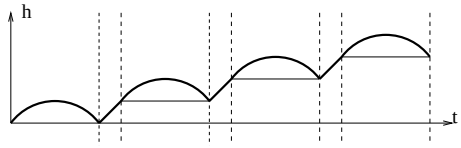

Fig. 7. A ballot walk can be described in terms of return walks.

Anisotropic length generating functions on the $\mathbb{T}$ lattice can be used to construct length generating functions for ballot walks ending at height k under various metrics. Indeed, if $\mathbf{B}_k(x, y, d; \kappa, \mu)$ is a generating function enumerating ballot walks that end at height k above the wall by types of steps and also by return contacts, then

$$\mathbf{B}_k(x, y, d; \kappa, \mu) = \mathbf{L}(v, d; \kappa, \mu) y^k L(xy, d)^k \,, \tag{3.27}$$

and a function enumerating ballot walks by types of steps, return contacts and height is then

$$\mathbf{B}(x, y, d; \kappa, \mu; w) = \sum_{k \geq 0} \mathbf{B}_k(x, y, d; \kappa, \mu) w^k = \frac{\mathbf{L}(v, d; \kappa, \mu)}{1 - yL(xy, d)w} \,. \tag{3.28}$$

4. Return Walks by Length and Area

4.1. *Continued fraction generating functions*

With $\mathcal{W}$ denoting the set of return walks on the $\mathbb{T}$ lattice, let $A(v, d; q)$ be the generating function

$$A(v, d; q) = \sum_{w \in \mathcal{W}} v^{a(w)} d^{c(w)} q^{i(w)}$$

that enumerates return walks by types of steps and standard area, where the standard area of a return walk on the $\mathbb{T}$ lattice is the number of triangular cells enclosed between it and the wall. A walk w with $a(w)$ up (and so down) steps and $c(w)$ horizontal steps that encloses $i(w)$ units of area between it and the wall then contributes a $v^{a(w)} d^{c(w)} q^{i(w)}$ term to $A(v, d; q)$.

Example 4.1. There are six return walks on the $\mathbb{T}$ lattice that consist of an up step, a down step and two horizontal steps. Of these, the walks of (a), (b) and (c) in Fig. 8 each enclose one (triangular) cell, (d) and (f) each enclose three cells

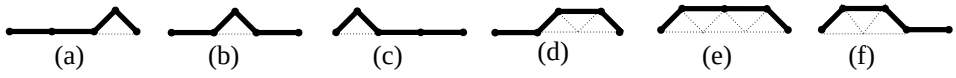

Fig. 8. Cells enclosed by return walks that each have anisotropic length term of vd^2.

and the elevated walk (e) encloses five cells. Thus these six walks contribute a $vd^2(3q + q^3 + q^5)$ term to $A(v, d; q)$.

A continued fraction representation of $A(v, d; q)$ is found here by decomposing return walks at their first return to the wall, as was done to find $L(v, d)$. By considering the area enclosed before the first return for each category of walk in the decomposition of Fig. 4 the equation

$$A(v, d; q) = 1 + dA(v, d; q) + vqA(vq^2, dq^2; q)A(v, d; q) \tag{4.29}$$

is obtained. The similar relation (2.2) for $L(v, d)$ had an algebraic solution, but Eq. (4.29) does not, due to the $A(vq^2, dq^2; q)$ term. By collecting the $A(v, d; q)$ terms, however, a continued fraction representation of $A(v, d; q)$ is found as

$$\begin{aligned} A(v, d; q) &= \frac{1}{1 - d - vqA(vq^2, dq^2; q)} \\ &= \frac{1}{1 - d -} \frac{vq}{1 - dq^2 -} \frac{vq^3}{1 - dq^4 -} \cdots \frac{vq^{2h+1}}{1 - dq^{2h+2} - \cdots}. \end{aligned} \tag{4.30}$$

A corresponding function for elevated walks is then

$$\hat{A}(v, d; q) = vqA(vq^2, dq^2; q) \frac{vq}{1 - dq^2 -} \frac{vq^3}{1 - dq^4 -} \cdots \frac{vq^{2h+1}}{1 - dq^{2h+2} - \cdots}. \tag{4.31}$$

An alternative derivation of these continued fractions, presented in Ref. 10 and also noted in Ref. 52, is to include in the function $L^{\#}$ for example, i.e. in Eq. (2.8), the area under steps at each height level via substitutions such as $v_i \to q^{2i+1}v^i$.

4.2. *Infinite sum generating functions*

In previous sections the set of return walks was assumed to be already constructed, and relations satisfied by generating functions were derived by categorising the walks in the set by their component sections between contacts with the wall. If, instead, the set of return walks is built up by starting with walks of minimal length and applying operators to construct progressively longer walks, then relations satisfied by generating functions can also be derived from the construction process.

In particular, a "local expansion" of the *last fall* (of down steps to the ending site) of return walks that was introduced in Ref. 63 can be used to construct walks recursively from other walks. An equation satisfied by a generating function enumerating return walks by their length, area and number of steps in their last fall can be derived from the expansion. This method of enumerating combinatorial objects

by constructing objects of given size (here length) from objects of smaller size has been applied to find generating functions enumerating return walks by length and standard area, and also length and the so-called non-decreasing-point-area (which we will denote $\triangle$-area: see later for definition) in Refs. 31 and 63. It is known as the *Enumerating Combinatorial Objects method* (or ECO method) and can be used for the enumeration of more general combinatorial objects also. More details and examples can be found in Refs. 64 and 65 and the references therein.

In this section, the ECO method is used to find an equation satisfied by a generating function that enumerates *elevated* walks on the $\mathbb{T}$ lattice by types of steps, standard area and steps in their last fall. The function $\hat{A}(v, d; q)$ is obtained from this equation by an iterative technique. We then consider contact weights.

4.3. *The Enumerating Combinatorial Objects method*

The essence of the Enumerating Combinatorial Objects (ECO) method is the following proposition that is found in Ref. 63, amongst others:

Proposition 4.1. *Let $\mathcal{S}$ be a class of combinatorial objects and $\mathcal{S}_n$ the subsets of objects having a fixed size n. Define the operator Θ on $\mathcal{S}_n$ as a function from $\mathcal{S}_n$ to the power set of the elements of $\mathcal{S}_{n+1}$. Suppose that Θ is an operator on $\mathcal{S}$ (and so on $\mathcal{S}_n$ for all n).*

If for all $Y \in \mathcal{S}_{n+1}$, there exists an $X \in \mathcal{S}_n$ such that $Y \in \Theta(X)$, and, if for all $X_1, X_2 \in \mathcal{S}_n$ with $X_1 \neq X_2$, $\Theta(X_1) \cap \Theta(X_2) = \emptyset$, then the set family $\mathcal{O} = \{\Theta(X) | X \in \mathcal{S}_n\}$ is a partition of $\mathcal{S}_{n+1}$.

That is, if for a given class $\mathcal{S}$ such an operator Θ can be found, each element of $\mathcal{S}_{n+1}$ can be constructed via Θ from one and only one element of $\mathcal{S}_n$. The elements of $\mathcal{S}_n$ would then have a recursive description. Often, as is the case here, a functional equation for a generating function enumerating elements of $\mathcal{S}$ can be derived from this description.

Here, the ECO method is used to enumerate elevated walks; from this an expression for the area-perimeter function $\hat{A}(v, d; q)$ is obtained. The method requires a set of objects and an operator on that set in order to generate the objects recursively. Let the set of elevated walks on the $\mathbb{T}$ lattice be denoted by $\mathcal{E}$. An appropriate class of elevated walks on which to apply the ECO method is the set $\mathcal{E}_{2n}$ defined here as those walks that have ending site at $(t, h) = (2n, 0)$. A satisfactory choice of operator is one that from $\mathcal{E}_{2n}$ constructs all elements of the set of elevated walks $\mathcal{E}_{2n+2}$ by inserting an up-and-down peak (represented by $xy = v$) or a horizontal step (d) into the last fall of w. If this operator is denoted as $\Theta_{\mathcal{E}}$, then

$$\begin{aligned}
&\Theta_{\mathcal{E}} : \mathcal{E}_{2n} \to \mathcal{E}_{2n+2}, \\
&\Theta_{\mathcal{E}}(w) = \{u \in \mathcal{E}_{2n+2}, u = w' C w'', \text{ with } w = w' w'', \\
&\qquad\qquad w'' \in \{y, yy, yyy, \ldots\}, C \in \{v, d\}\}\,. \qquad (4.32)
\end{aligned}$$

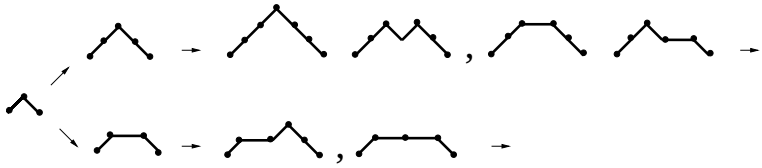

Fig. 9. Construction of the set of elevated walks from the up-down step pair walk via the operator $\Theta_{\mathcal{E}}$.

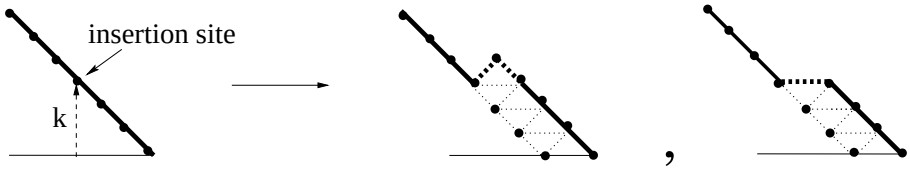

Fig. 10. Elevated walks obtained by inserting a peak or horizontal step in the last fall of an elevated walk, with extra cells enclosed shown.

Proof that this operator $\Theta_{\mathcal{E}}$ on $\mathcal{E}$ satisfies Proposition 4.1 follows the proofs of similar results in Refs. 31 and 63 and is not detailed here. The construction of the sets $\mathcal{E}_{2n}$ from the (shortest) elevated walk, the up-down step pair, is shown for small n in Fig. 9.

The insertion of an extra step or step pair to the last fall adds both steps and units of area to an elevated walk. Let the variable s count the number of steps in the last fall of the walk and let $\hat{W}(s; v, d; q)$ (or $\hat{W}(s)$ for short) be the generating function

$$\hat{W}(s; v, d; q) = \sum_{w \in \mathcal{E}} s^{\mathrm{fall}(w)} v^{a(w)} d^{c(w)} q^{i(w)} \tag{4.33}$$

that enumerates elevated walks by steps in the last fall, types of steps and standard area. The desired function, the area-perimeter function $\hat{A}(v, d; q)$, is then simply $\hat{W}(1; v, d; q)$.

The set of elevated walks $\mathcal{E}$ can be reclassified into sets according to the number of steps $\mathrm{fall}(w)$ of the last fall. For any elevated walk w, suppose the insertion in the last fall is made at height k, where $1 \le k \le \mathrm{fall}(w)$ since the result of applying $\Theta_{\mathcal{E}}$ must still be an elevated walk. If the insertion is a peak, this constructs a new walk with $\mathrm{fall}(w) = k+1$ and area $2k+1$ units larger than that of w. Similarly, inserting a horizontal step constructs a new walk with $\mathrm{fall}(w) = k$ and area increased over that of w by $2k$ units. These insertions are shown in Fig. 10.

A functional equation for $\hat{W}(s)$ is found by collecting together the results of applying $\Theta_{\mathcal{E}}$ on all elevated walks, and adding to this the shortest elevated walk, the up-down step pair, that cannot be generated by $\Theta_{\mathcal{E}}$.

Thus

$$\begin{aligned}\hat{W}(s) &= svq + \sum_{w\in\mathcal{E}}\sum_{k=1}^{\mathrm{fall}(w)}\{s^{k+1}v^{a(w)+1}d^{c(w)}q^{i(w)+2k+1} + s^k v^{a(w)}d^{c(w)+1}q^{i(w)+2k}\}\\ &= svq + (d+svq)\frac{sq^2}{1-sq^2}\sum_{w\in\mathcal{E}} v^{a(w)}d^{c(w)}q^{i(w)}(1-(sq^2)^{\mathrm{fall}(w)})\\ &= svq + (d+svq)\frac{sq^2}{1-sq^2}(\hat{W}(1)-\hat{W}(sq^2))\,. \end{aligned} \tag{4.34}$$

4.4. *Iterative solutions of functional equations*

The functional equation (4.34) contains the desired $\hat{W}(1)$ term but also a $\hat{W}(s)$ and a $\hat{W}(sq^2)$ term. It cannot be solved immediately for $\hat{W}(1)$ if information about the area enclosed by the walk, given by the exponent of q, is to be retained, since some contribution to this exponent comes from the $\hat{W}(sq^2)$ term. Commonly a solution for $\hat{W}(1)$ is found by iterating the functional equation to remove the $\hat{W}(sq^2)$ term. The telescoping technique used below is well-known; the presentation of it here is based upon that in Ref. 66.

If in Eq. (4.34), s is replaced with sq^2, then the equation

$$\hat{W}(sq^2) = svq^3 + (d+svq^3)\frac{sq^4}{1-sq^4}(\hat{W}(1)-\hat{W}(sq^4)) \tag{4.35}$$

is obtained, so that the $\hat{W}(sq^2)$ term can be removed in Eq. (4.34), leaving

$$\begin{aligned}\hat{W}(s) = svq &- (d+svq)\frac{sq^2}{1-sq^2}svq^3\\ &+ (d+svq)\frac{sq^2}{1-sq^2}\left(1-(d+svq^3)\frac{sq^4}{1-sq^4}\right)\hat{W}(1)\\ &+ (d+svq)\frac{sq^2}{1-sq^2}(d+svq^3)\frac{sq^4}{1-sq^4}\hat{W}(sq^4)\,. \end{aligned} \tag{4.36}$$

The substitution $s\to sq^2$ can then be used in Eq. (4.35) to obtain a relation between $\hat{W}(sq^4)$, $\hat{W}(1)$ and $\hat{W}(sq^6)$, and then again in this latter relation to obtain a further relation between $\hat{W}(sq^6), \hat{W}(1)$ and $\hat{W}(sq^8)$, and so on. After N iterations of the substitution,

$$\begin{aligned}\hat{W}(s) = svq &\left(1+\sum_{n\geq 1}^{N}(-1)^n\prod_{j=1}^{n}sq^2\frac{q^{2j}(d+svq^{2j-1})}{1-sq^{2j}}\right)\\ &+\left(\sum_{n\geq 0}^{N}(-1)^n\prod_{j=0}^{n}sq^2\frac{q^{2j}(d+svq^{2j+1})}{1-sq^{2j+2}}\right)\hat{W}(1)\\ &-\left((-1)^N\prod_{j=0}^{N}sq^2\frac{q^{2j}(d+svq^{2j+1})}{1-sq^{2j+2}}\right)\hat{W}(sq^{2N+2})\,. \end{aligned} \tag{4.37}$$

The coefficient that is the left part of the final term of Eq. (4.37) is a product, not a sum of products. If the length variables d and v in the equation are isotropised to z^γ and $z^{\alpha+\beta}$, then the minimum exponent of z in the entire final term will be at least either $(N+1)\gamma$ or $(N+1)(\alpha+\beta)$, both of which increase with N. Thus in the limit $N \to \infty$, then, Eq. (4.37) is

$$\hat{W}(s) = svq \left(1 + \sum_{n\geq 1} (-1)^n \prod_{j=1}^{n} sq^2 \frac{q^{2j}(d + svq^{2j-1})}{1 - sq^{2j}} \right) + \left(\sum_{n\geq 0} (-1)^n \prod_{j=0}^{n} sq^2 \frac{q^{2j}(d + svq^{2j+1})}{1 - sq^{2j+2}} \right) \hat{W}(1)\,. \tag{4.38}$$

The functional equation (4.34) has now been reduced to an equation with just $\hat{W}(1)$ and $\hat{W}(s)$ terms. The variable s counting the last fall is not needed in $\hat{A}(v, d; q) = \hat{W}(1)$, so setting s to 1 in Eq. (4.38) and rearranging gives the desired $\hat{A}(v, d; q)$ as

$$\hat{A}(v, d; q) = \frac{vq \sum_{n\geq 0} (-1)^n q^{n(n+3)} (q^2; q^2)_n^{-1} \prod_{j=1}^{n} (d + vq^{2j-1})}{\sum_{n\geq 0} (-1)^n q^{n(n+1)} (q^2; q^2)_n^{-1} \prod_{j=1}^{n} (d + vq^{2j-1})}, \tag{4.39}$$

where the notation

$$(a; q)_j = \prod_{j=0}^{n-1} (1 - aq^j), \qquad (a; q)_0 = 1 \tag{4.40}$$

has been used.

Hence the generating function for return walks is found from Eqs. (4.30), (4.31) and (4.39) as

$$A(v, d; q) = \frac{\sum_{n\geq 0} (-1)^n q^{n(n+1)} (q^2; q^2)_n^{-1} \prod_{j=1}^{n} (d + vq^{2j-1})}{\sum_{n\geq 0} (-1)^n q^{n(n-1)} (q^2; q^2)_n^{-1} \prod_{j=1}^{n} (d + vq^{2j-1})}\,. \tag{4.41}$$

Case 4.1 (Return walks on the isotropic $\mathbb{S}$ lattice). The $\mathbb{S}$ lattice is the $\mathbb{T}$ lattice under the $(1, 1, -)$ metric, so from Eq. (4.41) we have

$$A(z^2, 0; q) = \frac{1}{1-} \frac{z^2 q}{1-} \frac{z^2 q^3}{1-} \cdots \frac{z^2 q^{2h+1}}{1 - \cdots} = \frac{\sum_{n\geq 0} (-z^2)^n q^{2n^2+n} (q^2; q^2)_n^{-1}}{\sum_{n\geq 0} (-z^2)^n q^{2n^2-n} (q^2; q^2)_n^{-1}}\,. \tag{4.42}$$

A lattice derivation of the first line of this equation can be found in Ref. 10, whilst the second line is a special case of a more general result [Ref. 14, Thm.12] which was derived using a different method. The equation is also an identity related to the so-called Rogers–Ramanujan continued fraction.[67]

Both representations of $A(z^2, 0; q)$ in Eq. (4.42) are q-analogues of $L(z^2, 0)$. Similarly, the representation of $\hat{A}(v, d; q)$ in Eq. (4.39) is a q-analogue of $\hat{L}(v, d)$ just

as was the representation in Eq. (4.31). Unlike continued fractions, however, with ratios of infinite sums it is not possible to set q to 1 and obtain the anisotropic length generating function, because the expressions are singular at $q = 1$. Nonetheless, length generating functions can still be obtained from intermediate results in the derivation of the infinite sums. For example, the function $\hat{L}(v, d)$ can be obtained by setting $q = 1$ in Eq. (4.34) and collecting terms. Such a derivation is an example of what has become known as the *kernel method*, for which see Ref. 68 (with references therein) and also Ref. 69

4.5. *Return walks with contact weights and area*

In a similar manner to the perimeter-only generating functions in Sec. 3, contact weights can be included in the discussion by using the decomposition of return walks into pieces including elevated walks. The same can be done for length-area generating functions. Indeed, a return walk can be split by returns to the wall into single horizontal steps along the wall and elevated walks, and we note that horizontal steps along the wall do not enclose any area. Hence, the generating function $\mathbf{A}(v, d; q; \kappa, \mu)$ enumerating return walks according to their steps, the area under the walks, and the types of return contact (as described in Sec. 3) weighted by κ and μ satisfies the functional equation

$$\mathbf{A}(v, d; q; \kappa, \mu) = \frac{1}{1 - \mu d - \kappa \hat{A}(v, d; q)}. \tag{4.43}$$

Substitution of Eq. (4.39) and some rearrangement leads to

$$\mathbf{A}(v, d; q; \kappa, \mu) = \frac{\sum_{n\geq 0}(-1)^n q^{n(n+1)}(q^2; q^2)_n^{-1} \prod_{j=1}^{n}(d + vq^{2j-1})}{\sum_{n\geq 0} \mathbf{G}_n(d; q; \kappa, \mu)(-1)^n q^{n(n-1)}(q^2; q^2)_n^{-1} \prod_{j=1}^{n}(d + vq^{2j-1})}, \tag{4.44}$$

where

$$\mathbf{G}_n(d; q; \kappa, \mu) = \kappa(1 - q^{2n}) + q^{2n} + (\kappa - \mu)dq^{2n}. \tag{4.45}$$

4.6. *Walks by length and $\triangle$-area*

The $\triangle$-area of a return walk on the $\mathbb{T}$ lattice is the number of *up* triangular cells enclosed between the walk and the wall. An *up* triangle, denoted $\triangle$, is one which has an apex pointing upwards. Functions that are derived using $\triangle$-area are given a up-pointing triangular ($_\triangle$) subscript. The $\triangle$-area is also known as the non-decreasing-point-area.

Example 4.2. Of the six return walks on the $\mathbb{T}$ lattice represented by the anisotropic length term vd^2, the walks (a)–(c) in Fig. 11 enclose one unit of $\triangle$-area, (d) and (f) each enclose two units and (e) encloses three units.

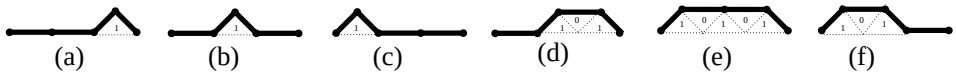

Fig. 11. The △-area of walks that are represented by the anisotropic length term vd^2, as the sum of the number of up triangles.

Generating functions enumerating elevated or return walks by △-area as well as other characteristics can be found by the same processes that led to the corresponding standard area functions above. Such functions, however, are linked by the observation that the standard area for single walks can be found in terms of the △-area:

$$A_{\triangle}(v, d; q) = A(\sqrt{q}v, d; \sqrt{q}) \tag{4.46}$$

and

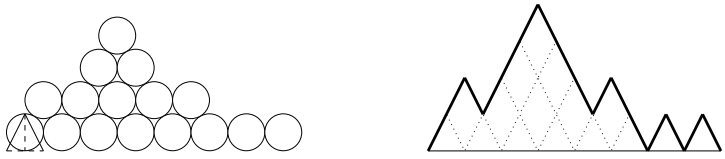
$$\hat{A}_{\triangle}(v, d; q) = \hat{A}(\sqrt{q}v, d; \sqrt{q})\,. \tag{4.47}$$

It appears that △-area was first used as a definition of the area of a walk in Ref. 63 for Motzkin paths; these biject to walks under the $(1, 1, 1)$ metric, so giving $A_{\triangle}(z^2, z; q)$. The △-area has since been used to find $A_{\triangle}(z^2, dz^2; q)$, i.e. to consider return walks under the $(1, 1, 2)$ metric also enumerated by the number of horizontal steps; these walks were then related to permutations with forbidden sequences enumerated by number of inversions in Ref. 31. Both of these previous uses considered walks on one lattice; here they have been generalised by the enumeration of walks by types of steps on the $\mathbb{T}$ lattice, and by the inclusion of contact weights.

4.7. *Fountains of coins*

A *fountain* of coins is an arrangement of identical circles in rows such that any circle not in the bottom row is supported by, i.e. touches, exactly two circles in the row below. An (n, k)-fountain is then an arrangement of n coins into rows such that there are k coins in the bottom row.[70] A $(16, 8)$-fountain is shown in Fig. 12(a). Fountains of coins have been studied in both statistical mechanics and combinatorics over the past fifty years. An early study of fountains of coins is Ref. 71, in which fountains were used to enumerate partitions of a set into smaller sets under certain restrictions. The fountains used had a single contiguous block of coins in each row (since called *block fountains*[72]). Another partition enumeration problem, solved in Ref. 73, gave a combinatorial interpretation of the continued fraction of $A_{\triangle}(z^2, 0; q)$, in that the number of partitions of $n + \binom{k}{2}$ for which the largest part is k and for all $i, 1 \leq i \leq k$, the ith part is at least i, is $[z^{2k}q^n]A_{\triangle}(z^2, 0; q)$. This second partition problem can also be represented by fountains (see Ref. 70).

An expression for $A_{\triangle}(z^2, 0; q)$ as a generating function enumerating fountains of coins is found in Ref. 70. There, the function was found by decomposing fountains in a manner similar to decomposing walks by their first return to the wall. These



(a) (b)

Fig. 12. (a) A $(16, 8)$-fountain; (b) the return walk on the parallelogram lattice corresponding to the fountain.

general (i.e. not just block) fountains had previously been mentioned in Ref. 74. Here, in a different method, a construction linking fountains and triangles of $\triangle$-area of return walks on the $\mathbb{S}$ lattice is used to show that $A_{\triangle}(z, 0; q)$ is a generating function enumerating fountains by coins in the bottom row (counted by z) and coins in total (counted by q).

A section of a parallelogram lattice can be constructed from a fountain as is clear from Fig. 12. Each coin corresponds to one unit of $\triangle$-area, as can be seen by inserting a horizontal line across the middle of each parallelogram cell of the lattice and marking the up-pointing triangles. This parallelogram lattice is equivalent under a planar isomorphism to the $\mathbb{S}$ lattice. Thus an (n, k)-fountain bijects to a return walk on the $\mathbb{S}$ lattice of length $2k$ and $\triangle$-area of n units. A similar bijection was given in Ref. 75.

A generating function for (n, k)-fountains according to total number of coins (counted by q) and number of coins in the bottom row (counted by z) is then

$$A_{\triangle}(z, 0; q) = \frac{1}{1-}\frac{zq}{1-}\frac{zq^2}{1-}\cdots\frac{zq^{h+1}}{1-\cdots} = \frac{\sum_{n\geq 0}(-z)^n q^{n(n+1)}(q;q)_n^{-1}}{\sum_{n\geq 0}(-z)^n q^{n^2}(q;q)_n^{-1}}\,. \tag{4.48}$$

It is well-known (for example, see Refs. 4 and 70) that the number of fountains with k coins in the bottom row (regardless of n) is the kth Catalan number c_k; this can be deduced by treating fountains as return walks.

Another question asked about fountains, however, seeks to find the number of fountains of n coins in total, regardless of the number in the bottom row. This question is then equivalent to one asking for the number of return walks of given $\triangle$-area on the $\mathbb{S}$ lattice, regardless of length, and is answered by setting $z = 1$ and considering only the area variable q in Eq. (4.48).

5. First Area-Moment of Walks

Let $\mathbf{TA}(v, d; \kappa, \mu)$ be the generating function

$$\mathbf{TA}(v, d; \kappa, \mu) = \sum_{w\in\mathcal{W}} i(w) v^{a(w)} d^{c(w)} \kappa^{m(w)} \mu^{n(w)} \tag{5.49}$$

that enumerates return walks by types of steps and by return contacts, and in which each walk is given a coefficient weighting equal to its standard area $i(w)$.

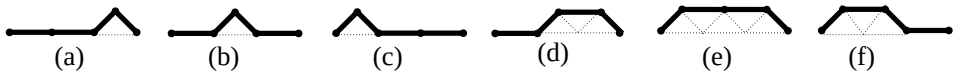


Fig. 13. Return walks that have anisotropic length term of vd^2.

The coefficient of $v^a d^c$ in $\mathbf{TA}(v, d; \kappa, \mu)$ is then the contact-weighted total of the areas of all return walks with that set of steps. The functions $\mathbf{TA}_{\triangle}(v, d; \kappa, \mu)$, for which $\triangle$-area is counted, and $\widehat{TA}(v, d)$ and $\widehat{TA}_{\triangle}(v, d)$, which enumerate the first area-moment enclosed by elevated walks in units of standard area and $\triangle$-area respectively, are defined similarly. Here generating functions enumerating the first area-moment of walks by their length are called *first area-moment* functions.

Example 5.1. Of the six return walks on the $\mathbb{T}$ lattice that have anisotropic length term of vd^2, three enclose one unit of standard area each, two enclose three units each and one encloses five units. Thus the total of the standard areas of those return walks is 14 units. Since the $\triangle$-area of a return walk is the number of up triangles enclosed between the walk and the wall, the total of the $\triangle$-areas of return walks that have anisotropic length term of xyd^3 is 10 units.

In theory, all area-moment functions could be calculated as q-derivatives of the corresponding length-area functions found in Sec. 4. For example,

$$\mathbf{TA}(v, d; \kappa, \mu) = \left[q \frac{\partial}{\partial q} \mathbf{A}(v, d; q; \kappa, \mu) \right]_{q=1} . \tag{5.50}$$

It is possible to find such derivatives from the functional equations, such as Eq. (4.29) for first area-moment functions. We however take a different route, more combinatorial in nature that can prove useful in more complex situations. Here, first area-moment functions are found considering the two-dimensional area as a sum of one-dimensional heights. The standard area of a walk on the $\mathbb{T}$ lattice is also the sum of the heights of the walk at all integer values of the t coordinate since the area in one column of the walk is simply the height of that column. If the height of the walk, w, at $t = i$ is denoted by $h_i(w)$, then

$$\mathbf{TA}(v, d; \kappa, \mu) = \sum_{w \in \mathcal{W}} \left\{ \sum_{i \geq 0} h_i(w) \right\} v^{a(w)} d^{c(w)} \kappa^{m(w)} \mu^{n(w)} . \tag{5.51}$$

The first area-moment of the set of elevated walks of a given length on the $\mathbb{T}$ lattice under the $(1, 1, 2)$ metric has been studied in Ref. 76 and the generating function $\widehat{TA}(z^2, z^2)$ in Ref. 52. In Refs. 77 and 78, both this function and the corresponding $\mathbb{S}$ lattice function $\widehat{TA}(z^2, 0)$ were considered, and in Ref. 40, the first area-moments of "generalised Motzkin paths", including both of these previous cases, were studied. The first area-moment of return walks on the $\mathbb{S}$ lattice, i.e. $TA(z^2, 0)$, was considered in Refs. 59 and 79, and the function $TA(z^2, z^2)$ was studied in Ref. 52. The generalisation to return walks on graphs that are not necessarily

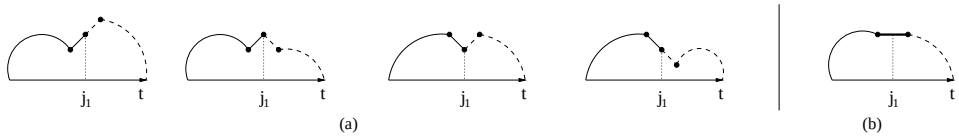

Fig. 14. Elevated walks that pass through (j_1, k): (a) at the end of a step; (b) in the middle of a horizontal step.

lattices formed from tilings of the plane was made in Ref. 80, and more recently in Ref. 14.

The total $\triangle$-area of a set of walks, however, does not appear to have been studied. The alternate (and original) definition of the $\triangle$-area of a walk is as the sum of the heights of the walk at the endpoint of each up step or horizontal step. Thus, if $\mathcal{I}_{\triangle}(w)$ is used to denote the subset of the integer t coordinates at which up or horizontal steps of a walk w end,

$$\mathbf{TA}_{\triangle}(v, d; \kappa, \mu) = \sum_{w \in \mathcal{W}} \left\{ \sum_{i \in \mathcal{I}_{\triangle}(w)} h_i \right\} v^{a(w)} d^{c(w)} \kappa^{m(w)} \mu^{n(w)} \,. \tag{5.52}$$

In this section, general expressions are found for $\widehat{TA}(v, d)$ and $\mathbf{TA}(v, d; \kappa, \mu)$, and for the corresponding $\triangle$-area functions also. Length metrics are then used to give examples of first area-moment functions on various lattice systems.

5.1. *First area-moment of elevated walks*

To find a generating function enumerating the first area-moment of elevated walks by their length, it is convenient to take the collection of height values of all the walks and regroup them by the value of the height. Here, this is done for the standard area case; the $\triangle$-area case can be derived in the same manner.

If $\widehat{K}_k(v, d)$ is a generating function in which the coefficient of $v^{a(w)} d^{c(w)}$ is the number of points at integer coordinates of t that are at height k in all elevated walks with that set of steps, then

$$\widehat{TA}(v, d) = \sum_{k \geq 0} k \hat{K}_k(v, d) \,. \tag{5.53}$$

The function $\widehat{TA}(v, d)$ is found here by first deriving an expression for $\hat{K}_k(v, d)$ via a convolution previously used in Refs. 40 and 79 which in turn is based upon the one in Ref. 81.

Suppose an elevated walk ends at $(t, h) = (j_2, 0)$. If the walk passes through the coordinate (j_1, k), then at that point, the walk is either at the end of a step or in the middle of a horizontal step, as is shown in Fig. 14.

In the first case, the number of walk configurations from $(0, 0)$ to (j_1, k) is equal to the number of ballot walks from the origin to (j_1, k) that do not return to the wall. The remainder of the elevated walk, from (j_1, k) to the endpoint, is then the *reverse*

of a similarly restricted ballot walk from the origin to $(j_2 - j_1, k)$. In the second case, since the walk must include a horizontal step from $(j_1 - 1, k)$ to $(j_1 + 1, k)$, the relevant ballot walks are from the origin to $(j_1 - 1, k)$ and $(j_2 - j_1 - 1, k)$. The anisotropic length generating function of ballot walks from the origin to a site at height k that do not return to the wall is, from Eq. (3.27), equal to $y^k L(xy, d)^k$ and so the corresponding function for reversed ballot walks from height k that end at the wall but do not drop down to it before then is $x^k L(xy, d)^k$. Thus, summing ballot walks over j_1 and j_2 gives, for $k \geq 1$, and where as previously $v = xy$,

$$\widehat{K}_k(v, d) = v^k L(v, d)^{2k}(1 + d)\,, \tag{5.54}$$

from which

$$\begin{aligned}\widehat{TA}(v, d) = (1 + d)\sum_{k\geq 0} k v^k L(v, d)^{2k} &= (1 + d)\frac{vL(v, d)^2}{\left(1 - vL(v, d)^2\right)^2} \\ &= (1 + d)\frac{v}{\left(1 - d - 2vL(v, d)\right)^2} \\ &= \frac{v(1 + d)}{(1 - d)^2 - 4v}\,,\end{aligned} \tag{5.55}$$

where the second-last equality follows from Eq. (2.2) and the final equality from Eq. (2.4).

The corresponding function for the total $\triangle$-area of elevated walks of a given set of steps, $\widehat{TA}_{\triangle}(v, d)$, can be found by a similar convolution of ballot walks as

$$\widehat{TA}_{\triangle}(v, d) = \frac{v}{(1 - d)^2 - 4v}\frac{1 + dL(v, d)}{L(v, d)} = \frac{v}{(1 - d)^2 - 4v}\frac{1 + d + \sqrt{(1 - d)^2 - 4v}}{2}\,. \tag{5.56}$$

5.2. *First area-moment of return walks*

Generating functions enumerating the first area-moment of return walks by types of steps and return contacts can be derived from the corresponding functions for elevated walks. The method used in this section, as was used for similar derivations in the first two sections, is that of decomposing a return walk at its returns to the wall.

The following lemma relates the value of a function summed across all integer coordinates passed through by an elevated walk to the value of the same function summed across a return walk, and is styled on a similar lemma for walks on the $\mathbb{S}$ lattice in Ref. 59.

Lemma 1. *Let ϕ be a real-valued function on the non-negative integers and suppose that $\phi(0) = 0$. For $\mathcal{W}$ (sim. $\mathcal{E}$) the set of return (elevated) walks on the $\mathbb{T}$*

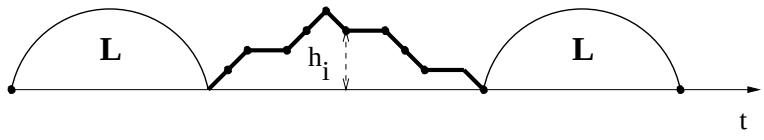

Fig. 15. Isolation of an elevated component of a return walk.

lattice, $\mathcal{I}(w)$ *the set of integer values of the* t *coordinate passed through by a walk* w *and* h_i *the* h *coordinate of a walk at* $t = i$*, the generating functions*

$$\mathbf{F}_\phi(v, d; \kappa, \mu) = \sum_{w \in \mathcal{W}} \left\{ \sum_{i \in \mathcal{I}(w)} \phi(h_i) \right\} v^{a(w)} d^{c(w)} \kappa^{m(w)} \mu^{n(w)} \tag{5.57}$$

and

$$\widehat{F}_\phi(v, d) = \sum_{w \in \mathcal{E}} \left\{ \sum_{i \in \mathcal{I}(w)} \phi(h_i) \right\} v^{a(w)} d^{c(w)} \tag{5.58}$$

satisfy

$$\mathbf{F}_\phi(v, d; \kappa, \mu) = \kappa \hat{F}_\phi(v, d) \mathbf{L}(v, d; \kappa, \mu)^2 \,, \tag{5.59}$$

where $\mathbf{L}(v, d; \kappa, \mu)$ *is a generating function enumerating return walks by types of steps and return contacts.*

Proof. The function ϕ is summed across its values at the heights of the walk at each integer t coordinate. Since ϕ takes the value zero at any coordinate at which the walk is at height 0, the coefficient of the term in $\mathbf{F}_\phi(v, d; \kappa, \mu)$ contributed by a return walk is therefore the sum of the areas of each of its elevated walk components. Any return walk w that does not have an elevated walk component is a concatenation of zero or more horizontal steps along the wall. The sum of the values of $\phi(h_i)$ across such a walk is then zero, so walks without elevated components can be discarded from consideration.

A new set of walks can be constructed by making as many copies of every walk $w \in \mathcal{W}$ as there are elevated components in w, and in each copy marking one of the components. This new set of *marked area walks* can be reordered by grouping together all walks that have the same marked component. Each element in a group can be characterised as being an elevated walk wedged between two (possibly empty) return walks, as is shown in Fig. 15. These two return walks are of arbitrary length, so if $w_1 \in \mathcal{E}$ is the marked elevated component, then the group of walks with that marked component contributes a

$$\mathbf{L}(v, d; \kappa, \mu) \left(\sum_{i \in \mathcal{I}(w_1)} \phi(h_i) v^{a(w_1)} d^{c(w_1)} \kappa \right) \mathbf{L}(v, d; \kappa, \mu) \tag{5.60}$$

term to $\mathbf{F}_\phi(v,d;\kappa,\mu)$. The result follows from summing over all possible elevated walk components. □

Corollary 1. *With* $\phi(h_i)=h_i$,

$$\mathbf{TA}(v,d;\kappa,\mu)=\kappa\widehat{TA}(v,d)\mathbf{L}(v,d;\kappa,\mu)^2\,. \tag{5.61}$$

Lemma 5.1 can be modified to relate the generating functions that enumerate the total $\triangle$-area of elevated and return walks by their types of steps. Indeed, if the set $\mathcal{I}$ is changed to $\mathcal{I}_\triangle$, i.e. the integer values of only the t coordinates at the endpoint of up and horizontal steps of a walk, then for $\phi(h_i)=h_i$

$$\mathbf{TA}_\triangle(v,d;\kappa,\mu)=\kappa\widehat{TA}_\triangle(v,d)\ \mathbf{L}(v,d;\kappa,\mu)^2\,. \tag{5.62}$$

Lemma 5.1 could also be generalised to replace the ϕ functions by, for example, the "possibility functions" described in Ref. 10, or by further changing the restrictions on the coordinate set $\mathcal{I}$, but these extensions are not studied here.

5.3. *Special cases*

Five special cases of first area-moment generating functions for elevated walks now follow. The first three cases use the standard area of a walk, whilst the final two use the $\triangle$-area. The first area-moment generating function for return walks is easily found in each case from Eq. (5.61) or (5.62), and is not always mentioned in the examples.

Case 5.1. Under the $(1,1,-)$ metric, i.e. on the $\mathbb{S}$ lattice,

$$\widehat{TA}(z^2,0)=\frac{z^2}{1-4z^2}\,, \tag{5.63}$$

so the total standard area of all elevated walks of length $2n+2$ is 4^n triangles or $4^n/2$ squares. This is well-known. The result for return walks that have unit contact weights on the square lattice, $\mathbf{TA}(z^2,0;1,1)$, i.e. $TA(z^2,0)$, is

$$TA(z^2,0)=\widehat{TA}(z^2,0)L(z^2,0)^2=\frac{(1-\sqrt{1-4z^2})^2}{4z^2(1-4z^2)}\,, \tag{5.64}$$

which was derived by other means in Ref. 80 and also in Refs. 59 and 79. Asymptotics for this and other first area-moment generating functions are found in Ref. 80.

Case 5.2. Under the $(1,1,2)$-metric,

$$\widehat{TA}(z^2,z^2)=\frac{z^2(1+z^2)}{1-6z^2+z^4}. \tag{5.65}$$

The coefficient of z^{2n} in $\widehat{TA}(z^2,z^2)$ is usually represented as f_n. In Ref. 76, it was shown that $f_n=\sum_{k\geq 0}2^k\binom{2n-1}{2k}$, and also that

$$f_{n+1}=6f_n-f_{n-1},\qquad n\geq 2\,, \tag{5.66}$$

where $f_0 = 1$ and $f_1 = 7$. This recurrence was mentioned again in Ref. 52, and combinatorial proofs of the recurrence which involve lattice walks are found in Refs. 77 and 78. Other articles that discuss this recurrence or the sequence obtained from it are Refs. 85–82. The asymptotics of the corresponding return walk function, $TA(z^2, z^2)$, are considered in Ref. 52.

Case 5.3. Under the $(1, 1, 1)$ metric,

$$\widehat{TA}(z^2, z) = \frac{z^2}{1 - 3z}, \tag{5.67}$$

which may have a combinatorial interpretation similar to that given in Ref. 77 for walks under the $(1, 1, 2)$ metric.

Case 5.4. Under the $(1, 1, -)$ metric, i.e. the $\mathbb{S}$ lattice, the generating function enumerating the total $\triangle$-area of elevated walks by types of steps is

$$\widehat{TA}_{\triangle}(z^2, 0) = \frac{z^2}{1 - 4z^2} \frac{2z^2}{1 - \sqrt{1 - 4z^2}} = \frac{z^2}{1 - 4z^2} \frac{1}{C(z^2)}, \tag{5.68}$$

where, again, $C(z)$ is the generating function of the Catalan numbers. The result for return walks is

$$TA_{\triangle}(z^2, 0) = \widehat{TA}_{\triangle}(z^2, 0) L(z^2, 0)^2 = \frac{1 - \sqrt{1 - 4z^2}}{2(1 - 4z^2)} = \frac{z^2 C(z^2)}{1 - 4z^2}. \tag{5.69}$$

Case 5.5. Under the $(1, 1, 1)$-metric,

$$\widehat{TA}_{\triangle}(z^2, z) = \frac{z^2}{1 - 2z - 3z^2} \frac{1 + z + \sqrt{1 - 2z - 3z^2}}{2} \tag{5.70}$$

and

$$TA_{\triangle}(z^2, z) = \widehat{TA}_{\triangle}(z^2, z) L(z^2, z)^2 = \frac{z^2}{1 - 2z - 3z^2} \frac{1 - z - 2z^2 - \sqrt{1 - 2z - 3z^2}}{2z^3}. \tag{5.71}$$

Although apparently not studied as sequences derived from lattice walks, each of the sequences of coefficients from these four $\triangle$-area functions is listed in Ref. 58; some already have other combinatorial interpretations.

6. Height Moments of Walks

For $r \geq 1$, the *rth total height moment* of a return walk w is here defined to be $\sum_{i \geq 0} (h_i)^r$, i.e. the sum of the rth powers of the height of the walk at each integer t coordinate. For example, the walk in Fig. 16 has sequence of heights $0, 1, 2, 1, 2, 3, 2, 2, 2, 1, 0$ as t ranges from 0 to 10. The first total height moment of the walk is then the sum of the heights (i.e. 16), the second moment the sum of the squares of the heights (32), the third moment the sum of the cubes of the heights (70) and so on. The first total height moment is also the first area moment but higher moments differ.

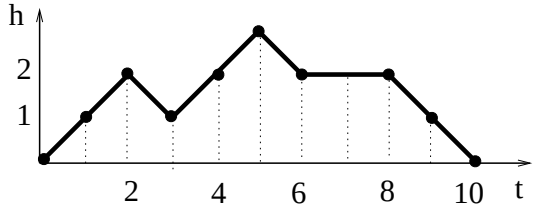

Fig. 16. An elevated walk with first total height moment of 16, second total height moment of 32 and third total height moment of 70.

For $r \geq 1$, let $\widehat{M}_r(v,d)$ be the generating function

$$\widehat{M}_r(v,d) = \sum_{w\in\mathcal{E}} \left\{ \sum_{i\geq 0} (h_i)^r \right\} v^{a(w)} d^{c(w)} \tag{6.72}$$

that enumerates the rth total height moments of elevated walks (the set of which is denoted $\mathcal{E}$) by types of steps. Here, with some abuse of notation, this function is called the *rth moment of elevated walks*. Similar functions have previously been considered in Refs. 40 and 59.

The corresponding moments for return walks are found from Lemma 5.1, with $\phi(h) = h^r$, as

$$\mathbf{M}_r(v,d;\kappa,\mu) = \kappa \widehat{M}_r(v,d)\mathbf{L}(v,d;\kappa,\mu)^2 \,. \tag{6.73}$$

We now derive a formula for $\widehat{M}_r(v,d)$ using a technique similar to that used to solve a $\mathbb{S}$ lattice moment problem in Ref. 86. From Eqs. (6.72), (5.53) and (5.54), an expression for the rth moment of elevated walks is

$$\widehat{M}_r(v,d) = \sum_{k\geq 0} k^r \widehat{K}_k(v,d) = \sum_{k\geq 0} k^r \ (1+d) v^k L(v,d)^{2k} \,. \tag{6.74}$$

An exponential generating function for the moments is

$$\widehat{K}(z) = \sum_{k\geq 1} \widehat{K}_k(v,d) e^{kz} = (1+d) \frac{vL(v,d)^2 e^z}{1 - vL(v,d)^2 e^z} \,, \tag{6.75}$$

in that

$$\left[\frac{z^r}{r!}\right] \widehat{K}(z) = \sum_{k\geq 1} k^r \widehat{K}_k(v,d) = \widehat{M}_r(v,d) \,, \tag{6.76}$$

so

$$\widehat{M}_r(v,d) = \left[\frac{\partial^r}{\partial z^r} \left(\frac{v(1+d)L(v,d)^2 e^z}{1 - vL(v,d)^2 e^z} \right) \right]_{z=0} . \tag{6.77}$$

In Ref. 86, it was mentioned that for a given function D, and for $A(r,j)$ the Eulerian numbers (for which see Ref. 21),

$$\frac{\partial^r}{\partial z^r} \frac{De^z}{1 - De^z} = \frac{\sum_{j=1}^r A(r,j) D^j e^{jz}}{(1 - De^z)^{r+1}} \,, \tag{6.78}$$

and also it was mentioned that that the coefficients $m(r,s)$ for which

$$\sum_{j=1}^{r} A(r,j)x^j = \sum_{s=1}^{\lceil r/2 \rceil} m(r,s)x^s(1+x)^{r+1-2s} \tag{6.79}$$

satisfy the recurrence

$$m(r,s) = sm(r-1,s) + 2(r-2s+2)m(r-1,s-1), \qquad r,s>1 \tag{6.80}$$

with $m(1,1)=1, m(1,p)=0$ for $p \neq 1$. A table of the values of $m(r,s)$ for small r and s is given in Table 1.

Table 1. Table of values of $m(r,s)$ for small r and s.

$s\backslash r$	1	2	3	4
1	1			
2	1			
3	1	2		
4	1	8		
5	1	22	16	
6	1	52	136	
7	1	114	720	272

If Eqs. (6.78)–(6.80) are applied in turn to Eq. (6.77), then

$$\begin{aligned}\widehat{M}_r(v,d) &= \left[\frac{(1+d)\sum_{j=1}^{r} A(r,j)v^j L(v,d)^{2j}e^{jz}}{(1-vL(v,d)^2e^z)^{r+1}}\right]_{z=0} \\ &= \frac{(1+d)\sum_{s=1}^{\lceil r/2 \rceil} m(r,s)v^s L(v,d)^{2s}(1+vL(v,d)^2)^{r+1-2s}}{(1-vL(v,d)^2)^{r+1}}\,, \end{aligned} \tag{6.81}$$

which, after two uses of the functional Eq. (2.2) for $L(v,d)$, becomes

$$\widehat{M}_r(v,d) = \frac{1+d}{\sqrt{((1-d)^2-4v)^{r+1}}} \sum_{s=1}^{\lceil r/2 \rceil} m(r,s)v^s(1-d)^{r+1-2s}\,. \tag{6.82}$$

This expression for the rth moment of elevated walks relies only on a linear combination of polynomials in the step variables v and d. From this final expression it also is clear that odd order moments are rational, whilst even order moments are algebraic.

The moment problem considered in Ref. 86 was that of finding the moments of the distance between two non-intersecting paths on the $\mathbb{S}$ lattice. This was as an instance of moments of Shapiro's "Catalan triangle".[87] The array, $\{w_{n,k}\}$ say, of the numbers of points at height k in the set of elevated walks on the $\mathbb{S}$ lattice that end at $(t,h)=(2n,0)$ is then another instance of the Catalan triangle, and thus the derivation of $\widehat{M}_r(v,d)$ given here is an extension of the moment problem in Ref. 86 to a system beyond the $\mathbb{S}$ lattice.

Unscrambling Address Lines

Andrei Broder* Michael Mitzenmacher* Laurent Moll*

Abstract

A writer leaves a message in a write-once memory accessible via address lines. Before the intended recipient has a chance to get the message, the address lines are permuted by an adversary. We provide a simple, nearly optimal algorithm for the reader and writer to communicate over such a channel.

This problem arose in the context of FPGA hardware design. Our algorithm has been implemented and is part of the design tool suite in use within Compaq.

1 Introduction

Consider the following problem regarding the transmission of a message between a writer and a reader facing an adversary. The writer stores logical zeroes and ones in a table of size 2^n stored in consecutive locations in a write-once memory. The memory is accessed through n one bit address lines. After the writing is complete, an adversary permutes the address lines. For example, for $n = 4$ there are sixteen memory locations: if the address lines are set to 0010, before the adversary acts, the memory returns the value stored in location 2. If the adversary permutes the second and third address line, the memory sees a request for location 0100 and returns the value stored in location 4.

The reader does not know the permutation used by the adversary, but can read all the memory locations. The reader's goal is to discover how the address lines were permuted, and, in addition, to obtain a message from the writer. Assuming the reader and writer establish a protocol ahead of time, how many bits can they communicate? More practically, what is a good protocol?

This problem arose in the context of Field-Programmable Gate Arrays (FPGAs) hardware design. An FPGA is a simple reconfigurable hardware device. The first commercial FPGA was introduced in 1986 [1]. For a large part of today's FPGAs, their basic logical element is equivalent to a look-up table [4]. The usual tools for FPGA design lay out a circuit on these logical elements, routing the wiring as appropriate. In particular, one tool currently in use permutes the address lines as appropriate to improve the wiring layout. This process is perfectly reasonable if the FPGA programmer want to use the design as a "black box." However, if the FPGA programmer wants to patch the design, an effective means of determining this permutation is necessary. The number of memory locations in the table dedicated to this end should be as low as possible, so that the rest of the table can be used for other purposes. (Because of the layered structure of the complex software used for wiring layout, keeping track of the permutation through the layers is not feasible.)

We describe a brute-force approach to the problem, as well as a simple algorithmic solution.

2 Brute force: table look-up

For any specific n, the problem can be solved by brute force. We divide all possible settings of table-content bits into equivalence classes; two settings are equivalent if and only if the first yields the same memory output as the second via some address lines permutation. We then count the number of equivalence classes with $n!$ distinct members. If C_n is the number of such classes, then the writer can effectively transmit any value in the range $[0 \ldots C_n - 1]$ in such a way that the reader can determine the value plus the permutation used by the adversary. This is accomplished by establishing one representative member from each of the C_n equivalence classes, and sending one of these C_n representatives. The value from $[0 \ldots C_n - 1]$ is determined by the reader from the class of the read memory bits; the permutation is similarly determined by which of the $n!$ permutations of the representative appears in the memory. Essentially, then, one can reduce the problem to a large table look-up.

In practice, however, this approach appears infeasible for all but the smallest values of n, as there are 2^{2^n} possible ways to set the memory. Using a brute force table-look up approach rapidly becomes infeasible in terms of memory utilization and preprocessing. The first few values of C_n are $2, 4, 16, 1792, 34339072, \ldots$. We have not determined a closed form for C_n; this remains an open problem.

In a similar vein, we might ask how many values D_n can be passed if we do not care whether the reader learns the adversarial permutation. In this case, all the

*Compaq Systems Research Center, Palo Alto, California. E-mail: {broder,michaelm,moll}@pa.dec.com

equivalence classes (and not just those with $n!$ members) count, as each class determines a possible value from $[0 \ldots D_n - 1]$. The first few values in this case are $2, 12, 80, 3984, 37333248, \ldots$. A closed form for D_n also remains an open problem. We note that neither C_n or D_n appear as sequences in the famous Sloane's list [2, 3].

3 An algorithmic solution

We have devised a simple algorithmic solution which requires at most $n \log_2 n$ memory probes to determine the permutation, and uses only $n \log_2 n$ of the 2^n bits of the memory. These are both within a $1 + o(1)$ factor of optimal, since on average (a) it takes at least $\log_2(n!)$ memory probes to determine the permutation; and (b) the writer cannot transmit more than $2^n - \log_2(n!)$ bits of information if the writer has to specify a permutation as well. (Note that if the reader does not need to determine the permutation, then our algorithm still works, but we can no longer claim that it is within an $1 + o(1)$ factor of optimal. Finding non-trivial bounds for this case remains open.)

We establish the appropriate notation. Initially, we assume that the number of address lines is $n = 2^r$ for some r. We label the memory locations by n-dimensional $\{0,1\}$ vectors. Originally the writer assigns bit values $f(x) \in \{0,1\}$ to the vectors (locations) $x \in \{0,1\}^n$. We denote the permutation chosen by the adversary as π and view it as a permutation of the numbers 0 to $n-1$. We use $\hat{\pi}$ to represent the action of π on vectors in the natural way: for example, if there are 4 address lines, and $\pi(0) = 0, \pi(1) = 2, \pi(2) = 1$, and $\pi(3) = 3$, then $\hat{\pi}(x) = \hat{\pi}(x_3x_2x_1x_0) = x_3x_1x_2x_0$. The values returned by the memory, after the adversary's evil deed, are denoted by $g(x)$, where $g(x) = f(\hat{\pi}(x))$.

The reader learns the permutation π after r rounds. For each round the reader reads the value of $g(x)$ in n distinct locations. These locations are independent of π and different from round to round. As we explain, before the permutation, the writer sets only the locations that eventually will be read. Hence $n \log_2 n$ values in the table are stored and read by our algorithm and the other locations are available for message transmission. We maintain the following invariant: after round k, for each line i, we know $\pi(i)$ modulo 2^k. Note that this invariant is trivially true before round 1. We call this the *bit-by-bit* approach. To simplify exposition, we describe the writing and the reading round by round, although in fact the writer does all the writing before the reading begins.

For the first round (round 1), the writer sets $f(x)$ to be 1 for all unit vectors $x = e_i$ for odd i, and 0 for all unit vectors $x = e_i$ for even i. The reader sets exactly one line j to 1 and all the others to 0. The memory returns 1 if and only if $\pi(j) = 1$, that is, j is mapped to an odd-numbered line.

Similarly, for round k, let the values of z range over $[0 \ldots 2^k - 1]$. The writer sets $f(x)$ for all x with a 1 in *all* positions x_i with $i = z - 1 \bmod 2^k$, exactly one 1 in one of the $n/2^k$ positions x_i with $i = z \bmod 2^k$ (call this position j), and 0's elsewhere. Note that there are n possibilities for x corresponding to the n possible values for j. The writer sets $f(x)$ to 1 if $(j - z)/2^k$ is odd and to 0 otherwise.

The reader, given the information gathered in prior rounds, can determine the permuted position of each line modulo 2^k. Hence it can compute all x such that $\hat{\pi}(x)$ has $\hat{\pi}(x)_i = 1$ in *all* positions with $i = z - 1 \bmod 2^k$, $\hat{\pi}(x)$ has exactly one 1 in one of the $n/2^k$ positions $\hat{\pi}(x)_i$ with $i = z \bmod 2^k$. Let j be the index of this particular position within x. That is, the reader can determine how to set the address bits to read values $g(x) = f(\hat{\pi}(x))$ precisely for the x's that the writer has defined for this round. Again, these reads determine for each j whether the $(k+1)$'st bit from the right of $\pi(j)$ is 0 or 1. Our invariant is maintained, and hence only $n \cdot r = n \log_2 n$ values are set and read in the memory.

Minor improvements can be made. For example, the reader need not read n values each round, but only $n-1$ values, since the nth value to be read is determined by the other $n - 1$.

When $n = 2^r + a$, where $0 < a < 2^r$, we use an $(r+1)$'st round for locations which are not determined by the first r bits from the right. The same argument shows that the total number of memory locations that need to be set and read is at most $n \cdot r + 2a = n\lfloor \log_2 n \rfloor + 2a$.

4 Acknowledgement

We wish to thank Mike Burrows, who computed the computable terms of the C_n and D_n sequences.

Abstract for R23 of Volume 8(1), 2001

Alex Brodsky, Stephane Durocher and Ellen Gethner

The Rectilinear Crossing Number of K_{10} is 62

The rectilinear crossing number of a graph G is the minimum number of edge crossings that can occur in any drawing of G in which the edges are straight line segments and no three vertices are collinear. This number has been known for $G = K_n$ if $n \leq 9$. Using a combinatorial argument we show that for $n = 10$ the number is 62.

Divisible Tilings in the Hyperbolic Plane

S. Allen Broughton, Dawn M. Haney, Lori T. McKeough, and Brandy Smith Mayfield

Published: October 4, 2000

Keywords: tiling, Fuchsian groups, reflection groups, crystallographic groups, hyperbolic plane

Subject: 05B45, 29H10, 20H15, 51F15, 52C20, 51M10

Abstract:

We consider triangle-quadrilateral pairs in the hyperbolic plane which ``kaleidoscopically'' tile the plane simultaneously. In this case the tiling by quadrilaterals is called a \emph{divisible tiling. } All possible such divisible tilings are classified. There are a finite number of 1, 2, and 3 parameter families as well as a finite number of exceptional cases.

Zpìt

La fonction τ de Ramanujan.

François Brunault.

Exposé au séminaire des doctorants de théorie
des nombres de Chevaleret, le 18 mars 2003.

Nous supposerons connues les bases de la théorie des formes modulaires (définition d'une forme modulaire de poids $k \geq 4$ pair et de niveau 1). Le lecteur pourra se référer à [Z] qui est une très bonne introduction.

1 Définitions.

Pour tout entier $k \geq 4$ pair, on définit la *série d'Eisenstein de poids k* par :

$$G_k(z) = \frac{(k-1)!}{2(2\pi i)^k} \sum_{(m,n)\in\mathbf{Z}^2}{}' \frac{1}{(mz+n)^k}. \tag{1}$$

Le symbole $\sum'$ indique que l'on somme sur les $(m,n) \neq (0,0)$. Cette série converge absolument car l'exposant de $(mz+n)$ est > 2. Elle définit une fonction holomorphe sur le demi-plan de Poincaré $\mathcal{H} = \{z \in \mathbf{C},\ \Im(z) > 0\}$. Il n'est pas très difficile de vérifier que G_k est modulaire de poids k, c'est-à-dire

$$G_k\left(\frac{az+b}{cz+d}\right) = (cz+d)^k G_k(z) \qquad \left(\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL_2(\mathbf{Z})\right). \tag{2}$$

La série d'Eisenstein G_k est une *forme modulaire de poids k*. Elle admet le développement de Fourier suivant, que l'on peut obtenir grâce à la formule de sommation de Poisson :

$$G_k(z) = -\frac{B_k}{2k} + \sum_{n=1}^{\infty} \sigma_{k-1}(n) e^{2i\pi nz}, \tag{3}$$

où B_k désigne le k-ième nombre de Bernoulli [S], et $\sigma_{k-1}(n)$ désigne la somme des puissances $(k-1)$-ièmes des diviseurs positifs de n.

Nous noterons $q = e^{2i\pi z}$, de telle sorte que G_k peut être vue comme une série entière en q, de rayon de convergence égal à 1. Notons également que le membre de droite de (3) a encore un sens pour $k = 2$, ce qui permet de définir G_2. En revanche, G_2 ne vérifie plus la condition de modularité (2). Pour les premières valeurs de k, on calcule facilement les développements suivants :

$$\begin{array}{rcccccccccccccc} G_2 & = & -\frac{1}{24} & + & q & + & 3q^2 & + & 4q^3 & + & 7q^4 & + & 6q^5 & + & 12q^6 & + & \dots \\ G_4 & = & \frac{1}{240} & + & q & + & 9q^2 & + & 28q^3 & + & 73q^4 & + & 126q^5 & + & 252q^6 & + & \dots \\ G_6 & = & -\frac{1}{504} & + & q & + & 33q^2 & + & 244q^3 & + & 1057q^4 & + & 3126q^5 & + & 8052q^6 & + & \dots \end{array}$$

Ces développements renferment de nombreuses propriétés arithmétiques. Par exemple, le coefficient de q^6 est toujours égal au produit du coefficient de q^2 par le coefficient de q^3 (c'est une conséquence de la multiplicativité de la fonction σ_{k-1}). D'autres propriétés existent, on peut par exemple chercher la relation entre le coefficient de q^2 et celui de q^4.

Remarque 1. *Le membre de droite de (3) a encore un sens et est non trivial pour k impair. On ne peut en revanche pas l'écrire sous la forme (1) car, pour des raisons de parité, cette dernière série s'annule identiquement pour $k \geq 3$ impair. Il serait donc intéressant d'interpréter autrement le membre de droite de (3) lorsque k est impair.*

Nous allons maintenant définir la fonction τ de Ramanujan.

Définition 2. *Soit Δ la série entière en q suivante*

$$\Delta = 8000G_4^3 - 147G_6^2. \tag{4}$$

Pour tout entier $n \geq 1$, on note $\tau(n)$ le coefficient de q^n dans Δ. On a donc par définition

$$\Delta = \sum_{n=1}^{\infty} \tau(n) q^n. \tag{5}$$

La fonction τ sur $\mathbf{N}^*$ ainsi obtenue est appelée fonction τ de Ramanujan.

Le calcul des premiers termes donne

$$\Delta = q - 24q^2 + 252q^3 - 1472q^4 + 4830q^5 - 6048q^6 + \dots. \tag{6}$$

Proposition 3. *La série entière Δ, vue comme fonction holomorphe sur $\mathcal{H}$, est une forme modulaire de poids 12.*

Démonstration. On sait que G_4 est de poids 4, et que G_6 est de poids 6. En conséquence G_4^3 et G_6^2 sont modulaires de poids respectifs $4 \times 3 = 12$ et $6 \times 2 = 12$. Il en résulte que Δ est également une forme modulaire de poids 12. □

Notons que par choix des coefficients devant G_4^3 et G_6^2, le terme constant du développement de Fourier de Δ vaut 0. On dit que Δ est une *forme parabolique* de poids 12. Cela signifie que

$$\lim_{\Im(z) \to +\infty} \Delta(z) = 0.$$

On peut même voir que $\Delta(z)$ décroît exponentiellement vite en $\Im(z)$, lorsque $\Im(z) \to +\infty$.

Avant d'entamer l'étude de la fonction τ, signalons que $\tau(n)$ a été calculé par Ramanujan pour $1 \leq n \leq 30$, puis par Lehmer pour $1 \leq n \leq 300$. Le calcul efficace de la fonction τ est l'objet de recherches actuelles [C].

2 Une congruence de Ramanujan.

Nous commençons par la proposition suivante.

Proposition 4. *La fonction τ est à valeurs entières : pour tout $n \geq 1$, on a $\tau(n) \in \mathbf{Z}$.*

Démonstration. Il est clair a priori que la fonction τ est à valeurs rationnelles. La difficulté vient du fait que les termes constants de G_4 et G_6 ne sont pas entiers.

Posons

$$G_4 = \frac{1}{240} + H_4 \qquad \text{et} \qquad G_6 = -\frac{1}{504} + H_6.$$

On a alors

$$\begin{aligned}\Delta &= 8000G_4^3 - 147G_6^2 \\ &= 8000\left(\frac{1}{240} + H_4\right)^3 - 147\left(-\frac{1}{504} + H_6\right)^2 \\ &= 8000H_4^3 - 147H_6^2 + 100H_4^2 + \frac{5H_4 + 7H_6}{12}.\end{aligned}$$

Il suffit donc de montrer que $\frac{5H_4+7H_6}{12}$ est à coefficients entiers. Or, par définition de G_4 et G_6, le n-ième coefficient de cette série entière vaut $\frac{5\sigma_3(n)+7\sigma_5(n)}{12}$.

Il s'agit donc de montrer que 12 divise $5\sigma_3(n) + 7\sigma_5(n)$, pour tout $n \geq 1$. Or

$$\begin{aligned}5\sigma_3(n) + 7\sigma_5(n) &= \sum_{d|n} 5d^3 + 7d^5 \\ &\equiv \sum_{d|n} 7d^5 - 7d^3 \qquad \pmod{12} \\ &\equiv 7\sum_{d|n} d^3(d+1)(d-1) \pmod{12} \\ &\equiv 0 \qquad \pmod{12}\end{aligned}$$

car $d^3(d+1)(d-1)$ est divisible par 12 pour tout $d \in \mathbf{Z}$ (en effet il l'est par 4, et par 3). □

Proposition 5. *On a la congruence (dite de Ramanujan)*

$$\tau(n) \equiv \sigma_{11}(n) \pmod{691} \qquad (n \geq 1). \tag{7}$$

Démonstration. Nous admettrons que l'espace M_{12} des formes modulaires de poids 12 est un espace vectoriel complexe de dimension 2 (voir [Z] pour une démonstration). En conséquence le sous-espace S_{12} des formes paraboliques est de dimension 1, et il est engendré par Δ. On a

$$G_{12} = \frac{691}{65520} + \underbrace{\cdots}_{\in \mathbf{Z}[[q]]} \in M_{12},$$
$$G_6^2 = \frac{1}{504^2} + \underbrace{\cdots}_{\in \frac{1}{504}\mathbf{Z}[[q]]} \in M_{12}.$$

Nous en déduisons

$$\underbrace{65520 G_{12}}_{\in \mathbf{Z}[[q]]} - 691 \times \underbrace{504^2 G_6^2}_{\in \mathbf{Z}[[q]]} \in S_{12} \cap \mathbf{Z}[[q]].$$

Il existe donc α complexe tel que $65520 G_{12} - 691 \times 504^2 G_6^2 = \alpha\Delta \in S_{12} \cap \mathbf{Z}[[q]]$. Puisque $\tau(1) = 1$, on a nécessairement $\alpha \in \mathbf{Z}$. En identifiant les n-ièmes coefficients des séries entières on obtient

$$65520\sigma_{11}(n) \equiv \alpha\tau(n) \pmod{691} \qquad (n \geq 1).$$

En faisant $n = 1$ on obtient $\alpha \equiv 65520 \equiv 566 \pmod{691}$, en particulier α est inversible modulo 691 (qui est premier). En simplifiant l'équation ci-dessus par α, on obtient $\sigma_{11}(n) \equiv \tau(n) \pmod{691}$, ce qui est la congruence recherchée. □

Il existe beaucoup d'autres congruences vérifiées par les nombres $\tau(n)$. Voici quelques exemples

$$\tau(n) \equiv n\sigma_3(n) \pmod{7} \qquad (n \geq 1) \tag{8}$$
$$\tau(n) \equiv n^2\sigma_7(n) \pmod{27} \qquad (n \geq 1) \tag{9}$$

Pour plus de détails sur les congruences vérifiées par la fonction τ, ainsi que le lien avec les représentations l-adiques, on pourra se reporter à l'exposé de Serre [S2], qui est par ailleurs un très bon exposé (c'est un pléonasme) sur la fonction τ de Ramanujan.

3 Une interprétation elliptique de Δ.

Théorème 6. *(Jacobi) On a l'identité de séries formelles suivante*

$$\Delta = q \prod_{n=1}^{\infty} (1 - q^n)^2 4. \tag{10}$$

La démonstration de ce résultat peut être trouvée dans [Z] ou dans [S]. Un corollaire de ce théorème est que Δ ne s'annule pas sur $\mathcal{H}$.

La forme modulaire Δ est intimement liée aux courbes elliptiques. En effet, pour $z \in \mathcal{H}$, notons E_z la surface de Riemann compacte définie par

$$E_z = \frac{\mathbf{C}}{\mathbf{Z} + z\mathbf{Z}}.$$

On sait que E_z est isomorphe à la courbe elliptique sur $\mathbf{C}$ définie par l'équation

$$E_z : y^2 = 4x^3 - g_2(z)x - g_3(z)$$

où l'on a posé $g_2(z) = 20 \cdot (2\pi)^4 G_4(z)$ et $g_3(z) = -\frac{7}{3}(2\pi)^6 G_6(z)$ (attention au changement d'indice, nous avons adopté ici les notations standard).

Proposition 7. *La valeur de la forme modulaire Δ en z est égale, à un facteur près, au discriminant de la courbe elliptique E_z :*

$$\Delta(E_z) := g_2(z)^3 - 27g_3(z)^2 = (2\pi)^{12}\Delta(z) \qquad (z \in \mathcal{H}).$$

Le discriminant d'une courbe elliptique sur un corps K n'est défini qu'à un élément de $(K^*)^{12}$ près. Ici $K = \mathbf{C}$, donc $(K^*)^{12} = \mathbf{C}^*$. Cela explique le terme 'à un facteur près' dans la proposition précédente.

4 Propriétés arithmétiques de la fonction Δ.

Le développement de Fourier (6) de Δ, que nous récrivons ici :

$$\Delta = q - 24q^2 + 252q^3 - 1472q^4 + 4830q^5 - 6048q^6 + \dots$$

a des propriétés arithmétiques très intéressantes. En guise d'exercice (et sans lire la suite !), on peut chercher la relation entre les coefficients de q^2, q^3 et q^6, ou encore celle entre les coefficients de q^2 et q^4.

Ramanujan a le premier observé, et conjecturé en 1916, que les coefficients $\tau(n)$ sont multiplicatifs, i.e. satisfont

$$\tau(mn) = \tau(m)\tau(n) \qquad (m \text{ et } n \geq 1 \text{ premiers entre eux}). \tag{11}$$

On le vérifie ici pour $m = 2$ et $n = 3$. Cette conjecture a été démontrée un an plus tard par Mordell. Pour donner une idée de la démonstration de Mordell, nous sommes amenés à introduire les formes modulaires de Hecke.

Définition 8. *Soit $f = \sum_{n=0}^{\infty} a_n q^n \in M_k$ une forme modulaire de poids $k \geq 4$ pair. On dit que f est une* forme de Hecke *lorsque $f \neq 0$ et*

$$a_{mn} = a_m a_n \qquad (m \text{ et } n \geq 1 \text{ premiers entre eux}). \tag{12}$$

Sous cette hypothèse on a toujours $a_1 = 1$. On dit que les formes de Hecke sont *normalisées*. Les séries d'Eisenstein G_k ($k \geq 4$ pair) sont des exemples de formes de Hecke. Un théorème célèbrede Hecke affirme que les formes de Hecke de M_k (resp. S_k) forment une base de M_k (resp. S_k). La conjecture de Ramanujan découle immédiatement de ce théorème : l'espace S_{12} auquel appartient Δ est de dimension 1, et l'on a $\tau(1) = 1$, par conséquent Δ est une forme de

Hecke. En réalité, il n'est pas nécessaire d'utiliser le théorème de Hecke dans toute sa force pour démontrer la conjecture de Ramanujan. On peut se débrouiller en introduisant les opérateurs de Hecke (ce qu'a fait Mordell). On montre alors également la relation de récurrence suivante

$$\tau(p^{n+2}) = \tau(p)\tau(p^{n+1}) - p^{11}\tau(p^n) \qquad (p \text{ premier}, n \geq 0). \tag{13}$$

Cette relation permet de ramener le calcul des $\tau(n)$ $(n \geq 1)$ à celui des $\tau(p)$, p premier.

5 Ordre de grandeur de la fonction τ.

Intéressons-nous maintenant à l'ordre de grandeur de $\tau(n)$. Commençons par l'ordre de grandeur des coefficients de Fourier des séries d'Eisenstein.

Proposition 9. *Soit k un entier pair ≥ 2. On a l'estimation suivante pour le n-ième coefficient de Fourier de G_k, lorsque n tend vers l'infini :*

$$a_n(G_k) = \sigma_{k-1}(n) = \begin{cases} O(n^{k-1}) & si\ k \geq 4, \\ O(n^{1+\epsilon}) & si\ k = 2 \qquad (\epsilon > 0). \end{cases} \tag{14}$$

Il n'est pas difficile de voir que ces estimations sont les meilleures possibles, du point de vue de l'exposant de n. À l'aide de la définition (4) de Δ et de cette proposition, on peut montrer à la main que

$$\tau(n) = O(n^{11}).$$

Il existe en fait un résultat plus général.

Théorème 10. *Soient k un entier pair ≥ 4 et $f = \sum_{n=0}^{\infty} a_n q^n \in M_k$ une forme modulaire de poids k. Alors on a l'estimation, lorsque n tend vers l'infini :*

$$a_n = O(n^{k-1}) \tag{15}$$

et

$$a_n = O(n^{\frac{k}{2}}) \qquad si\ f \in S_k. \tag{16}$$

En particulier, $\tau(n) = O(n^6)$.

On pourra trouver une démonstration dans [Z].

On peut encore améliorer l'exposant lorsque $f \in S_k$, mais cela demande beaucoup plus de travail !

Théorème 11. *(Deligne). Soit $f = \sum_{n=1}^{\infty} a_n q^n \in S_k$ une forme de Hecke de poids k pair ≥ 4. Alors*

$$|a_p| \leq 2p^{\frac{k-1}{2}} \qquad (p\ premier) \tag{17}$$

ou de façon équivalente

$$|a_n| \leq \sigma_0(n) n^{\frac{k-1}{2}} \qquad (n \geq 1). \tag{18}$$

Ici, $\sigma_0(n)$ est le nombre de diviseurs > 0 de n. En particulier, lorsque n tend vers l'infini :

$$\tau(n) = O(n^{\frac{11}{2}+\epsilon}) \qquad (\epsilon > 0). \tag{19}$$

Ce résultat a été conjecturé par Ramanujan dans le cas de Δ, et par Petersson dans le cas général. En 1969, Deligne a montré que ce résultat était une conséquence des conjectures de Weil portant sur les variétés algébriques sur les corps finis. Il a ensuite démontré les conjectures de Weil, en 1974.

Signalons une autre conséquence du théorème de Deligne : soit $f = \sum_{n=1}^{\infty} a_n q^n \in S_k$ une forme parabolique quelconque. Définissons la fonction L de f par

$$L(f, s) := \sum_{n=1}^{\infty} \frac{a_n}{n^s} \qquad (s \in \mathbf{C}). \tag{20}$$

Alors $L(f, s)$ converge pour $\Re(s) > \frac{k+1}{2}$. On peut démontrer de manière élémentaire que la fonction $L(f, s)$ se prolonge en une fonction entière sur $\mathbf{C}$ (ceci n'utilise pas le théorème de Deligne).

Notons que le problème de l'estimation des coefficients de Fourier des formes modulaires (ou plus généralement des formes automorphes) est un des problèmes majeurs de la théorie des nombres.

6 Une conjecture pour finir.

Terminons ce petit tour d'horizon de la fonction τ par la conjecture de Lehmer.

Conjecture 12. *(Lehmer) Pour tout entier $n \geq 1$, on a $\tau(n) \neq 0$.*

Par la propriété de multiplicativité (12), on se ramène au cas où n est une puissance d'un nombre premier. En utilisant la relation de récurrence (13), il me semble (mais je ne l'ai pas rédigé) que l'on peut se ramener au cas où n est un nombre premier p.

Conjecture 13. *Pour tout nombre premier p, on a $\tau(p) \neq 0$.*

À l'heure actuelle, la conjecture de Lehmer est connue pour $n \leq 22689242781695999$ [JK]. Un problème lié à la conjecture de Lehmer est le suivant :

Problème ouvert 1. *Pour quels nombres premiers p a-t-on $\tau(p) \equiv 0 \pmod{p}$?*

À l'aide d'un ordinateur, on trouve que les premières valeurs de p satisfaisant $\tau(p) \equiv 0 \pmod{p}$ sont $p = 2$, 3, 5, 7 et 2411.

La condition $\tau(p) \equiv 0 \pmod{p}$ se traduit conjecturalement en terme de la représentation l-adique associée à τ (voir [S2]). Plus généralement, il est intéressant d'étudier les propriétés de τ d'un point de vue géométrique, c'est-à-dire en étudiant les propriétés du *motif* associé.

Pour de plus amples renseignements sur la fonction τ de Ramanujan, on pourra se reporter à la page web [Sl], qui contient de nombreuses références. Attention cependant, car j'ai trouvé un lien vers une page qui démontre tout bonnement la conjecture de Lehmer !

ABSTRACT

Let $w_1 = d, w_2, \ldots, w_s$ be the weights of the nonzero codewords in a binary linear $[n, k, d]$ code C, and let $w_1', w_2', \ldots, w_{s'}'$ be the nonzero weights in the dual code $C^\perp$. Let t be an integer in the range $0 < t < d$ such that there are at most $d-t$ weights w_i' with $0 < w_i' \le n-t$. Assmus and Mattson proved that the words of any weight w_i in C form a t-design. We show that if $w_2 \ge d+4$ then either the words of any nonzero weight w_i form a $(t+1)$-design or else the codewords of minimal weight d form a $\{1, 2, \ldots, t, t+2\}$-design. If in addition C is self-dual with all weights divisible by 4 then the codewords of any given weight w_i form either a $(t+1)$-design or a $\{1, 2, \ldots, t, t+2\}$-design. The special case of this result for codewords of minimal weight in an extremal self-dual code with all weights divisible by 4 also follows from a theorem of Venkov and Koch; however our proof avoids the use of modular forms.

* This paper appeared in *IEEE Trans. Inform. Theory*, **37** (1991), pp. 1261-1268.

1. A strengthened Assmus-Mattson theorem

Let C be a binary, linear $[n, k, d]$ code with nonzero weights $w_1 = d, w_2, \ldots, w_s$, and let $w_1', \ldots, w_{s'}'$ be the nonzero weights in the dual code $C^\perp$. Our starting point is the following theorem.

Theorem 1 (Assmus and Mattson [2]). *Let t be the greatest integer in the range $0 < t < d$ such that there are at most $d - t$ weights w_i' with $0 < w_i' \le n - t$. Then the codewords of any weight w_i in C form a t-design.*

Venkov [21], answering a question raised in [20], showed that this theorem has an analogue for extremal even unimodular lattices in Euclidean space of dimension $24m$. The expected analogue was that the lattice vectors of any fixed nonzero length would form a spherical 11-design. Venkov proved this and more: he showed that these vectors possess an additional symmetry, forming what he called a spherical 11½-design. His proof uses the theory of modular forms.

Venkov [21] also announced that similar results could be obtained for self-dual codes. These results are stated by Koch [15] (see also [14], [16]). In particular, Venkov and Koch show that, in any extremal binary self-dual doubly-even code C, the set P of minimal weight words has the property that a certain linear form associated with P is constant on $(t+2)$-sets. Here $t = 5$ if the length n of the code is a multiple of 24, $t = 3$ if $n \equiv 8 \pmod{24}$, and $t = 1$ if $n \equiv 16 \pmod{24}$. To prove their result they associate a unimodular lattice with C and again apply the theory of modular forms.

Our strengthened version of Theorem 1 involves the concept of a T-design, defined as follows (cf. [8]). Let Ω be the set of all d-subsets of the n-set $[1,n] = \{1, \ldots, n\}$, with $d \le n/2$. We identify Ω with the set of all points $\xi = (\xi_1, \ldots, \xi_n)$ in R^n that satisfy $\xi_p \in \{0,1\}$ for all p and $\Sigma_{p=1}^n \xi_p = d$. The vector space R^Ω of mappings from Ω to R is invariant under the natural

action of the symmetric group S_n. The irreducible S_n-invariant subspaces of R^Ω are the *harmonic spaces* $\mathrm{harm}(i)$, $i = 0, 1, \ldots, d$. (These spaces are described in detail in Section 2, where in particular we give an explicit basis for $\mathrm{harm}(i)$.)

Let P be a subset of Ω, i.e. a constant weight code, and let $\pi(\mathsf{P}) \in \mathsf{R}^\Omega$ be the corresponding characteristic vector. The importance of the harmonic space $\mathrm{harm}(i)$ is that if the projection of $\pi(\mathsf{P})$ onto $\mathrm{harm}(i)$ is zero, then there is some regularity in the way the vectors of P meet an arbitrary i-subset of $[1, n]$. In particular (see [10]), P is a t-design if and only if, for all $i = 1, 2, \ldots, t$, the inner product $\langle \pi(\mathsf{P}), f \rangle = 0$ for all $f \in \mathrm{harm}(i)$. As in [8] we extend the definition of a design to subsets $T \subseteq [1, n]$ other than $[1, t]$ by saying that a collection P is a *T-design* if, for all $i \in T$, the inner product $\langle \pi(\mathsf{P}), f \rangle = 0$ for all $f \in \mathrm{harm}(i)$. (In case $0 \in T$, a T-design is defined to be a T'-design with $T' = T \setminus \{0\}$.)

When combined with the results of Section 3 of the present paper (in particular Theorem 7), the Venkov-Koch result mentioned above implies that the codewords of minimal weight in an extremal self-dual doubly-even code C form a $\{1, 2, \ldots, t, t+2\}$-design. (For in this case the linear form in Theorem 7 reduces to Venkov's form, given on page 461 of Koch [15].)

The purpose of the present paper is to give a similar generalization of the Assmus-Mattson theorem that does not assume the code is self-dual and whose proof avoids the use of modular forms. Our main theorem is the following.

Theorem 2. *Let C be a binary $[n, k, d]$ code with nonzero weights $w_1 = d, w_2, \ldots, w_s$, and let $w_1', \ldots, w_{s'}'$ be the nonzero weights in the dual code $C^\perp$. Let t be the greatest integer in the range $0 < t < d$ such that there are at most $d - t$ weights w_i' with $0 < w_i' \le n - t$. If $w_2 \ge d + 4$ then either the codewords in C of any nonzero weight w_i form a $(t+1)$-design or else the codewords of minimal weight d form a $\{1, 2, \ldots, t, t+2\}$-design.*

The proof is given in Section 4. In one important special case we can prove slightly more.

Theorem 3. *If, in addition to the hypotheses of Theorem* 2, *C is self-dual with all weights divisible by* 4 *then the codewords of any given weight* w_i *form either a* $(t+1)$*-design or a* $\{1, 2, \ldots, t, t+2\}$*-design.*

The proof is given in Section 5.

A list of the known extremal codes is given in [6, p. 194] and [7]. We may conclude for example that the codewords of minimal weight in the [24, 12, 8] Golay code and the [48, 24, 12] extended quadratic residue code form $\{1, 2, 3, 4, 5, 7\}$-designs. The minimal weight codewords in any of the five [32, 16, 8] self-dual doubly-even codes ([5], [7]) or in the extremal self-dual codes of lengths 56, 80 and 104 form $\{1, 2, 3, 5\}$-designs, and the minimal weight words in the extremal self-dual codes of lengths 16, 40, 64, 88 and 136 form $\{1, 3\}$-designs. Other examples are given in Section 4.

The invariant linear forms associated with codes are further investigated in [3], [4]. Generalizations to nonlinear codes and other fields are considered in [3].

2. The harmonic space harm(i)

In this section we give a more precise definition of and an explicit basis for the harmonic space harm(i).

We first define the *homogeneous space* hom(i) $(0 \le i \le n)$. This is the subspace of R^{Ω} represented by homogeneous polynomials $f(z) = f(z_1, \ldots, z_n)$ of total degree i and degree at most 1 in each variable z_p. Note that, since these functions are defined on Ω, z_p^2 and z_p $(1 \le p \le n)$ represent the same function, and $z_1 + z_2 + \cdots + z_p$ is the constant function d. The latter assertion implies that hom(j) is a subspace of hom(i) for $0 \le j \le i$.

The monomials $z_{p_1} z_{p_2} \cdots z_{p_i}$ are linearly independent and span hom(i). Thus the dimension of hom(i) is $\binom{n}{i}$ (cf. [10]).

The Laplacian Δ is the differential operator given by

$$\Delta f(z) = \sum_{p=1}^{n} \frac{\partial f(z)}{\partial z_p} .$$

This maps hom(i) onto hom($i-1$), and the kernel is the *harmonic space* harm(i). In [10] it is shown that there is an orthogonal decomposition

$$\hom(i) = \mathrm{harm}(i) \oplus \hom(i-1) , \qquad (1 \le i \le n) ,$$

with respect to the inner product $\langle f, g \rangle = \sum_{\xi \in \Omega} f(\xi) g(\xi)$, from which it follows that the dimension of harm(i) is $\binom{n}{i} - \binom{n}{i-1}$ Hom(0) = harm(0) is the 1-dimensional space of constant functions.

Theorem 4. *For any i-subset* $\{q_1, \ldots, q_i\}$ *of* $[1,n]$ *we define an element* ϕ *of* R^{Ω} *by*

$$\phi(z_1, \ldots, z_n) = \sum_{j=0}^{i} (-1)^j \binom{i}{j}^{-1} \binom{d-j}{i-j} \binom{n-i+1}{j} \sigma_j(z_{q_1}, \ldots, z_{q_i}) , \qquad (1)$$

where $\sigma_j(z_{q_1}, \ldots, z_{q_i})$ *is the sum of the characteristic functions* $z_{p_1} z_{p_2} \cdots z_{p_j}$ *of all j-subsets* $\{p_1, \ldots, p_j\}$ *of* $\{q_1, \ldots, q_i\}$. *Then the set of all* $\binom{n}{i}$ *such* ϕ*'s spans* harm(i).

Proof. Consider a monomial $m(z)$ in hom(i). Without loss of generality we may take

$$m(z) = z_1 z_2 \cdots z_i .$$

For an integer $u \in [0, i]$ we define $\phi_u(z) \in \hom(i)$ to be the sum of all monomials of degree i having exactly u variables z_p in common with $m(z)$. We first show that

$$\Delta \phi_u(z) = (i-u+1) g_{u-1}(z) + (n-2i+u+1) g_u(z) , \qquad (2)$$

where $g_j(z) \in \hom(i-1)$ is the sum of all monomials of degree $i-1$ having exactly j variables in common with $m(z)$. We write $z = (x, y)$, where $x = (z_1, \ldots, z_i)$ and $y = (z_{i+1}, \ldots, z_n)$. Then by definition,

$$\phi_u(z) = \sigma_u(x)\sigma_{i-u}(y) , \qquad g_j(z) = \sigma_j(x)\sigma_{i-j-1}(y) , \tag{3}$$

where $\sigma_j(w) = \sigma_j(w_1, \ldots, w_r) = \Sigma\, w_{p_1} w_{p_2} \cdots w_{p_j}$ denotes the elementary symmetric function of degree j in the variables $w_1, \ldots, w_r$. Note that $\sigma_j(x)$ is the sum of all monomials of degree j dividing $m(z)$. Equation (2) follows from the identities

$$\Delta\sigma_u(x) = (i-u+1)\sigma_{u-1}(x) \quad \text{and} \quad \Delta\sigma_r(y) = (n-i-r+1)\sigma_{r-1}(y) .$$

We now define

$$\phi(z) = \sum_{u=0}^{i} (-1)^u \binom{i}{u}^{-1} \binom{n-2i+u}{u} \phi_u(z) . \tag{4}$$

It follows readily from (2) that $\phi(z)$ is a solution of the Laplace equation $\Delta\phi(z) = 0$. Thus we have associated an eigenfunction $\phi \in \mathrm{harm}(i)$ with the given monomial $m \in \hom(i)$.

We next prove that $\phi(z)$ satisfies Eq. (1). First a simple counting argument yields

$$\sigma_u(x)\sigma_l(x) = \sum_{j=\max\{u,l\}}^{u+l} \binom{i}{u}\binom{u}{j-l}\binom{i}{j}^{-1} \sigma_j(x) , \tag{5}$$

for all u and l with $u + l \le i$. We then obtain the identity

$$\sigma_r(y) = \sum_{l=0}^{r} (-1)^l \binom{d-l}{r-l} \sigma_l(x) , \tag{6}$$

for $r \le i$. This can be proved by induction on r, as follows. We use the two relations

$$\sigma_1(y) = d - \sigma_1(x)$$

(which is the case $r = 1$ of (6)) and

$$\sigma_1(\cdot)\sigma_l(\cdot) = l\,\sigma_l(\cdot) + (l+1)\sigma_{l+1}(\cdot)$$

(which is a special case of (5)) together with (6) to obtain

$$(r+1)\sigma_{r+1}(y) = \sum_{l=0}^{r+1} (-1)^l \left[(d-r-l) \binom{d-l}{r-l} + l \binom{d+1-l}{r+1-l} \right] \sigma_l(x) ,$$

which is (6) with r replaced by $r+1$.

Using (3)-(5) and the combinatorial identity

$$\sum_l (-1)^l \binom{d-l}{i-u-l} \binom{u}{j-l} = (-1)^{j-u} \binom{d-j}{i-j}$$

(which follows from [13], p. 58, Eq. (24)), we obtain a representation for $\phi_u(z)$ in the simple form

$$\phi_u(z) = \sum_{j=u}^{i} (-1)^{j-u} \binom{i}{u} \binom{d-j}{i-j} \sigma_j(x) . \qquad (7)$$

Equation (1) now follows from (4) and (7), after applying the classical identity $\sum_u \binom{i-u}{j-u} \binom{n-2i+u}{u} = \binom{n-i+1}{j}$ ([12], Eq. (3.2)), together with $\binom{i}{j}\binom{j}{u} = \binom{i}{u}\binom{i-u}{j-u}$.

The set of all $\phi(z)$ associated with monomials m of degree i spans the whole space harm(i). For by construction the linear space spanned by these functions is invariant under the symmetric group S_n; and as the harmonic spaces harm(j) are the *irreducible* S_n-invariant subspaces of R^Ω, this implies that the space in question coincides with harm(i). This completes the proof of Theorem 4.

We conclude this section with an application of Theorem 4. (A stronger result will be given in Section 3.)

Theorem 5. *A classical* $(l-2)$*-design* P *is also an* $\{l\}$*-design if and only if for any l-subset x of* $[1,n]$ *the quantity*

$$L_x = \{l(d-l+1) - (n-2l+2)\}\mu_{l,x} + (d-l+1)\mu_{l-1,x}\,, \tag{8}$$

where $\mu_{j,x}$ *is the number of blocks in* P *that have exactly j points in common with x, is independent of the choice of x.* (*We shall therefore call* L_x *an invariant linear form.*)

Proof. Let λ_j $(0 \le j \le l-2)$ be the number of blocks of P containing a particular set of j points. If x is any l-subset of $[1,n]$ then since P is an $(l-2)$-design we have

$$\langle \pi(\mathsf{P}),\, \sigma_j(x) \rangle = \begin{bmatrix} l \\ j \end{bmatrix}_2 \lambda_j\,, \quad j = 0, 1, \ldots, l-2\,,$$

$$\langle \pi(\mathsf{P}),\, \sigma_{l-1}(x) \rangle = l\,\mu_{l,x} + \mu_{l-1,x}\,,$$

$$\langle \pi(\mathsf{P}),\, \sigma_l(x) \rangle = \mu_{l,x}\,.$$

Now P is an $\{l\}$-design if and only if $\langle \pi(\mathsf{P}),\, f \rangle = 0$ for all $f \in \mathrm{harm}(l)$, or equivalently (from Theorem 4) if and only if $\langle \pi(\mathsf{P}),\, \phi(x) \rangle = 0$ for all l-subsets x of $[1,n]$. Using (1) with $i = l$, and the trivial calculation that

$$\frac{(-1)^l \begin{bmatrix} d-l \\ 0 \end{bmatrix}_2 \begin{bmatrix} n-l+1 \\ l \end{bmatrix}_2 \begin{bmatrix} l \\ l \end{bmatrix}_2}{(-1)^{l-1} \begin{bmatrix} d-l+1 \\ 1 \end{bmatrix}_2 \begin{bmatrix} n-l+1 \\ l-1 \end{bmatrix}_2 \begin{bmatrix} l \\ l-1 \end{bmatrix}_2} = -\frac{n-2l+2}{d-l+1}$$

we see that $\langle \pi(\mathsf{P}),\, \phi(x) \rangle = 0$ for all x implies that L_x is independent of x. Conversely, if L_x is independent of x, the inner product

$$\langle \pi(\mathsf{P}),\, \sum_{j=0}^{l} (-1)^j \begin{bmatrix} l \\ j \end{bmatrix}_2^{-1} \begin{bmatrix} d-j \\ l-j \end{bmatrix}_2 \begin{bmatrix} n-l+1 \\ j \end{bmatrix}_2 \sigma_j(x) \rangle = A\,,$$

for some constant A independent of x. Since

$$\sum_x \sigma_j(x) \in \mathrm{hom}(0)\,, \quad \text{for all} \quad j\,,$$

$$\sum_{j=0}^{l} (-1)^j \begin{bmatrix} l \\ j \end{bmatrix}_2^{-1} \begin{bmatrix} d-j \\ l-j \end{bmatrix}_2 \begin{bmatrix} n-l+1 \\ j \end{bmatrix}_2 \sigma_j(x) \in \mathrm{harm}(l)\,, \quad \text{for all} \quad x\,,$$

we have

$$\sum_x \sum_{j=0}^{l} (-1)^j \binom{l}{j}^{-1} \binom{d-j}{l-j} \binom{n-l+1}{j} \sigma_j(x) \in \hom(0) > \mathrm{harm}(l) = \{0\} ,$$

and so $A = 0$. This completes the proof.

3. Invariant linear forms

Any S_n-invariant subspace ζ of $\mathbb{R}^{\Omega}$ is the sum of harmonic subspaces:

$$\zeta = \sum_{i \in T} \mathrm{harm}(i) , \tag{9}$$

where T is a well-defined subset of $\{0, 1, \ldots, d\}$, and $\sum$ denotes an orthogonal sum. There are 2^{d+1} such subspaces ζ.

Let $\mathbb{P}$ be a subset of Ω. A subspace ζ of $\mathbb{R}^{\Omega}$ will be said to be $\mathbb{P}$*-regular* if

$$\langle \pi(\mathbb{P}), \psi \rangle = \frac{|\mathbb{P}|}{|\Omega|} \langle \pi(\Omega), \psi \rangle , \quad \text{for all} \quad \psi \in \zeta . \tag{10}$$

Note that since $\pi(\Omega)$ is the function 1 (which spans $\mathrm{harm}(0)$), the inner product $\langle \pi(\Omega), \psi \rangle$ vanishes for all $\psi \in \mathrm{harm}(j)$ with $j \geq 1$.

Theorem 6. *A non-empty subset* $\mathbb{P} \subseteq \Omega$ *is a T-design if and only if the subspace* ζ *defined by* (9) *is* $\mathbb{P}$*-regular.*

Proof. If ζ is $\mathbb{P}$-regular it follows from (9) and (10) that

$$\langle \pi(\mathbb{P}), \psi \rangle = 0, \quad \text{for all} \quad \psi \in \mathrm{harm}(j) \quad \text{with} \quad j \in T,\ j \neq 0 , \tag{11}$$

i.e. $\mathbb{P}$ is a T-design. Conversely, if $\mathbb{P}$ is a T-design with $0 \notin T$ then

$$\pi(\mathbb{P}) \in \sum_{i \notin T} \mathrm{harm}(i) \tag{12}$$

and so $\zeta = \sum_{i \in T} \mathrm{harm}(i)$ is $\mathbb{P}$-regular.

We can now give the generalization of Theorem 5 that will be used to prove the main

theorem. We replace (8) by a more general invariant form, (13).

Theorem 7. *Let* P *be a non-empty subset of* Ω. *Suppose that for some integer* l *with* $1 \le l \le d$ *there exist real numbers* a, b, c, *not all zero, such that*

$$a\,\mu_{l,x} + b\,\mu_{l-1,x} = c \tag{13}$$

for all l*-subsets* x *of* $\{1, 2, \ldots, n\}$ ($\mu_{j,x}$ *was defined in Theorem* 5). *Then*

$$\begin{aligned} &\mathsf{P} \text{ is an } \{l\}\text{-design}, \qquad \text{if} \quad a \ne lb, \\ &\mathsf{P} \text{ is an } \{l-1\}\text{-design}, \quad \text{if} \quad a = lb. \end{aligned} \tag{14}$$

In particular, if P *is not an* $\{l-1\}$*-design then* P *is an* $\{l\}$*-design.*

Proof. For a given l-set $x = \{p_1, \ldots, p_l\}$ let us define a function $\psi_x \in \mathsf{R}^{\Omega}$ by

$$\begin{aligned} \psi_x(\xi_1, \ldots, \xi_n) &= a\,\xi_{p_1}\xi_{p_2}\cdots\xi_{p_l} + \\ b[(1-\xi_{p_1})\xi_{p_2}\cdots\xi_{p_l} &+ \xi_{p_1}(1-\xi_{p_2})\xi_{p_3}\cdots\xi_{p_l} + \cdots + \xi_{p_1}\cdots\xi_{p_{l-1}}(1-\xi_{p_l})]. \end{aligned} \tag{15}$$

The assumption (13) can be written as

$$\langle \pi(\mathsf{P}), \psi_x \rangle = c, \quad \text{for all} \quad l\text{-sets} \quad x. \tag{16}$$

The value of c can be deduced from a and b by summing (13) over all l-sets x; this yields

$$\left[a \binom{d}{l} + b \binom{d}{l-1} \binom{n-d}{1} \right] |\mathsf{P}| = c \binom{n}{l}. \tag{17}$$

Now $\langle \pi(\Omega), \psi_x \rangle$ is clearly constant, and this constant, c' say, is given by

$$\left[a \binom{d}{l} + b \binom{d}{l-1} \binom{n-d}{1} \right] |\Omega| = c' \binom{n}{l}. \tag{18}$$

It follows from (17), (18) that (16) amounts to

$$\langle \pi(\mathsf{P}), \psi_x \rangle = \frac{|\mathsf{P}|}{|\Omega|} \langle \pi(\Omega), \psi_x \rangle, \quad \text{for all} \quad l\text{-sets} \quad x. \tag{19}$$

Consider the linear space ζ spanned by the functions ψ_x (for all l-sets x). By definition, ζ is S_n-invariant. Furthermore it follows from (19) that ζ is P-regular. Hence P is a T-design with respect to the set T defined from the harmonic decomposition (9) of ζ. In view of (15) we have

$$\psi_x(\xi) = (a - lb)\xi_{p_1} \cdots \xi_{p_l} + \theta_{l-1}, \tag{20}$$

where θ_{l-1} is a member of $\hom(l-1)$. Hence ζ is a subspace of $\hom(l)$, and ζ is a subspace of $\hom(l-1)$ if and only if $a = lb$. Furthermore it is easily seen from (15) that (assuming a, b, c are not all zero) ζ is not a subspace of $\hom(l-2)$. (This is obvious if $a \neq lb$. When $a = lb$,

$$\begin{aligned}
\sum_{\substack{x = \{1, \ldots, l-1, i\} \\ \text{where } i = l, \ldots, n}} \psi_x(\xi) &= b \sum_{i=l}^{n} [\xi_2 \xi_3 \cdots \xi_{l-1} + \xi_1 \xi_3 \cdots \xi_{l-1} + \cdots + \xi_1 \xi_2 \cdots \xi_{l-2}]\xi_i \\
&\quad + b(n-l+1)\xi_1 \cdots \xi_{l-1} \\
&= b[\xi_2 \cdots \xi_{l-1} + \cdots + \xi_1 \cdots \xi_{l-2}]\left(d - \sum_{i=1}^{l-1} \xi_i\right) \\
&\quad + b(n-l+1)\xi_1 \cdots \xi_{l-1} \\
&= b(n-2l+2)\xi_1 \cdots \xi_{l-1} \\
&\quad + b(d-l+2)[\xi_2 \cdots \xi_{l-1} + \cdots + \xi_1 \cdots \xi_{l-2}],
\end{aligned}$$

and since $n - 2l + 2$ is not zero, this sum cannot belong to $\hom(l-2)$ unless b, and hence a and c, are zero.) Thus if $a \neq lb$ then P is an $\{l\}$-design, and if $a = lb$ then P is an $\{l-1\}$-design. This completes the proof.

4. Proof of Theorem 2

Suppose C satisfies the hypotheses of Theorem 2. By Theorem 1 the codewords of any weight w_i in C form a t-design. If $k = \dim C = 1$, only the repetition code yields a t-design. In this case $C^{\perp}$ consists of all even weight vectors and gives trivial designs. So from now on we assume $k > 1$.

It is easy to see (the argument is given on page 165 of [17]) that there are no codewords of $C^{\perp}$ with weight w' satisfying $n-t < w' < n$, and hence that there are two cases: (i) C is even, $w'_{s'} = n$, $s' = d-t+1$, or (ii) C is not even, $w'_{s'} \neq n$, $s' = d-t$. Thus we can write

$$s' = d - t + 1 - \delta , \tag{21}$$

where $\delta = 0$ if C is even, $\delta = 1$ if C is not even.

We work in the framework of the Hamming association scheme $H(n,2)$ – see [8], [9], [11], [17, Chap. 21] for background. The *Krawtchouk polynomial* of degree i is defined to be

$$P_i(\xi) = \sum_{j=0}^{i} (-1)^j \binom{\xi}{j} \binom{n-\xi}{i-j} \quad (0 \le i \le n) ,$$

and the *annihilator polynomial* of C is

$$\alpha(\xi) = 2^{n-k} \prod_{i=1}^{s'} \left(1 - \frac{\xi}{w'_i}\right).$$

Let us expand

$$\xi^m \, \alpha(\xi) = \sum_{i=0}^{s'+m} \alpha_i^{(m)} \, P_i(\xi), \qquad m = 0, 1, \ldots .$$

We set $\alpha_i^{(0)} = \alpha_i$. Note that $\alpha_{s'+m}^{(m)} \neq 0$ for all m.

It was shown in [9] that for all $x \in \mathbb{F}_2^n$,

$$\sum_{i=0}^{s'+m} \alpha_i^{(m)} \, b_i(x) = \begin{cases} 1, & m = 0, \\ 0, & m \ge 1, \end{cases} \tag{22}$$

where $b_i(x)$ is the number of codewords in C at distance i from x.

We next prove a lemma.

Lemma 8. *Let C be a binary $[n, k, d]$ code with nonzero weights $w_1 = d, w_2, \ldots, w_s$, and let $w'_1, \ldots, w'_{s'}$ be the nonzero weights in the dual code $C^{\perp}$. Let t be the greatest integer in the range $0 < t < d$ such that there are at most $d - t$ weights w'_i with $0 < w'_i \le n - t$, and suppose $w_2 \ge d + 4$. If the codewords of minimal weight form a $(t+1)$-design then so do the codewords of any nonzero weight w_i.*

Proof. Let x be an arbitrary subset of $\{1, 2, \ldots, n\}$ of size $l = t + 1$. Setting $m = w_2 - d - 2 + \delta > 0$ in (22) we obtain

$$\sum_{i=0}^{w_2 - t - 1} \alpha_i^{(m)} \, b_i(x) = 0 . \tag{23}$$

The zero codeword contributes to the sum in (23) if and only if $l \le w_2 - t - 1$. The contributions from the codewords of weight d are independent of x, since by hypothesis these words form a $(t+1)$-design. Codewords of weight greater than w_2 do not contribute to the sum at all, since

$$w_3 - l > w_2 - l = w_2 - t - 1 . \tag{24}$$

We now consider the contributions from the codewords c of weight w_2. Suppose c intersects x in j points. Then

$$\mathrm{dist}(c, x) = w_2 + l - 2j \le w_2 - t - 1 , \tag{25}$$

implying $j = t + 1$, i.e. codewords of weight w_2 contribute to the sum in (23) if and only if they contain x. Therefore (23) implies that the number of codewords of weight w_2 containing x is independent of x, or in other words the codewords of weight w_2 form a $(t+1)$-design. Similarly, by taking $m = w_j - d - 2 + \delta$ in (22), we find that the words of weight w_j form a $(t+1)$-design. This proves the lemma.

We now complete the proof of Theorem 2. The set of minimal weight words in C will be

denoted by P, and $\mu_{j,x}$ is the number of words in P that have exactly j points in common with a given l-set x.

Case (i), C even, $s' = d - t + 1$. Suppose first that there is a smallest integer f in the range $0 \le f \le [(d-t)/2]$ such that $\alpha_{d-t-2f} \ne 0$. Let x be an arbitrary subset of $\{1, 2, \ldots, n\}$ of size $l = t + 2f$. Since C is even, the distances from x to C are all congruent to t (modulo 2), and from (22) we have

$$\sum_{\substack{i=0 \\ i \equiv t \pmod 2}}^{d-t-2f} \alpha_i \, b_i(x) \;=\; 1 \,. \tag{26}$$

Proceeding as in the proof of the lemma, we find that only the zero codeword and the codewords of weight d contribute to the sum in (26), and the words of weight d contribute if and only if they contain x. Equation (26) then reads

$$\alpha_{d-t-2f} \, \mu_{t+2f,x} \;=\; 1 \;-\; \alpha_{t+2f} \, \varepsilon_{d-2t-2f-2} \,, \tag{27}$$

where we set

$$\varepsilon_p \;=\; \begin{cases} 0 & p < 0, \\ 1 & p \ge 0. \end{cases}$$

If $f \ge 1$ we conclude from (27) that P is a $(t+2f)$-design, in particular a $(t+1)$-design, and therefore by Lemma 8 that the codewords of every nonzero weight form $(t+1)$-designs.

On the other hand suppose $f = 0$. We take x to have weight $l = t + 2$, and find that (22) becomes

$$\alpha_{d-t-2} \, \mu_{t+2,x} \;+\; \alpha_{d-t} \, \mu_{t+1,x} \;=\; 1 \;-\; \alpha_{t+2} \, \varepsilon_{d-2t-2} \,, \tag{28}$$

where both coefficients on the left side are nonzero. From Theorem 7 we conclude that P is a $\{t+1\}$-design or a $\{t+2\}$-design, and hence either a $(t+1)$-design or a $\{1, \ldots, t, t+2\}$-design. In the former case Lemma 8 extends this to codewords of every nonzero weight.

The third possibility is that no such f exists, and all coefficients α_{d-t-2i} are zero. But in this case taking x in (22) to have weight t leads to a contradiction (that left side of (26) vanishes but the right side does not).

Case (ii), C not even, $s' = d-t$. Let x have weight $t+2$. Equation (22) implies

$$\alpha_{d-t-2}\,\mu_{t+2,x} + \alpha_{d-t}\,\mu_{t+1,x} = 1 - \alpha_{t+2}\,\varepsilon_{d-2t-2}\,,$$

where $\alpha_{d-t} \neq 0$. From Theorem 7 we conclude that P is a $\{t+1\}$-design or a $\{t+2\}$-design, and Lemma 8 completes the proof.

An alternative proof of Theorem 2. The above argument shows only that an invariant linear form of the type (13) exists; by Theorem 7 this is enough to prove the desired result. However it is possible to give a proof in which a ''computation miracle'' produces an explicit invariant linear form. We give this direct proof in the case when C is even. We suppose that P is not a $(t+1)$-design.

By applying (22) with $m = 0$ and 1 to a $(t+1)$-set x we obtain

$$\alpha_{d-t-1}\,\mu_{t+1,x} + \alpha_{d-t+1}\,\mu_{t,x} = 1 - \alpha_{t+1}\,\varepsilon_{d-2t}\,, \tag{29}$$

$$\alpha^{(1)}_{d-t-1}\,\mu_{t+1,x} + \alpha^{(1)}_{d-t+1}\,\mu_{t,x} = -\,\alpha^{(1)}_{t+1}\,\varepsilon_{d-2t+1}\,, \tag{30}$$

where $\alpha_{d-t+1} \neq 0$. Since P is a t-design,

$$(t+1)\,\mu_{t+1,x} + \mu_{t,x} = (t+1)\,\lambda_t\,, \tag{31}$$

where λ_t is the number of blocks through t given points. Since P is not a $(t+1)$-design, the left sides of (29)-(31) must be proportional (or else $m_{t+1,x}$ would be independent of x). Therefore

$$\alpha_{d-t-1} = (t+1)\,\alpha_{d-t+1}\,, \tag{32}$$

$$\alpha^{(1)}_{d-t-1} = (t+1)\,\alpha^{(1)}_{d-t+1}\,, \tag{33}$$

and so $\alpha_{d-t-1} \neq 0$. From the Krawtchouk recurrence [17, p. 152]

$$(i+1)\,P_i(\xi) = (n-2\xi)\,P_i(\xi) - (n-i+1)\,P_{i-1}(\xi)$$

($i \geq 1$), with $P_0(\xi) = 1$, $P_1(\xi) = n-2\xi$, we obtain

$$2\alpha_i^{(1)} = -(n-i)\alpha_{i+1} + n\alpha_i - i\alpha_{i-1} \tag{34}$$

($i \geq 1$). In particular,

$$2\alpha_{d-t+1}^{(1)} = n\alpha_{d-t+1} - (d-t+1)\alpha_{d-t}\,, \tag{35}$$

$$2\alpha_{d-t-1}^{(1)} = -(n-d+t+1)\alpha_{d-t} + n\alpha_{d-t-1} - (d-t-1)\alpha_{d-t-2}\,. \tag{36}$$

Furthermore $\alpha_{d-t} \neq 0$, or else (as shown in the first proof) P is a $(t+1)$-design. From (32), (33), (35), (36) we obtain

$$\alpha_{d-t-2} = \frac{(t+2)(d-t-1) - (n-2t-2)}{d-t-1}\,\alpha_{d-t}\,. \tag{37}$$

We now apply (22) with $m=0$ to a $(t+2)$-set x and find

$$\{(t+2)(d-t-1) - (n-2t-2)\}\,\mu_{t+2,x} + (d-t-1)\mu_{t+1,x}$$
$$= \frac{d-t-1}{\alpha_{d-t}}\,(1-\alpha_{t+2}\,\varepsilon_{d-2t-1})\,. \tag{38}$$

The left-hand side of (38) is the desired linear form, independent of x. Theorem 7 and Lemma 8 complete the proof. The most interesting aspect of this argument is the leverage provided by the assumption that P is *not* a $(t+1)$-design.

Examples. An example with $t=5$ is provided by the set of 759 minimal weight words in the [24, 12, 8] Golay code. In this case we have the identity $\mu_{7,x} + \mu_{6,x} = 1$ for any 7-set x. (There are only two possibilities, $(\mu_{7,x}, \mu_{6,x}) = (0,1)$ or $(1,0)$, corresponding to the two kinds of 7-subsets of $[1, 24]$ under the action of the Mathieu group M_{24} – cf. [6, Fig. 10.1].) The 759 words form a $\{1, 2, 3, 4, 5, 7\}$-design.

A second example with $t=5$ is provided by the 17296 minimal weight words in the $[48, 24, 12]$ extended quadratic-residue code (or in any self-dual doubly even $[48, 24, 12]$ code). In this case we have the identity $\mu_{7,x} + \mu_{6,x} = 8$ for any 7-set x. (There are only two possibilities: $(\mu_{7,x}, \mu_{6,x}) = (0,8)$ or $(1,7)$.) Again the minimal weight words form a $\{1, 2, 3, 4, 5, 7\}$-design.

A more trivial example with $t=1$ is provided by the $[n=2m, 2, m]$ code $\{0^{2m}, 0^m 1^m, 1^m 0^m, 1^{2m}\}$. The two words of weight m form a $\{1,3\}$-design.

A further example: complementation. The $\{1, 2, \ldots, l, l+2\}$-design property is preserved when the blocks of P are complemented. To see this, let $\overline{\mathsf{P}} = \{[1,n] \setminus B \mid B \in \mathsf{P}\}$, and let $\nu_{j,x}$ be the number of blocks in $\overline{\mathsf{P}}$ meeting a given $(l+2)$-set x in exactly j points. Then $\nu_{j,x} = \mu_{l+2-j,x}$, and we must therefore show that

$$\bar{a}\,\mu_{0,x} + \bar{b}\,\mu_{1,x} = \bar{c} \tag{39}$$

for all x, for suitable real numbers $\bar{a}, \bar{b}, \bar{c}$ not all zero. Since $\overline{\mathsf{P}}$ is a $\{1, 2, \ldots, l, l+2\}$-design we have invariant linear forms

$$a\,\mu_{l+2,x} + b\,\mu_{l+1,x} = c\,, \quad \text{where} \quad b \neq 0\,, \tag{40}$$

$$\sum_{i=j}^{l+2} \binom{i}{j} \mu_{i,x} = \binom{l+2}{j} \lambda_j\,, \quad j=0, 1, \ldots, l\,, \tag{41}$$

where λ_j is the number of blocks of P through j given points. Equations (40), (41) form a triangular system of $l+2$ equations in the $l+3$ quantities $\mu_{j,x}$, $j=0, \ldots, l+2$. From this we obtain

$$\mu_{0,x} = \alpha\,\mu_{l+2,x} + \beta\,, \quad (\alpha, \beta \text{ not both zero})\,,$$

$$\mu_{1,x} = \gamma\,\mu_{l+2,x} + \delta\,, \quad (\gamma, \delta \text{ not both zero})\,,$$

for suitable real numbers $\alpha, \beta, \gamma, \delta$, and Equation (39) follows.

5. Extension to codewords of higher weight and the proof of Theorem 3

Lemma 8 shows that if the codewords of minimal weight form a $(t+1)$-design then so do the codewords of any nonzero weight. To extend the $\{1, 2, \ldots, t, t+2\}$-design property to codewords of higher weight it is necessary to make some assumptions about the gap sizes $w_i - w_{i-1}$ for $i \geq 3$. In the sequel we shall only consider self-dual codes with all weights divisible by 4, even though the arguments apply to a wider class of codes.

We begin with an example, the $[24, 12, 8]$ Golay code. The annihilator polynomial is

$$\begin{aligned} \alpha(\xi) &= 2^{12}\left(1-\frac{\xi}{8}\right)\left(1-\frac{\xi}{12}\right)\left(1-\frac{\xi}{16}\right)\left(1-\frac{\xi}{24}\right) \\ &= \sum_{i=0}^{3} P_i(\xi) + \frac{1}{6} P_4(\xi) \, . \end{aligned} \tag{42}$$

Given an arbitrary 7-set x, let $M_{j,x}^{w}$ be the number of codewords of weight w that meet x in exactly j points. From (38), (41) we obtain the invariant linear forms

$$M_{7,x}^{8} + M_{6,x}^{8} \, , \tag{43}$$

$$21M_{7,x}^{8} + 6M_{6,x}^{8} + M_{5,x}^{8} \, . \tag{44}$$

Next we apply (22) with $m = 1$ to obtain the invariant form

$$\alpha_1^{(1)} M_{7,x}^{8} + \alpha_3^{(1)} M_{6,x}^{8} + \alpha_5^{(1)} M_{5,x}^{8} + \alpha_5^{(1)} M_{7,x}^{12} \, . \tag{45}$$

Before calculating the shifted Krawtchouk coefficients $\alpha_j^{(1)}$ we can see that there are two possibilities. The first is that the form

$$\alpha_1^{(1)} M_{7,x}^{8} + \alpha_3^{(1)} M_{6,x}^{8} + \alpha_5^{(1)} M_{5,x}^{8} \tag{46}$$

is a linear combination of (43) and (44). Since $\alpha_5^{(1)} \neq 0$, we may conclude that in this case the codewords of weight 12 form a 7-design. The second possibility is that (43), (44), (46) form a basis for the space of linear forms in the variables $M_{j,x}^{8}$ $j = 5, 6, 7$. Now we understand the Golay

code well enough to know that the first possibility does not occur, but it is precisely this argument that we will apply to an arbitrary doubly-even code. We may in fact calculate the shifted Krawtchouk coefficients from (34), finding that $\alpha_0^{(1)} = \alpha_1^{(1)} = \alpha_2^{(1)} = 0$, $\alpha_3^{(1)} = \frac{35}{4}$, $\alpha_4^{(1)} = 0$, $\alpha_5^{(1)} = -\frac{5}{12}$, so (45) becomes

$$21\, M_{6,x}^8 - M_{5,x}^8 - M_{7,x}^{12} . \tag{47}$$

Next we apply (22) with $m = 3$ to obtain the invariant form

$$\alpha_1^{(3)}\, M_{7,x}^8 + \alpha_3^{(3)}\, M_{6,x}^8 + \alpha_5^{(3)}\, M_{5,x}^8 + \alpha_7^{(3)}\, M_{4,x}^8 + \alpha_5^{(3)}\, M_{7,x}^{12} + \alpha_7^{(3)}\, M_{6,x}^{12} , \tag{48}$$

where $\alpha_7^{(3)} \neq 0$. From (41) we have a second invariant form involving the new variable $M_{4,x}^8$, namely

$$35\, M_{7,x}^8 + 15\, M_{6,x}^8 + 5\, M_{5,x}^8 + M_{4,x}^8 . \tag{49}$$

Since (43), (44), (46), (47) are a basis for the space of linear forms in the variables $M_{j,x}^8$ $j = 4, 5, 6, 7$, we may eliminate these variables from (48) and obtain an invariant form

$$a\, M_{7,x}^{12} + b\, M_{6,x}^{12} ,$$

of type (13). In this case $a/b = 5$, and so the codewords of weight 12 in the Golay code form a $\{1, 2, 3, 4, 5, 7\}$-design.

The proof of Theorem 3 is a straightforward generalization of this example. From Theorem 1 the codewords of any given weight w_p form a t-design, so (generalizing (41)) we have invariant linear forms

$$L_{w_p, j} = \sum_{h=1}^{t+2} \alpha_j^h M_{h,x}^{w_p}, \quad j = 0, 1, \ldots, t, \quad p = 1, \ldots, d - t , \tag{50}$$

where x is an arbitrary $(t+2)$-subset of $[1, n]$. From (22) we also have invariant forms (generalizing (45) and (48)):

$$H_m = \sum_{\substack{w_i, j \\ w_i+t+2-2j \le d-t+1+m}} \alpha^{(m)}_{w_i+t+2-2j} \, M^{w_i}_{j,x} , \quad m = 1, 3, 5, \ldots . \tag{51}$$

Finally Theorem 2 provides an invariant form

$$a \, M^d_{t+2,x} + b \, M^d_{t+1,x} , \quad b \neq 0 . \tag{52}$$

The theorem is proved by induction. For $i = 2, \ldots$, let $\Gamma(i)$ be the linear system in the variables $\{M^{w_p}_{j,x} : p < i, w_p + t + 2 - 2j < w_i - t - 2\}$ consisting of (52) and the linear forms

$$L_{w_p, j} \quad \text{for} \quad p < i, \quad w_p + t + 2 - 2j < w_i - t - 2 , \quad \text{and}$$

$$H_m \quad \text{for} \quad m < w_i - d - 3 , \quad m \quad \text{odd} .$$

The inductive hypothesis is that the corank of the linear system $\Gamma(i)$ is at most 1. This is certainly true for $i = 2$, since $\Gamma(2)$ includes the triangular system consisting of (52) and $L_{d,j}$ for $d + t + 2 - 2j < w_2 - t - 2$.

The linear system $\Gamma(i+1)$ involves variables $M^{w_p}_{j,x}$ that do not appear in $\Gamma(i)$. For each new variable $M^{w_p}_{j,x}$ with $w_p < w_{i+1}$ we have a linear form $L_{w_p, f}$, so these new variables do not change the corank. The linear form

$$H_{w_{i+1}-d-3} - \alpha^{(w_{i+1}-d-3)}_{w_{i+1}-t-2} \, M^{w_{i+1}}_{t+2,x} \tag{53}$$

only involves variables $M^{w_p}_{j,x}$ with $w_p < w_{i+1}$. We distinguish two cases.

The first is that (53) is a linear combination of forms from $\Gamma(i)$ and forms $L_{w_p, f}$ involving variables $M^{w_p}_{j,x}$ not appearing in $\Gamma(i)$. Then $M^{w_{i+1}}_{t+2,x}$ is independent of x, that is the codewords of weight w_{i+1} form a $(t+2)$-design. Now $\Gamma(i+1)$ includes the triangular system

$$M^{w_{i+1}}_{t+2,x}, \; (t+2) \, M^{w_{i+1}}_{t+2,x} + M^{w_{i+1}}_{t+1,x}, \; L_{w_{i+1}, j}$$

in the variables $M^{w_p}_{j,x}$, so the corank of $\Gamma(i+1)$ is at most 1.

The second case is that the linear form (53), together with the forms in $\Gamma(i)$ and the forms $L_{w_p, f}$ involving variables $M_{j,x}^{w_p}$ not appearing in $\Gamma(i)$, form a basis for the space of linear forms in the variables appearing in (53). Now consider $H_{w_{i+1}-d-1}$. We may eliminate variables from $H_{w_{i+1}-d-1}$ to obtain a linear form

$$a\, M_{t+2,x}^{w_{i+1}} + b\, M_{t+1,x}^{w_{i+1}}, \tag{54}$$

where $b \neq 0$. By Theorem 7 we may conclude that the codewords of weight w_{i+1} form a $(t+1)$-design or a $\{1, 2, \ldots, t, t+2\}$-design. The rank of $\Gamma(i+1)$ restricted to variables $M_{j,x}^{w_p}$ for $p < i+1$ is full. Since $\Gamma(i+1)$ includes the triangular system $\{(54), L_{w_{i+1}, j}\}$ in the variables $M_{j,x}^{w_{i+1}}$, the corank of $\Gamma(i+1)$ is at most 1.

Remarks. The proof leaves open the possibility that the codewords of weight w_i might form a $(t+1)$-design while the codewords of weight w_j $(j \neq i)$ form a $\{1, \ldots, t, t+2\}$-design.

sci-tchr@3wave.com

The first author is a professor of mathematics at UT Martin. He lives on a small "farm" in rural northwest Tennessee with his wife, five children, two cats, and numerous chickens. The second author is a schoolteacher and amateur number theorist. He is an avid chess player.

The prime counting function, $\pi(x)$, counts exactly how many primes there are less than or equal to x. The second author discovered the following "curio" (see [1]):

$$\pi(6521) = 6! + 5! + 2! + 1!.$$

If we write the positive integer x in base 10:

$$x = a_k \ldots a_2 a_1 a_0 \qquad (\text{with } a_k \geq 0)$$

are there any other prime solutions to

$$f(x) := \sum_{i=0}^{k} a_i! = \pi(x) \; ? \tag{1}$$

How many solutions could be generated if we allow x to be composite? Is there an upper bound on how far we would need to look? What if we work in a base other than 10 or use other functions? Below we provide answers to these questions, and then pose new areas for further investigation.

Searching for another

By the prime number theorem [2, pp. 225-227], the prime counting function $\pi(x)$ is asymptotic to $x / \ln x$. In fact, Dusart [3] has shown that, when $x \geq 599$,

$$\frac{x}{\ln x}\left(1 + \frac{0.992}{\ln x}\right) < \pi(x) < \frac{x}{\ln x}\left(1 + \frac{1.2762}{\ln x}\right). \tag{2}$$

The factorial $a_i!$ is at most 9! for each of the [1+log x] digits of x, so any solution x to (1) must satisfy

$$\frac{x}{\ln x}\left(1+\frac{0.992}{\ln x}\right) < \pi(x) = f(x) \le 9!\left[1+\frac{\ln x}{\ln 10}\right]. \qquad (3)$$

This statement is false for $x > 48{,}657{,}759$, so this is an upper bound for solutions. If x is an eight-digit solution beginning with 4, then the second digit is at most 8 and we can use the tighter bound

$$f(x) \le 4! + 8! + 9!\,6 < \pi(40{,}000{,}000) = 2{,}433{,}654$$

to see that there are no such solutions. Now we know $x < 40{,}000{,}000$. After checking to see that 39,999,999 does not work, we note that for $N_1 = (3.8)10^7 \le x < 39{,}999{,}999$ we have

$$f(x) \le 3! + 8! + 9!\,6 < \pi(N_1) = 2{,}318{,}966.$$

Similarly for $N_2 = (3.6)10^7 \le x < N_1$ we have

$$f(x) \le 3! + 7! + 9!\,6 < \pi(N_2) = 2{,}204{,}262.$$

Therefore there are no solutions with $x \ge N_2$.

For $N_3 = (3.0)10^7 \le x < N_2$, first we check the cases where x ends in six '9's individually; then for the remaining integers x we have

$$f(x) \le 3! + 5! + 8! + 9!\,5 < \pi(N_3) = 1{,}857{,}859.$$

A check of the integers $x \le N_3$ using the public domain program UBASIC [4] shows the following 23 solutions:

6500, 6501, 6510, 6511, **6521**, 12066, 50372, 175677, 553783, **5224903**, 5224923, 5246963, 5302479, 5854093, 5854409, 5854419, 5854429, 5854493, 5855904, 5864049, 5865393, 10990544, 11071599 [5, seq. A049529].

Of these, only 6,521 and 5,224,903 are prime [6, p. 11].

Bases other than 10

We can write x in a base B other than 10

$$x = b_k \ldots b_2 b_1 b_0 \qquad (\text{with } b_k > 0)$$

and ask whether the equation

$$g(x) := \sum_{i=0}^{k} b_i! = \pi(x) \tag{4}$$

has any solutions. Now $b_i! \le (B-1)!$ so we can replace the inequality (3) with

$$\frac{x}{\ln x} < \pi(x) = g(x) \le (B-1)!\left[1+\frac{\ln x}{\ln B}\right]. \tag{5}$$

Omitting the factor $1+0.992/\ln x$ from (3) ensures that the leftmost inequality holds for $x \ge 11$ rather than $x \ge 599$.

For each value of B the right side of (5) grows like a multiple of $\ln x$, whereas the left-hand side grows like $x/\ln x$, therefore the inequality is false for all large x. So there is a value $x_o(B)$ such that any solution satisfies $x \le x_o(B)$. We will show that we can take $x_o(B) = 2\,B\,B!\,\ln B$ for all bases $B > 2$. Since (5) is already false at $x = 13$ for $B = 2$, we may take $x_o(2) = 13$.

First note for any solution x we have $x \ge B$ (otherwise $x! = \pi(x)$), so (5) yields

$$\frac{x}{\ln x} < (B-1)!\left(1+\frac{\ln x}{\ln B}\right) \le \frac{2\,(B-1)!\,\ln x}{\ln B}. \tag{6}$$

We next show that $x < B^B$ (for $B \ge 3$). Otherwise, since $x/(\ln x)^2$ is an increasing function for $x > e^2$, the inequality above divided by $\ln x$ gives:

$$\frac{B^B}{B^2(\ln B)^2} \le \frac{x}{(\ln x)^2} < \frac{2\,(B-1)!}{\ln B} < \frac{2B}{\ln B}\left(\frac{B}{e}\right)^{B-1}.$$

The last inequality comes from $\ln (n-1)! \le n \ln n - n + 1$ (see [7, p. 79]). But this reduces to

$$e^{B-1} < 2B^2 \ln B,$$

which is false for $B \ge 6$. For the remaining bases 3, 4 and 5, we can verify $x < B^B$ individually using (5).

Finally, upon multiplying (6) by $\ln x$ and using our result $\ln x < B \ln B$, we have

$$x < 2\,(B-1)!\,B^2 \ln B,$$

which is the desired bound.

We used UBASIC and a slightly sharpened form of the bound above to lists all of the solutions for various small bases, the result of this search is in Table 1.

Insert Table 1 near here

Alternately we could choose an integer x and ask if there is any base B for which the equation (4) has a solution. Clearly $x \geq B$. If we find the least integer n such that $n! \geq \pi(x)$, then we know $b_0 = (x \bmod B) \leq n$, so B is a divisor of $x-i$ for some $i \leq n$. For each x we then have a relative short list of possible bases. In this way we find all of the prime integers $x \leq 160{,}000{,}000$ such that (4) holds (x and B are written in base 10):

(x,B) = (3,2), (3,3), (5,2), (5,3), (17,14), (19,4), (19,8), (97,24), (97,93), (101,5), (103,9), (229,5), (661,132), (661,656), (673,334), (701,232), (5449,908), (5449,5443), (5501,7), (6473,1078), (6521,10), (6719,7), (6733,7), (49037,49030), (49043,24518), (49277,7039), (56809,9467), (64921,8), (114599,8), (484061,484053), (485909,60738), (495491,9), (560437,9), (5222447,5222438), (5222501,2611246), (5222837,1305707), (5224451,580494), (5224903,10), (5378437,15), (6480811,15), (61194733,61194723), (61285057,6128505), (62009933,11) and (67717891,7524209).

There are infinitely many such solutions! To see this, let p_n be the nth prime, then $(x,B) = (p_{n!+1}, p_{n!+1}-n)$ is a solution to (4).

The multifactorials

Instead of the factorial function, we could use the double factorial function $n!!$ [8, p. 258] or its generalization—the multifactorial function. These are defined for integers n as follows.

$n! = 1$	for $n \leq 1$,	otherwise	$n! = n \cdot (n-1)!$	(n factorial)
$n!! = 1$	for $n \leq 1$,	otherwise	$n!! = n \cdot (n-2)!!$	(n double-factorial)
$n!!! = 1$	for $n \leq 1$,	otherwise	$n!!! = n \cdot (n-3)!!!$	(n triple-factorial)

and in general

$n!_k = 1$	for $n \leq 1$,	otherwise	$n!_k = n \cdot (n-k)!_k$	(n k-factorial).

For example, $13!!! = 13!_3 = 13 \cdot 10 \cdot 7 \cdot 4 \cdot 1$ and $23!_4 = 23 \cdot 19 \cdot 15 \cdot 11 \cdot 7 \cdot 3$.

The approach above can also be used to bound the integers to check for the multi-factorials. Using the double factorial function, we have four solutions: 34, 6288, 10982, and 11978. For the triple factorial function, we have these four solutions: 45, 117, 127, and 2199. If we restrict ourselves to prime solutions, then there are only two additional solutions provided by all of the multifactorial functions:

$$\pi(127) = 1!!! + 2!!! + 7!!!$$

and

$$\pi(97) = 9!_7 + 7!_7.$$

Other functions

If we just count the digits, there is one solution: 2 ($\pi(2) = 1$, and 2 has 1 digit). If we add the digits then there are four solutions: 0, 15, 27, and 39 (none of which is prime). Using higher powers, we find the following prime solutions:

$$\pi(93701) = 9^4 + 3^4 + 7^4 + 0^4 + 1^4$$

$$\pi(1776839) = 1^5 + 7^5 + 7^5 + 6^5 + 8^5 + 3^5 + 9^5$$

$$\pi(1264061) = 1^6 + 2^6 + 6^6 + 4^6 + 0^6 + 6^6 + 1^6$$

$$\pi(\mathbf{34543}) = 3^3 + 4^4 + 5^5 + 4^4 + 3^3.$$

Note that 34543, found by the first author, is also palindromic [9].

Questions for the reader

Why add the terms corresponding to each digit? We could multiply:

$$\pi(1321) = 1^3 \cdot 3^3 \cdot 2^3 \cdot 1^3$$

or alternate signs:

$$\pi(19) = -1 + 9$$

$$\pi(53) = 5^2 - 3^2, \quad \pi(227) = 2^2 - 2^2 + 7^2, \quad \pi(929) = 9^2 - 2^2 + 9^2$$

$$\pi(47501) = -4! + 7! - 5! + 0! - 1!.$$

How about backwards exponentiation: $\pi(17) = 7^1$ and $\pi(23) = 3^2$?

Exploring other functions such as the sum of divisors function, may also prove interesting. In all such cases, the authors would be pleased to hear of your results.

caldwell@utm.edu

Have you ever seen the great stone pyramids of ancient Egypt or Central America? For over 5000 years, mankind has been building, visiting, and even sleeping in pyramids. When Memphis, Tennessee, decided to build a new arena in 1991, they chose the shape of a pyramid—this time constructed of steel and glass rather than rock and rubble. In this paper we also build pyramids, ours built of the unbreakable stones of mathematics: the primes. But not just any primes, we have chosen the symmetry of nested palindromes as mortar. For example, beginning with the prime 2, we can build two pyramids of height five. (Unlike the ancients, we build our pyramids from the top down.)

2	2
929	929
39293	39293
7392937	3392933
373929373	733929337

Here each step is a palindromic prime with the previous step as its central digits. These two pyramids are the tallest that can be built beginning with the prime 2.

The tallest such pyramids that can be built from the other one-digit primes are as follows:

		5	5	5	
3	3	151	353	757	7
131	131	31513	33533	37573	373
11311	71317	3315133	1335331	9375739	93739

Like many that have come before us, we ask how can we build them higher? For example, if instead of just one-digit primes, we begin with larger palindromic primes, can they be taller? If instead of adding just one digit to each side, we allow two or more, how much taller can we get? Are these pyramids always finite? Join us on a quick tour as we seek answers to these questions, and pose others for our readers.

Simple Step Pyramids

Starting with a single digit prime and at each level adding just one digit to each side, we found the tallest possible prime-pyramids (using nested palindromes) had height five. This is because there are only four possible digits we can add at each step: 1, 3, 7, and 9. Starting with larger primes is unlikely to help much, but there are so many to choose from that we might get lucky. For example, Felice Russo [10, 11 seq. A046210] found the following truncated palindromic prime pyramid of height nine.

7159123219517
371591232195173
33715912321951733
7337159123219517337
973371591232195173379
39733715912321951733793
3397337159123219517337933
933973371591232195173379339
39339733715912321951733793393

However, if instead we add two digits on each side, there are forty pairs of digits we can add to each end (and still avoid our steps being divisible by 2 or 5). Starting with the prime 2, the tallest that can be built (with step two) has height 26. In fact, there are two pyramids of this height. One of these is shown in figure 1. The other is the pyramid ending in the following 101-digit prime:

Insert figure 1 on a page near here
---

1 3189272993 3733012747 5151938943 3901197127
2339635702 0753693327 2179110933 4983915157 4721033733 9927298131

How do we know these are the tallest? Using UBASIC [3] we started with 2 and built *every possible pyramid*--at each step discarding those for which the new number was not a Fermat probable-prime [7, pg. 140]. Then for those pyramids of maximum height, we used UBASIC's application program APRT-CL [5] to complete primality proofs for every step. We also applied this approach to pyramids starting with the other one-digit primes. There are three pyramids tied for tallest starting with the prime 3, each of height 28. There is one each starting with the primes 5 and 7, both of height 29. Further information is available on-line [4].

Surely increasing the step size to three (or more) should increase the height, but by how much? How many pyramids would we have to check for an exhaustive search? We address these questions in the next section.

Heights and Heuristics

First, let $l(n)$ be the number of digits (the length) of n. Let $f(n,h,d)$ be the number of palindromic primes pyramids with height h (not necessarily the maximal height), beginning with n and with step size d. For example, $f(2,1,d) = 1$ (there is only one pyramid starting with 2 and

height 1, that is just "2"). However, f(101,2,2) = 4 since there are four pyramids starting with 101 of height 2 and step 2:

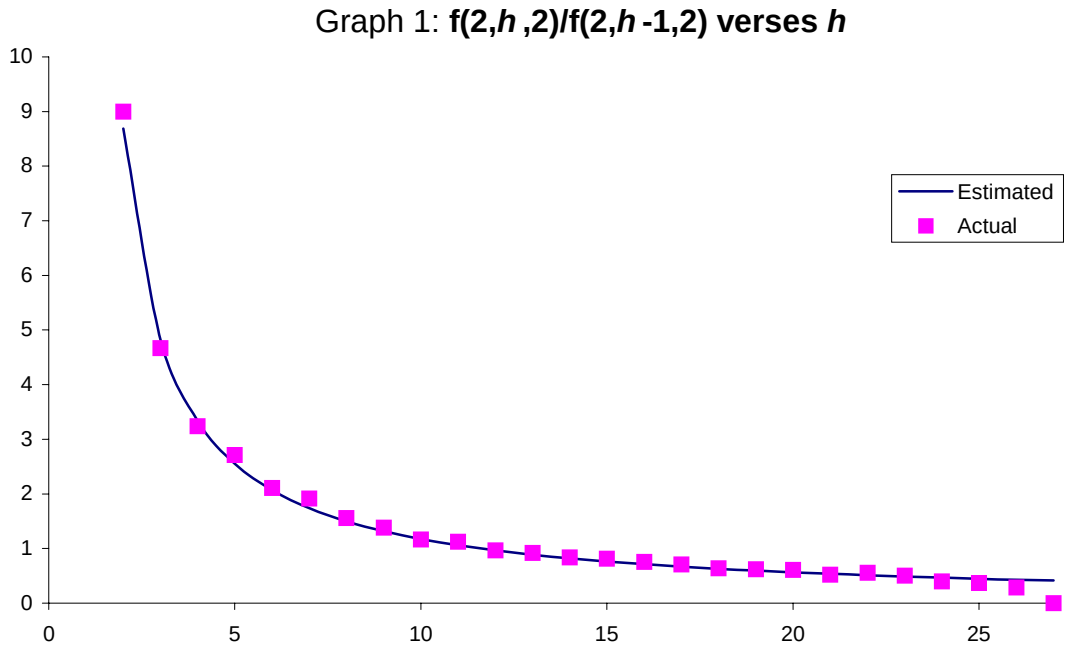
101	101	101	101
3310133	7310137	9110119	9610169

We will attempt to estimate f(n,h,d) and use this to estimate the maximum height.

Recall that the *prime number theorem* [7, pp. 225-227] states that the number of primes less than x is approximately $x/\ln x$. (Technically, the theorem says these quantities are asymptotic--so the larger x is, the better this estimate is). One interpretation of this theorem is that the probability of a random integer the size of the integer x being prime is about $1/\ln x$. When we move to the next step of a pyramid, there are 10^d integers to try, so if these new numbers behave as a random sample we would expect

$$\frac{f(n,h,d)}{f(n,h\text{-}1,d)} \approx \frac{10^d}{(l(n) + 2(h-1)d)\ln 10}. \qquad (1)$$

In graph 1 we see this rough estimate (graphed as a solid curve) compared to the actual ratios (graphed as individual squares) for n=2 and d=2.



These match surprisingly well! The drop off at the end is caused by the low numbers—we might expect 40% of two numbers to be prime, but in actuality only 0, 1, or 2 of them can be, not 0.80 of them. This is typical since this type of heuristic estimate (educated guess) works best for large numbers (see, for example, [2] or [12]).

As h grows, the ratio in (1) soon becomes one and then decreases to zero, so we would expect the number of pyramids to start decreasing at that point and then drop off to zero. From this we make the following conjecture.

Conjecture: All palindromic prime pyramids with fixed step size are finite.

We can predict more with this heuristic model. Repeatedly using the estimate (1), we have

$$\mathrm{f}(n,h,d) \approx \left(\frac{10^d}{\ln 10}\right)^{h-1} \frac{\mathrm{f}(n,1,d)}{(l(n)+2d(h-1))\,(l(n)+2d(h-2))\cdot\ldots\cdot(l(n)+2d)}. \tag{2}$$

The denominator of the second term is Pochhammer's symbol and can be expressed via the gamma function[1] [1, eq. 6.1.22]. This yields the following.

$$\mathrm{f}(n,h,d) \approx \left(\frac{10^d}{2d\ln 10}\right)^{h-1} \frac{\Gamma\left(\frac{l(n)}{2d}+1\right)}{\Gamma\left(\frac{l(n)}{2d}+h\right)}. \tag{3}$$

This estimate is one when h=1 (the top of the pyramid). Just past where this estimate is one again (for some larger h), we would expect to have the pyramid with greatest height. Using a computer program such as Maple [13] it is easy to solve for this value. Sadly, we can only test our estimates for small values of d where we expect the greatest relative error, but the comparisons still are heartening—see Table 1.

Table 1: **The average maximum height of pyramids**

length		**step d = 1**		**step d = 2**		**step d=3**	**step d=4**
***l*(*n*)**	number*	predicted	**actual**	predicted	**actual**	predicted	predicted
1	4	3.55	**3.75**	26.8	**28.0**	193	1471
3	15	1.31	**2.53**	25.0	**25.8**	191	1469
5	93	1**	**2.10**	23.3	**24.3**	190	1467
7	668	1**	**1.79**	21.7	**22.1**	188	1466
9	5172	1**	**1.58**	20.1	**20.2**	186	1464

* The number of starting values (palindromic primes) n of the given length $l(n)$
** The estimate (3) is only one once for these values of $l(n)$ (when h=1)

We found the actual values in table one by exhaustive search: for each palindromic prime of the given length, we found the pyramid of maximum height (by finding all pyramids beginning with this prime). We then averaged over all the palindromic primes of this length.

Notice that even for d=3 and n=2, this exhaustive approach would be beyond the world's current computing ability because when the height was 73, (2) predicts there should be almost 10^{30} pyramids to deal with. However, we can still test this heuristic by keeping a fixed number

[1] $\Gamma(n)$ is the analytic continuation of the familiar factorial function: $\Gamma(n+1) = n!$ for positive integers n.

of pyramids at each step. In our test we kept a maximum of 160 pyramids at each height, so beginning at h=74 (when the ratio (2) is one) and continuing until we get a product less than one, we predict we should find a maximum height of about 103. Starting with the primes 2, 3, 5 and 7 we found maximal pyramids of heights 94, 101, 102 and 100 respectively. This is reasonable agreement for the relatively small number of pyramids (a maximum of 160) involved. (Again, these prime pyramids are available on the web [4])

Related Sequences

Keeping the step size fixed (apparently) forever binds our pyramids to a finite height. But suppose we instead allow any step size? An argument similar to the one above suggests that for any starting prime we should be able to build as high as we like, though the taller the pyramids get the larger our step size must be (on the average).

There is one case that is especially interesting: Suppose we ask that each row be the smallest prime that can be used. Then our pyramid would begin as follows:

2
727
37273
333727333

When the first author built this pyramid, he was able to verify the primality of the first 33 rows.

This pyramid has also been presented as a sequence a_1, a_2, a_3, …. To do this let a_1=2 and then for each positive integer n, let a_{n+1} be the smallest palindromic prime with a_n as the central digits [11, seq. A053600]. We can condense this sequence by writing a_1, followed by the digits added on the left at each stage. Carlos Rivera [8] extended the first author's 33 terms using a probabilistic primality test and found the condensed sequence [11, seq. A052091] (most likely) begins:

2, 7, 3, 33, 9, 30, 18, 92, 3, 133, 18, 117, 17, 15, 346, 93, 33,
180, 120, 194, 126, 336, 331, 330, 95, 12, 118, 369, 39, 32, 165,
313, 165, 134, 13, 149, 195, 145, 158, 720, 18, 396, 193, 102,
737, 964, 722, 156, 106, 395, 945, 303, 310, 113, 150, 303, 715,
123

Finally, Russo took a different approach to palindromic prime pyramids, and asked what was the smallest palindromic prime a_n that generates a prime pyramid of maximum height n? This sequence [11, seq. A046210] begins 11, 131, 2, 929, 10301, 16361, 10281118201, 35605550653, 7159123219517…

Conclusion

As we look around in the world, we see many variations on the basic pyramids of Egypt. Above we have mentioned just a few of the variations on our pyramids that have appeared since the first author proposed the idea. For even more variations, look on-line [4, 6, 9, 11].

We have left many open questions and leave the reader with the most basic of challenges: build them higher! Perhaps you can develop a way of finding the tallest pyramids with fixed step sizes--something far better than exhaustive search. Or perhaps can you prove (rather than just heuristically suggest) that fixed step size pyramids are finite. We built pyramids in decimal (base 10), why not try another base (e.g., binary)?

In all cases, we would be glad to hear of your results.

Recounting the rationals

Neil Calkin

Herbert S. Wilf
Department of Mathematics, University of Pennsylvania
Philadelphia, PA 19104-6395

July 6, 1999

It is well known (indeed, as Paul Erdős might have said, every child knows) that the rationals are countable. However, the standard presentations of this fact do not give an explicit enumeration; rather they show how to *construct* an enumeration. In this note we will explicitly describe a sequence $b(n)$ with the property that every positive rational appears exactly once as $b(n)/b(n+1)$. Moreover, $b(n)$ is the solution of a quite natural counting problem.

The list of the positive rational numbers will begin like this:

$$\frac{1}{1}, \frac{1}{2}, \frac{2}{1}, \frac{1}{3}, \frac{3}{2}, \frac{2}{3}, \frac{3}{1}, \frac{1}{4}, \frac{4}{3}, \frac{3}{5}, \frac{5}{2}, \frac{2}{5}, \frac{5}{3}, \frac{3}{4}, \frac{4}{1}, \frac{1}{5}, \frac{5}{4}, \frac{4}{7}, \frac{7}{3}, \frac{3}{8}, \frac{8}{5}, \frac{5}{7}, \frac{7}{2}, \frac{2}{7}, \frac{7}{5}, \ldots$$

Some of the interesting features of this list are

1. The denominator of each fraction is the numerator of the next one. That means that the nth rational number in the list looks like $b(n)/b(n+1)$ $(n = 0, 1, 2, \ldots)$, where b is a certain function of the nonnegative integers whose values are

$$\{b(n)\}_{n\geq 0} = \{1, 1, 2, 1, 3, 2, 3, 1, 4, 3, 5, 2, 5, 3, 4, 1, 5, 4, 7, \ldots\}.$$

2. The function values $b(n)$ actually count something nice. In fact, $b(n)$ is the number of ways of writing the integer n as a sum of powers of 2, each power being used at most twice (i.e., once more than the legal limit for binary expansions). For instance, we can write $5 = 4 + 1 = 2 + 2 + 1$, so there are two such ways to write 5, and therefore $b(5) = 2$. Let's say that $b(n)$ is the number of *hyperbinary* representations of the integer n.

3. Consecutive values of this function b are always relatively prime, so that each rational occurs in reduced form when it occurs.

4. Every positive rational occurs once and only once in this list.

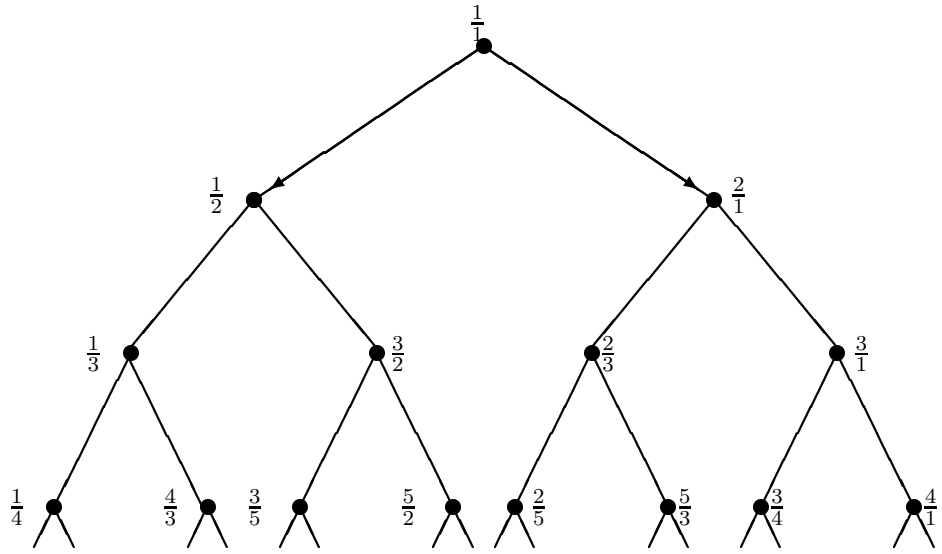

Figure 1: The tree of fractions

1 The tree of fractions

For the moment, let's forget about enumeration, and just imagine that fractions grow on the tree that is completely described, inductively, by the following two rules:

- $\frac{1}{1}$ is at the top of the tree, and
- Each vertex $\frac{i}{j}$ has two children: its left child is $\frac{i}{i+j}$ and its right child is $\frac{i+j}{j}$.

We show the following properties of this tree.

1. *The numerator and denominator at each vertex are relatively prime.* This is certainly true at the top vertex. Otherwise, suppose r/s is a vertex on the highest possible level of the tree for which this is false. If r/s is a left child, then its parent is $r/(s-r)$, which would clearly also not be a reduced fraction, and would be on a higher level, a contradiction. If r/s is a right child, then its parent is $(r-s)/s$, which leads to the same contradiction. □

2. *Every reduced positive rational number occurs at some vertex.* The rational number 1 certainly occurs. Otherwise, let r/s be, among all fractions that do not occur, one of smallest denominator, and among those the one of smallest numerator. If $r > s$ then $(r-s)/s$ doesn't

occur either, else one of its children would be r/s, and its numerator is smaller, the denominator being the same, a contradiction. If $r < s$, then $r/(s-r)$ doesn't occur either, else one of its children would be r/s, and it has a smaller denominator, a contradiction. □

3. *No reduced positive rational number occurs at more than one vertex.* First, the rational number 1 occurs only at the top vertex of the tree, for if not, it would be a child of some vertex r/s. But the children of r/s are $r/(r+s)$ and $(r+s)/s$, neither of which can be 1. Otherwise, among all reduced rationals that occur more than once, let r/s have the smallest denominator, and among these, the smallest numerator. If $r < s$ then r/s is a left child of two distinct vertices, at both of which $r/(s-r)$ lives, contradicting the minimality of the denominator. Similarly if $r > s$. □

It follows that a list of all positive rational numbers, each appearing once and only once, can be made by writing down 1/1, then the fractions on the level just below the top of the tree, reading from left to right, then the fractions on the next level down, reading from left to right, etc.

We claim that if that be done, then the denominator of each fraction is the numerator of its successor. This is clear if the fraction is a left child and its successor is the right child, of the same parent. If the fraction is a right child then its denominator is the same as the denominator of its parent and the numerator of its successor is the same as the numerator of the parent of its successor, hence the result follows by downward induction on the levels of the tree. Finally, the rightmost vertex of each row has denominator 1, as does the leftmost vertex of the next row, proving the claim.

Thus, after we make a single sequence of the rationals by reading the successive rows of the tree as described above, the list will be in the form $\{f(n)/f(n+1)\}_{n\geq 0}$, for some f.

Now, as the fractions sit in the tree, the two children of $f(n)/f(n+1)$ are $f(2n+1)/f(2n+2)$ and $f(2n+2)/f(2n+3)$. Hence from the rule of construction of the children of a parent, it must be that

$$f(2n+1) = f(n) \quad \text{and} \quad f(2n+2) = f(n) + f(n+1) \qquad (n = 0, 1, 2, \ldots).$$

These recurrences, together with $f(0) = 1$, evidently determine our function f on all nonnegative integers.

We claim that $f(n) = b(n)$, the number of hyperbinary representations of n, for all $n \geq 0$.

This is true for $n = 0$, and suppose true for all integers $\leq 2n$. Now $b(2n+1) = b(n)$, because if we are given a hyperbinary expansion of $2n+1$, the "1" must appear, hence by subtracting 1 from both sides and dividing by 2, we'll get a hyperbinary representation of n. Conversely, if we have such an expansion of n, then double each part and add a 1, to obtain a representation of $2n+1$.

Furthermore, $b(2n+2) = b(n) + b(n+1)$, for a hyperbinary expansion of $2n+2$ might have either two 1's or no 1's in it. If it has two 1's, then by deleting them and dividing by 2 we'll get an expansion of n. If it has no 1's, then we just divide by 2 to get an expansion of $n+1$. These maps are reversible, proving the claim.

It follows that $b(n)$ and $f(n)$ satisfy the same recurrence formulas and take the same initial values, hence they agree for all nonnegative integers. We state the final result as follows.

Theorem 1 *The nth rational number, in reduced form, can be taken to be $b(n)/b(n+1)$, where $b(n)$ is the number of hyperbinary representations of the integer n, for $n = 0, 1, 2, \ldots$. That is, $b(n)$ and $b(n+1)$ are relatively prime, and each positive reduced rational number occurs once and only once in the list $b(0)/b(1), b(1)/b(2), \ldots$.*

2 Remarks

There is a large literature on the closely related subject of Stern-Brocot trees [Ste, Bro]. In particular, an excellent introduction is in [GKP], and the relationship between these trees and hyperbinary partitions is explored in [Rez]. In Stern's original paper [Ste] of 1858 there is a structure that is essentially our tree of fractions, though in a different garb, and he proved that every rational number occurs once and only once, in reduced form. However Stern did not deal with the partition function $b(n)$. Reznick [Rez] studied restricted binary partition functions and observed their relationship to Stern's sequence. Nonetheless it seemed to us worthwhile to draw these two aspects together and explicitly note that the ratios of successive values of the partition function $b(n)$ run through all of the rationals.

Certificates of Integrality for Linear Binomials

1999

Say a sequence is *linear binomial*if its *n*th term is a quotient of (i) a binomial coefficient whose parameters are linear in *n*and (ii) a product *P(n)*of factors linear in *n*. An example is the familiar Catalan numbers (2*n*choose *n*)/(*n*+1) = {1,2,5,14,42,...}. This paper gives a simple criterion for (an integer multiple) of a linear binomial sequence to consist of integers. Roughly speaking, the criterion is: if and only if *P(n)*'s linear factors are distinct, and each appears more often in the "symbolic numerator" of the binomial coefficient than in its "symbolic denominator". The proof is algorithmic; applied to (2*n* choose (*n*-3))/*n*, it yields the integer multiplier "3" along with the identity 3(2*n* choose (*n*-3))/*n* = (2*n*-1) choose (*n*-3) -(2*n*-1) choose (*n*-4), which serves as a "Certificate of Integrality".

Abstract for R4 of Volume 2(1), 1995

Abstract for Peter J. Cameron, Counting Two-graphs Related to Trees

In an earlier paper, I showed that the classes of pentagon-free two-graphs and of pentagon-and-hexagon-free two-graphs could be represented in terms of trees. This paper gives formulae for the numbers of labelled objects in each of these classes, as well as the numbers of labelled reduced two-graphs in each class. The proofs use various enumeration results for trees. At least some of these results are well-known. To make the paper self-contained, I have included proofs.

Homogeneous Permutations

There are just five Fraïssé classes of permutations (apart from the trivial class of permutations of a singleton set); these are the identity permutations, reversing permutations, composites (in either order) of these two classes, and all permutations. The paper also discusses infinite generalisations of permutations, and the connection with Fraïssé's theory of countable homogeneous structures, and states a few open problems. Links with enumeration results, and the analogous result for circular permutations, are also described.

Product action

Peter J. Cameron,[*] Daniele A. Gewurz,[†] Francesca Merola[†]

May 30, 2003

Abstract

This paper studies the cycle indices of products of permutation groups. The main focus is on the product action of the direct product of permutation groups. The number of orbits of the product on n-tuples is trivial to compute from the numbers of orbits of the factors; on the other hand, computing the cycle index of the product is more intricate. Reconciling the two computations leads to some interesting questions about substitutions in formal power series. We also discuss what happens for infinite (oligomorphic) groups and give detailed examples. Finally, we briefly turn our attention to generalised wreath products, which are a common generalisation of both the direct product with the product action and the wreath product with the imprimitive action.

1 Introduction

Given two permutation groups (G_1, X_1) and (G_2, X_2), there are two 'natural' actions for the direct product and two for the wreath product, as follows. For the direct product $G_1 \times G_2$, we have the *intransitive action* $(G_1 \times G_2, X_1 \cup X_2)$, where the union is assumed disjoint; and the *product action* $(G_1 \times G_2, X_1 \times X_2)$. For the wreath product $G_1 \wr G_2$, we have the *imprimitive action* $(G_1 \wr G_2, X_1 \times X_2)$, and the *power action* $(G_1 \wr G_2, X_1^{X_2})$ (sometimes also called the product action).

We are interested in calculating the cycle index of these products, and its specialisations including the number of orbits on n-tuples and on n-sets. For the intransitive and imprimitive actions, there are well-known techniques for this, which we outline in the next section. However, for the power and product action, things are less simple. For the product action of the direct product, the cycle index can be calculated by an operation which we describe. The number of orbits on n-tuples is obtained from the corresponding numbers for the factors simply by multiplying them. It is not obvious how these two operations are related; we discuss this in detail in the third section of the paper. In the fourth section we make some preliminary remarks on the more complicated problems for power action of wreath products.

Bailey *et al.* defined a *generalised wreath product* of a family of permutation groups indexed by a poset. This reduces to the product action for direct product and to the imprimitive action for wreath product. In the final section of the paper we discuss this construction and outline what is known about enumeration.

2 Preliminaries

This section contains definitions of the actions of products that we consider, and a summary of known material about cycle index.

2.1 Actions of direct and wreath products

Let (G_1, X_1) and (G_2, X_2) be permutation groups. The direct product $G_1 \times G_2$ acts on the disjoint union $X_1 \cup X_2$ by the rule

$$x(g_1, g_2) = \begin{cases} xg_1 & \text{if } x \in X_1, \\ xg_2 & \text{if } x \in X_2 \end{cases},$$

and on the Cartesian product $X_1 \times X_2$ by the rule

$$(x_1, x_2)(g_1, g_2) = (x_1 g_1, x_2 g_2).$$

Note that $X_1 \times X_2$ is naturally identified with the set of transversals of the two sets X_1 and X_2 in the disjoint union.

By $G_1 \wr G_2$ we mean the *permutational wreath product*, the split extension of the base group $B = G_1^{X_2}$ by G_2 (permuting the factors of the direct product in the way it acts on X_2). It acts on the Cartesian product $X_1 \times X_2$ by the rule

$$(x_1, x_2) f = (x_1 f(x_2), x_2), \qquad (x_1, x_2) g = (x_1, x_2 g),$$

and on $X_1^{X_2}$ by the rule

$$(\phi f)(x_2) = (\phi(x_2))(f(x_2)), \qquad (\phi g)(x_2) = \phi(x_2 g^{-1}),$$

for $f \in B = G_1^{X_2}$, $g \in G_2$, and $\phi \in X_1^{X_2}$. Again, there is a natural identification of $X_1^{X_2}$ with the set of transversals for the copies $X_1 \times \{x_2\}$ of X_1 in $X_1 \times X_2$.

2.2 Cycle index of products

The *cycle index* of a finite permutation group (G,X) is

$$Z(G) = \frac{1}{|G|} \sum_{g \in G} \prod_{i=1}^{n} s_i^{c_i(g)},$$

where $n = |X|$, $s_1, \ldots, s_n$ are indeterminates, and $c_i(g)$ is the number of i-cycles in the cycle decomposition of g. We denote the result of substituting z_i for s_i in $Z(G)$ by $Z(G; s_i \leftarrow z_i)$.

Knowledge of the cycle index enables various orbit-counting to be done. We let $f_n(G)$, $F_n(G)$ and $F_n^*(G)$ be the numbers of orbits of G on n-element subsets, n-tuples of distinct elements, and all n-tuples of elements of X respectively; and we let $f_G(t)$, $F_G(t)$, $F_G^*(t)$ be the ordinary generating function $\sum_{n \geq 0} f_n(G) t^n$ and the exponential generating functions $\sum_{n \geq 0} F_n(G) t^n/n!$ and $\sum_{n \geq 0} F_n^*(G) t^n/n!$ respectively. Then

$$\begin{aligned} f_G(t) &= Z(G; s_i \leftarrow t^i + 1), \\ F_G(t) &= Z(G; s_1 \leftarrow t+1, s_i \leftarrow 1 \text{ for } i > 1), \\ F_G^*(t) &= Z(G; s_1 \leftarrow \mathrm{e}^t, s_i \leftarrow 1 \text{ for } i > 1). \end{aligned}$$

Note that

$$F_G^*(t) = F_G(\mathrm{e}^t - 1).$$

This equation can also be expressed as

$$F_n^*(G) = \sum_{k=1}^{n} S(n,k) F_k(G),$$

where $S(n,k)$ are the Stirling numbers of the second kind; in other words, the sequence $(F_n^*(G))$ is the *Stirling transform* of $(F_n(G))$ [3]. Hence we can recover the second sequence from the first by the *inverse Stirling transform*:

$$F_n(G) = \sum_{k=1}^{n} s(n,k) F_k^*(G),$$

where $s(n,k)$ are the Stirling numbers of the first kind.

The cycle indices of direct and wreath products, with the intransitive and imprimitive actions respectively, are given by

$$\begin{aligned} Z(G_1 \times G_2) &= Z(G_1)Z(G_2), \\ Z(G_1 \wr G_2) &= Z(G_2; s_i \leftarrow Z(G_1, s_j \leftarrow s_{i \cdot j})). \end{aligned}$$

This paper is mostly about the cycle indices of these groups in the product and power actions.

2.3 Oligomorphic groups

It is sometimes convenient to extend these definitions to infinite permutation groups. Such a group (G,X) is said to be *oligomorphic* if G has only a finite number of orbits on X^n for all natural numbers n.

For (G,X) a (finite or) oligomorphic permutation group, we define the *modified cycle index* $\tilde{Z}(G)$ by the rule

$$\tilde{Z}(G) = \sum_{\Delta} Z(G^{\Delta}_{\Delta}),$$

where G^{Δ}_{Δ} denotes the permutation group on Δ induced by its setwise stabiliser in G, and the sum is over a set of representatives of the G-orbits on finite subsets of X.

If it happens that G is a finite permutation group, then we have nothing new:

$$\tilde{Z}(G) = Z(G; s_i \leftarrow s_i + 1).$$

Some particular oligomorphic groups of interest to us are:

- S, the symmetric group on an infinite set;
- A, the group of order-preserving permutations of the rational numbers;
- C, the group of permutations preserving the cyclic order on the set of complex roots of unity.

See [2] for further details.

We note one example here. If $G = S$, then G is n-transitive for all $n \geq 0$, and so

$$F^*_n(S) = \sum_{k=1}^{n} S(n,k) = B(n)$$

the *n*th *Bell number* (the number of partitions of an *n*-set). Using the imprimitive action of the wreath product, we find also that

$$F_n(S \wr S) = B(n)$$

(it is not difficult to construct a bijection between $S \wr S$-orbits on *n*-tuples of distinct elements and *S*-orbits on arbitrary *n*-tuples); and so

$$F_n^*(S \wr S) = \sum_{k=1}^{n} S(n,k)B(k).$$

This is the number of (possibly improper) chains $\pi_1 \leq \pi_2$ in the poset of partitions of an *n*-set ordered by refinement, and is sequence A000258 in the *Encyclopedia of Integer Sequences* [5].

3 Product action of direct product

In this section we consider the product action of the direct product. Changing notation slightly, we have permutation groups (G,X) and (H,Y), and are interested in $G \times H$ in its action on $X \times Y$.

In what follows we shall discuss how the sequences associated with a direct product of permutation groups (in the product action) are related to the sequences of the factors. We shall see that the tamest sequence in this regard is (F_n^*), for which $F_n^*(G \times H) = F_n^*(G)F_n^*(H)$ holds. This is because an *n*-tuple of pairs is determined by the *n*-tuples of its first and second components, and this correspondence respects the action of $G \times H$.

The sequence (F_n) and the cycle index are also in principle easy to compute, although less immediately, while (f_n) tends to be, more often than not, quite wild.

In the former part we deal mostly with finite groups. In the latter part we shall study the sequences for groups obtained as products of the groups *S*, *A* and *C*; in particular, for $S \times S$, $A \times A$, and $C \times C$.

3.1 Cycle index

Take an *i*-cycle in a permutation $g \in G$ and a *j*-cycle in a permutation $h \in H$. The pair (g,h) acts on the product of the supports of these two cycles as $\gcd(i,j)$ cycles each of length $\mathrm{lcm}(i,j)$. Hence the cycle index of $G \times H$ can be computed

as follows: define $s_i \circ s_j = (s_{\mathrm{lcm}(i,j)})^{\gcd(i,j)}$, and extend multiplicatively to arbitrary monomials and then additively to arbitrary polynomials. Then

$$Z(G \times H) = Z(G) \circ Z(H).$$

The equality $F_n^*(G \times H) = F_n^*(G)F_n^*(H)$ will be deduced from this fact.

In what follows, we often have to substitute $s_1 \leftarrow \mathrm{e}^t$ and $s_i \leftarrow 1$ for $i > 1$ into a cycle index; we denote this particular substitution by (C). We also use the notation $[x^n]A(x)$, where $A(x)$ is a power series, to denote the coefficient of x^n in $A(x)$. Now we have:

$$\begin{aligned}
F_n^*(G \times H) &= \left[\frac{t^n}{n!}\right] F^*_{G\times H}(t) && (1)\\
&= \left[\frac{t^n}{n!}\right] F_{G\times H}(\mathrm{e}^t - 1) && (2)\\
&= \left[\frac{t^n}{n!}\right] Z(G \times H; (C)) && (3)\\
&= \left[\frac{t^n}{n!}\right] (Z(G) \circ Z(H); (C)). && (4)
\end{aligned}$$

The equality in (1) is just the definition of the exponential generating function $F_G^*(t)$. That in (2) relates the sequences (F_n) and (F_n^*), and that in (3) relates them to the cycle index of G, as described earlier.

On the other hand, we have:

$$\begin{aligned}
F_n^*(G)F_n^*(H) &= \left[\frac{t^n}{n!}\right] F_G^*(t) \left[\frac{t^n}{n!}\right] F_H^*(t) && (5)\\
&= \left[\frac{t^n}{n!}\right] (F_G^*(t) \bullet F_H^*(t)) && (6)\\
&= \left[\frac{t^n}{n!}\right] (Z(G; (C)) \bullet Z(H; (C))). && (7)
\end{aligned}$$

We have denoted by $\bullet$ the operation between exponential generating functions given by

$$\sum \frac{a_n t^n}{n!} \bullet \sum \frac{b_n t^n}{n!} := \sum \frac{a_n b_n t^n}{n!},$$

that is, the operation induced on the e.g.f. by the termwise product of the corresponding sequences.

So we have to prove the equality between (4) and (7). Here it is, slightly rephrased.

Proposition 3.1 *If A and B are polynomials in $s_1, s_2, \ldots$,*

$$(A \circ B)((C)) = A((C)) \bullet B((C)).$$

Proof Firstly, the thesis holds for the s_is:

$$(s_1 \circ s_1)((C)) = s_1((C)) = \mathrm{e}^t, \text{ and } s_1((C)) \bullet s_1((C)) = \mathrm{e}^t \bullet \mathrm{e}^t = \mathrm{e}^t;$$

for $i > 1$,

$$(s_1 \circ s_i)((C)) = s_i((C)) = 1, \text{ and } s_1((C)) \bullet s_i((C)) = \mathrm{e}^t \bullet 1 = 1;$$

and finally, for i and j both greater than 1,

$$(s_i \circ s_j)((C)) = (s_{\mathrm{lcm}(i,j)})^{\gcd(i,j)}((C)) = 1, \text{ and } (s_i((C)) \bullet s_j((C)) = 1 \bullet 1 = 1.$$

This holds for monomials as well. In fact, assuming $a < b < \ldots < z$,

$$(s_a^{m_a} s_b^{m_b} \ldots s_z^{m_z})((C)) = s_a^{m_a}((C))$$

(that is, is equal to 1 if $a > 1$, or to e^{m_a} if $a = 1$). So, we can limit ourselves to considering polynomials consisting only of monomials in which a single indeterminate appears.

$$\begin{aligned}
\left((s_1^l + s_i^m) \circ (s_1^p + s_j^q)\right)((C)) & \\
&= \left(s_1^l \circ s_1^p + s_1^l \circ s_j^q + s_i^m \circ s_1^p + s_i^m \circ s_j^q\right)((C)) \\
&= \left(s_1^{lp} + s_j^{lq} + s_i^{mp} + (s_{\mathrm{lcm}(i,j)})^{mq \cdot \gcd(i,j)}\right)((C)) \\
&= \mathrm{e}^{lpt} + 3;
\end{aligned}$$

and

$$\begin{aligned}
& (s_1^l + s_i^m)((C)) \bullet (s_1^p + s_j^q)((C)) \\
= \; & (\mathrm{e}^{lt} + 1) \bullet (\mathrm{e}^{pt} + 1) \\
= \; & \left\{ 2, \sum_{r_1 + \ldots + r_l = n} \binom{n}{r_1, \ldots, r_l} \right\}_{n=1}^{\infty} \bullet \left\{ 2, \sum_{s_1 + \ldots + s_p = n} \binom{n}{s_1, \ldots, s_p} \right\}_{n=1}^{\infty} \\
= \; & \left\{ 4, \sum_{a_1 + \ldots + a_{lp} = n} \binom{n}{a_1, \ldots, a_{lp}} \right\}_{n=1}^{\infty} \\
= \; & \mathrm{e}^{lpt} + 3.
\end{aligned}$$

$\diamondsuit$

Here we have identified a sequence and its exponential generating function, and used the notation (from Wilf [9]) that denotes by $\{b_n\}_{n=0}^{\infty}$ the sequence corresponding to the e.g.f. $\sum_n b_n t^n/n!$. Expressions for the terms of products and powers of e.g.f.s can also be found in Wilf's book.

The fact that the equality $\sum \binom{n}{r_1,\ldots,r_l} \sum \binom{n}{s_1,\ldots,s_p} = \sum \binom{n}{a_1,\ldots,a_{lp}}$ holds is for instance a consequence of it being just $l^n \cdot p^n = (lp)^n$ in disguise.

3.2 Which substitutions work?

One could ask what happens to the equality in Prop. 3.1 if one substitutes for the indeterminates s_i generic functions $f_i(t) = \sum_{n\geq 0} f_{i,n} t^n/n!$. Here is a partial answer.

Let us see for which f_is one gets

$$(s_j \circ s_k; s_i \leftarrow f_i(t)) = (s_j; s_i \leftarrow f_i(t)) \bullet (s_k; s_i \leftarrow f_i(t)).$$

We have

$$\begin{aligned}
& (s_j \circ s_k; s_i \leftarrow f_i(t)) \\
= \; & ((s_{\mathrm{lcm}(j,k)})^{\gcd(j,k)}; s_i \leftarrow f_i(t)) \\
= \; & \left(f_{\mathrm{lcm}(j,k)}(t)\right)^{\gcd(j,k)} \\
= \; & \left(\sum_{n\geq 0} \frac{f_{\mathrm{lcm}(j,k),n}\, t^n}{n!}\right)^{\gcd(j,k)} \\
= \; & \sum_{n\geq 0} \left(\sum_{r_1+\cdots+r_{\gcd(j,k)}=n} \binom{n}{r_1 \cdots r_{\gcd(j,k)}} f_{\mathrm{lcm}(j,k),r_1} \cdots f_{\mathrm{lcm}(j,k),r_{\gcd(j,k)}} \right) \frac{t^n}{n!}.
\end{aligned}$$

On the other hand,

$$\begin{aligned}
& (s_j; s_i \leftarrow f_i(t)) \bullet (s_k; s_i \leftarrow f_i(t)) \\
= \; & f_j(t) \bullet f_k(t) \\
= \; & \sum_{n\geq 0} \left[\frac{t^n}{n!}\right] f_j(t) \left[\frac{t^n}{n!}\right] f_k(t) \frac{t^n}{n!} \\
= \; & \sum_{n\geq 0} \frac{f_{j,n} f_{k,n}}{n!} t^n.
\end{aligned}$$

Thus, we are asking for conditions on the functions $f_i(t)$ under which the following happens:

$$f_{j,n}\, f_{k,n} = \sum_{r_1+\cdots+r_{\gcd(j,k)}=n} \binom{n}{r_1 \cdots r_{\gcd(j,k)}} f_{\mathrm{lcm}(j,k),r_1} \cdots f_{\mathrm{lcm}(j,k),r_{\gcd(j,k)}}. \quad (8)$$

If we examine what happens for the first few coefficients, i.e., for $n = 0, 1, 2, \ldots$ we find, not too surprisingly:

$$f_{j,0}\, f_{k,0} = (f_{\mathrm{lcm}(j,k),0})^{\gcd(j,k)}, \quad (9)$$

that is an analogue of the defining relations for the product between s_is (but one must remark that here we are considering numbers, not indeterminates). The next steps are less enlightening:

$$\begin{aligned} f_{j,1}\, f_{k,1} &= D \cdot f_{L,1}\, (f_{L,0})^{D-1}, \\ f_{j,2}\, f_{k,2} &= D \cdot f_{L,2}\, (f_{L,0})^{D-1} + D(D-1) \cdot (f_{L,1})^2\, (f_{L,0})^{D-2}, \end{aligned}$$

having denoted $\gcd(j,k)$ by D and $\mathrm{lcm}(j,k)$ by L.

We can describe quite explicitly the terms of the sequence $(f_{i,0})$ by means of the following proposition, which describes the consequences of the relation (9).

Proposition 3.2 *Let (a_i) be a sequence of natural numbers such that*

$$a_i a_j = (a_{\mathrm{lcm}(i,j)})^{\gcd(i,j)}.$$

Then:

1. *all terms in the sequence are* 0 *or* 1 *(except possibly a_2);*
2. *the sequence is multiplicative (i.e., for i, j coprime, $a_{ij} = a_i a_j$); so it is determined by its terms of prime power index;*
3. *if p is a prime and $a_{p^k} = 0$ then $a_{p^l} = 0$ for each $l > k$ (thus, for p odd, one has $\ldots = a_{p^{N-1}} = a_{p^N} = 1$ and $a_{p^{N+1}} = a_{p^{N+2}} = \ldots = 0$ for some N).*

Proof 1. For each i, $a_i a_i = (a_i)^i$: so, if $a_i \neq 0$, $i = 2$ or else $(a_i)^{i-2} = 1$. In the latter case a_i is a $(i-2)$th root of unity; if we restrict ourselves to natural numbers, it has to be 1. In the former case we have no restraints on the values of a_2; but, as $a_2\, a_{2k} = (a_{2k})^2$ (for any natural k), if there is a k such that $a_{2k} \neq 0$, we have $a_2 = a_{2k} = 1$.

2. Obvious.

3. If $k < l$, $a_{p^k} a_{p^l} = (a_{p^l})^{p^k} = a_{p^l}$ etc.

$\diamondsuit$

Analogous, but less neat, descriptions can be given for the sequences $(f_{i,1})$ (whose terms turn out to be 0 or i), $(f_{i,2})$ (with terms 0, i, $i(1-i)$ or i^2) etc.

We can also fix our attention on a sequence $(f_{i,n})$ for a fixed i (which is more meaningful, as this is the sequence of the coefficient of $\sum_{n\geq 0} f_{i,n}t^n/n! = f_i(t)$). The equation (8), setting $j = k = i$, gives a recursion for the terms of the sequence $(f_{i,n})$ (fixed i):

$$f_{i,n}^2 = \sum_{r_1+\cdots+r_i=n} \binom{n}{r_1 \cdots r_i} f_{i,r_1} \cdots f_{i,r_i}.$$

Unfortunately, this recursion is quite unwieldy due to the appearance in it of products of i terms. However, at least for $i = 1$ and $i = 2$ it yields useful descriptions of $(f_{i,n})$.

For $i = 1$ it becomes just $f_{1,n}^2 = f_{1,n}$; thus, each term of the sequence has to be 0 or 1 (when they are all equal to 1, we get back $f_1(t) = \mathrm{e}^t$, where we started from).

Taking $i = 2$ gives

$$f_{2,n}^2 = \sum_{r=0}^{n} \binom{n}{r} f_{2,r} f_{2,n-r}.$$

If we take $f_{2,0} = 0$ or 1, we get respectively $f_{2,n} = \pm\sqrt{\sum_{r=1}^{n-1} \binom{n}{r} f_{2,r} f_{2,n-r}}$ and $f_{2,n} = 1 \pm \sqrt{1 + \sum_{r=1}^{n-1} \binom{n}{r} f_{2,r} f_{2,n-r}}$. The solution obtained by taking $f_{2,0} = 1$ and then always the sign "+" is $f_{2,n} = 2^n$.

3.3 The general case

The equality $F_n^*(G \times H) = F_n^*(G)F_n^*(H)$ holds in general (for finite or oligomorphic permutation groups). This makes computing the number of orbits on n-tuples of a direct product a somewhat easy task.

Given any two oligomorphic groups G and H acting on X and Y respectively, if we know their F_n-sequences, there is a straightforward way to work out the number of orbits on n-tuples of distinct elements of $X \times Y$:

- take $(F_n(G))$ and $(F_n(H))$;

- Stirling-transform them to obtain $(F_n^*(G))$ and $(F_n^*(H))$;
- multiply them to obtain $(F_n^*(G \times H))$;
- Stirling-invert it to obtain $(F_n(G \times H))$.

Example: $S \times S$ Let us turn our attention to the action of $S \times S$ on $\Omega \times \Omega$.

We start with the action on n-sets. The group is clearly transitive, so that $f_1 = 1$. There are three orbits on 2-sets: denoting by $\{(a,\alpha),(b,\beta)\}$ a generic 2-set, the orbits correspond to $a = b$, $\alpha = \beta$ or neither. A set of representatives for the six orbits on 3-sets is obtained, denoting by $\{(a,\alpha),(b,\beta),(c,\gamma)\}$ a generic set, from the following possibilities:

1. $a \neq b \neq c \neq a$ and $\alpha \neq \beta \neq \gamma \neq \alpha$;
2. $a = b = c$ and $\alpha \neq \beta \neq \gamma \neq \alpha$;
3. $a \neq b \neq c \neq a$ and $\alpha = \beta = \gamma$;
4. $a = b \neq c$ and $\alpha \neq \beta \neq \gamma \neq \alpha$;
5. $a \neq b \neq c \neq a$ and $\alpha = \beta \neq \gamma$;
6. $a \neq b = c$ and $\alpha = \beta \neq \gamma$.

In general, an orbit on n-sets in this action is determined by how many of the first components are equal to each other, plus the same for second components, plus how elements of equality classes of first components appear paired with those for second components. In other words, an orbit identifies (not univocally) two partitions of n.

The set of orbits on n-sets is in bijection with at least two other easily described sets: the set of binary (0-1) matrices with exactly n entries equal to 1 and no zero row or column, up to row and column permutations; and the set of bipartite graphs with a distinguished block, with n edges and no isolated vertex, up to isomorphism.

For the orbits on n-tuples we have pretty analogous correspondences, this time with labelled versions of those matrices or graphs. The analogue of considering binary matrices is taking matrices as above, with exactly one entry equal to 1, one equal to 2, ..., one equal to n, and the rest zero. The analogue of the graph interpretation is considering bipartite graphs as above with the edges labelled 1 to n.

While calculating the numbers $f_n(S \times S)$ appears to be difficult, we can use the procedure given above to work out $F_n(S \times S)$. We know that $F_n^*(S) = B_n$, the nth Bell number, and it is easy to see that with each partition of $\{1, 2, \ldots, n\}$ we can associate an orbit on n-tuples of not necessarily distinct elements, and vice versa. For instance, with the partition $\{\{1,3,4\},\{2,5\}\}$ we associate the orbit containing (a,b,a,a,b) ($a \neq b$).

So $F_n^*(S \times S)$ is equal to B_n^2 and an orbit on n-tuples of pairs corresponds to a pair of partitions of $\{1, 2, \ldots, n\}$: for instance with the pair of partitions

$$(\{\{1,3,4\},\{2,5\}\},\{\{1,4\},\{2,5\},\{3\}\})$$

we may associate the orbit containing

$$((a,x),(b,y),(a,z),(a,x),(b,y))$$

($a \neq b$, $x \neq y \neq z \neq x$).

Stirling-inverting $F_n^*(S \times S)$, we find that $F_n(S \times S) = \sum_{i=1}^n s(n,i) B_i^2$.

A generic pair of partitions corresponds to an n-tuple with repeated elements; to obtain n-tuples of distinct elements, we have to add the condition that the two partitions have meet $\{\{1\},\{2\},\ldots,\{n\}\}$ (where meet means the coarsest common refinement). (See the papers by Pittel ([7]) and Canfield ([4]).) The sequence $F_n(S \times S)$ is sequence A059849 in Sloane [5].

The above generalises in a natural way to the product of k copies of S in the product action: one has $F_n^*(S^k) = B_n^k$, and $F_n(S^k) = \sum_{i=1}^n s(n,i) B_i^k$.

Example: $A \times A$ The links between the sequences counting orbits on n-sets and n-tuples can be well described for the groups $G = A, A \times A, A \times A \times A, \ldots$

The key observation is that the group induced by such a G on n points (elements of Ω, $\Omega \times \Omega$, $\ldots$) is trivial. Therefore each orbit on n-sets gives rise to exactly $n!$ orbits on n-tuples of distinct elements, so that the ratio between the $F_n(G)/f_n(G)$ is equal to $n!$ for each n.

Let us now apply the procedure described above to the group $G = A \times A$ acting on $\mathbf{Q} \times \mathbf{Q}$.

Recall that for A one has $f_n = 1$ and $F_n = n!$ for each n. Applying the Stirling transform to $F_n(A)$, we get $F_n^*(A)$, which also gives the number of labelled total preorders, also called weak orders or preferential arrangements (this is sequence A000670 in [5]). The remaining steps of the procedure give $F_n(A \times A)$; dividing by $n!$ we obtain $f_n(A \times A)$. Using GAP [6], we find the first terms to be 1, 4, 24, 196, 2016, 24976, 361792, $\ldots$

Also in this situation one can give bijections between orbits and other structures: matrices, bipartite graphs, pairs of partitions.

Here we have one orbit on n-sets for each binary matrix with exactly n entries 1 (without allowing permutations on rows or columns); and one orbit on n-tuples of distinct elements for each matrix with entries 1, 2,..., n (one each) and zero elsewhere.

As for graphs, we consider here bipartite graphs with a total ordering on each of the blocks; label the edges to get the correspondence with orbits on n-tuples.

Lastly, the correspondence with pairs of partitions with meet $\{\{1\},\{2\},\ldots,\{n\}\}$ requires the additional condition for each of the partitions to be ordered (that is to be an ordered list of subsets of $\{1,2,\ldots,n\}$).

Example: $C \times C$ We may finally sketch what happens for the group $C \times C$; recalling that $f_n(C) = 1$ and $F_n(C) = (n-1)!$, one can apply the procedure to work out $F_n(C \times C)$. It is also straigthforward to describe the analogue of the bijections: for instance, orbits on n-sets correspond to binary matrix as above up to cyclic permutations of rows and columns.

4 Power action of wreath product

We do not have a convenient expression for the cycle index of a wreath product in the power action. For the orbits on n-tuples, we have the following result.

Proposition 4.1 *Let $G = G_1 \wr G_2$, in the power action. Then*

$$F_n^*(G) = Z(G_2; s_i \leftarrow F_n(G_1)^i).$$

Proof If $B = G_1^m$ is the base group, then each orbit of B on n-tuples is indexed by an m-tuple of orbits of G_1 on n-tuples. Taking the G_1-orbits on n-tuples as figures, each B-orbit is a function from $\{1,\ldots,m\}$ to the set of figures, and G-orbits on n-tuples correspond to G_2-orbits on such functions. The result follows from the Cycle Index Theorem. ♢

5 Generalised wreath products

Let I be a set with partial order ρ. Suppose that a permutation group (G_i, X_i) is associated with each element $i \in I$. Bailey *et al.* [1] defined the *generalised wreath product* $(G,X) = \prod_{i\in I}(G_i,X_i)$, in such a way that

- X is the Cartesian product $\prod_{i\in I} X_i$;
- if I is an antichain of size 2, then the generalised wreath product is the direct product with the product action;
- if I is a chain of size 2, then the generalised wreath product is the wreath product with the imprimitive action.

The generalised wreath product is defined as follows. For each $i \in I$, we define the group F_i to be the direct product of copies of G_i indexed by $\prod_{j>i} X_j$. The factor corresponding to an element $(x_j : j > i)$ in the product acts as follows. Take any element $(x'_k : k \in I)$ of X. If $x'_j = x_j$ for all $j > i$, then G_i acts on the ith coordinate; otherwise, G_i acts trivially.

Now the generalised wreath product $\prod_{i\in I}(G_i, X_i)$ is the group generated by the subgroups F_i for $i \in I$. For further information on the structure of this group we refer to [1]. We leave it as an exercise to check that it coincides with the product action of the direct product if I is a 2-element antichain, and with the imprimitive action of the wreath product if I is a 2-element chain.

The obvious question now is to calculate, if possible, the cycle index, or at least the orbit-counting series, for a generalised wreath product.

Some results are already known. Bailey *et al.* showed that, if all (G_i, X_i) are transitive, then (G, X) is transitive, and gave a description of the orbits of G on X^2 in terms of the orbits of G_i on X_i^2 and the antichains of the poset (I, ρ). Their result was as follows:

Theorem 5.1 *Let $(G, X) = \prod_{i\in I}(G_i, X_i)$ be a generalised wreath product. For each antichain S of I, and each choice of an orbit O_i of G_i on pairs of distinct elements of X_i for $i \in S$, there is an orbit of G on pairs $((x_i), (y_i))$ satisfying*

- *$x_i = y_i$ if i is not below any element of S;*
- *$(x_i, y_i) \in O_i$ if $i \in S$;*
- *no condition if $i < j$ for some $j \in S$.*

These are all the orbits of G on X^2.

This list includes the case where $x_i = y_i$ for all i (with $S = \emptyset$). Since $F_2^*(G) = 1 + F_2(G)$ for a transitive group G, we have the following result:

Theorem 5.2 *Let $(G,X) = \prod_{i\in I}(G_i,X_i)$, where each (G_i,X_i) is transitive. Then*

$$1 + F_2(G) = \sum_S \prod_{i\in S} F_2(G_i),$$

where the sum is over all antichains of I.

Example If each G_i is 2-transitive on X_i, then $F_2(G)$ is equal to the number of antichains in I. This number is also equal to the number of poset homomorphisms from I to the 2-element chain.

Example If I is the 2-element chain, then $1 + F_2(G) = 1 + F_2(G_1) + F_2(G_2)$. If I is the 2-element antichain then $1 + F_2(G) = (1 + F_2(G_1))(1 + F_2(G_2))$. These agree with our earlier results for imprimitive and product actions.

Subsequently, Praeger *et al.* [8] showed the following:

Theorem 5.3 *Let $(G,X) = \prod_{i\in I}(G_i,X_i)$. If (G_i,X_i) is n-transitive for all $i \in I$, then the number of orbits of G on X^n is equal to the number of poset homomorphisms from (I,ρ) to the poset $\mathcal{P}(n)$ of partitions of an n-set (ordered by refinement).*

In particular, $F_n^*(S^2, X^2) = B(n)^2$ (where $B(n) = |\mathcal{P}(n)|$ is the Bell number), and $F_n^*(S \wr S, X \times X)$ is the number of chains of length 2 in $\mathcal{P}(n)$ (including trivial chains (π,π)). These of course agree with our earlier results.

The main problem we wish to pose is to find a common generalisation of these two results to count orbits on n-tuples of an arbitrary generalised wreath product, or (better) to calculate its cycle index.

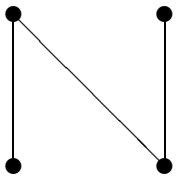

Figure 1: The poset N

Note that, if the poset (I,ρ) is *N-free* (that is, if it does not contain the poset shown in Figure 1 as induced subposet), then it can be constructed from singleton

posets by the operations of disjoint union and ordered sum, and so the generalised wreath product can be built from its factors by the operations of direct product (with the product action) and wreath product (with the imprimitive action). In these cases, the cycle index can be calculated in principle. However, the proportion of n-element posets which are N-free tends to 0 as $n \to \infty$.

Notes on primitive lambda-roots

Peter J. Cameron and D. A. Preece

Draft

This version of March 26, 2003 is on the Web at the address
http://www.maths.qmul.ac.uk/~pjc/csgnotes/lambda.pdf

Abstract

Euler's totient function ϕ has the property that $\phi(n)$ is the order of the group $U(n)$ of units in $\mathbb{Z}_n$ (the integers mod n). In the early years of the twentieth century, Carmichael defined a similar function λ, where $\lambda(n)$ is the exponent of $U(n)$. He called an element of $U(n)$ with order $\lambda(n)$ a primitive λ-root of n.

Subsequently, primitive λ-roots have not received much attention until recently, when they have been used in the construction of terraces and difference sets, and in cryptography.

The purpose of these notes is to outline the theory of primitive λ-roots and to describe some recent developments motivated by the design-theoretic applications.

1 Motivation

Consider the following sequence of the elements of $\mathbb{Z}_{35}$:

START
10 15 5 3 9 27 11 33 29 17 16 13 4 12 1 21 7 ↘
0
25 20 30 32 26 8 24 2 6 18 19 22 31 23 34 14 28 ↙
FINISH

The last 17 entries, in reverse order, are the negatives of the first 17, which, with the zero, can also be written

$$5^5 \ 5^6 \ 5^7 \mid 3^1 \ 3^2 \ 3^3 \ 3^4 \ 3^5 \ 3^6 \ 3^7 \ 3^8 \ 3^9 \ 3^{10} \ 3^{11} \ 3^{12} \mid 7^4 \ 7^5 \mid 0.$$

If we write the respective entries here as x_i ($i = 1,2,\ldots,18$), then the successive differences $x_{i+1} - x_i$ ($i = 1,2,\ldots,17$) are

$$5 \quad -10 \quad -2 \quad 6 \quad -17 \quad -16 \quad -13 \quad -4 \quad -12 \quad -1 \quad -3 \quad -9 \quad 8 \quad -11 \quad -15 \quad -14 \quad -7.$$

Ignoring minus signs, these differences consist of each of the values $1,2,\ldots,17$ exactly once. Thus the initial sequence of 35 elements is a special type of *terrace*. Indeed, it is a *narcissistic half-and-half power-sequence terrace* – see [2, 3] for the explanation of these terms. Its construction depends in particular on the sequence $3^1\ 3^2\ \ldots\ 3^{11}\ 3^{12}$ (with $3^{12} = 3^0 = 1$) consisting of the successive powers of 3, which is a *primitive* λ*-root* of 35.

Consider now the following sequence of the elements of $\mathbb{Z}_{15}$:

$$6 \quad 3 \,|\, 2 \quad 4 \quad 8 \quad 1 \,|\, 10 \,|\, 0 \,|\, 5 \,|\, 14 \quad 7 \quad 11 \quad 3 \,|\, 12 \quad 9.$$

This too is a terrace, and is of the same special type as before. Its construction depends in particular on the segment | 2 4 8 1 | which is | $2^1\ 2^2\ 2^3\ 2^4$ | (with $2^4 = 2^0 = 1$); this consists of the successive powers of 2, which is a primitive λ-root of 15. The second, third, fourth and fifth segments of the terrace make up a *Whiteman difference set* [17, Theorem 1, p. 112], with unsigned differences (written under the difference set, with the element in the ith row being the unsigned difference of the two elements i steps apart in the 0th row symmetrically above it) as follows:

2		4		8		1		10		0		5
	2		4		7		6		5		5	
		6		3		2		1		5		
			1		6		7		4			
				7		4		3				
					2		1					
						3						

Thus primitive λ-roots are important in the construction of both terraces and difference sets.

We have written these notes in expository style. Basic results on number theory and on finite abelian groups can be found in any standard text, for example Hardy and Wright [10] or LeVeque [12], and Hartley and Hawkes [11], respectively. We are grateful to Donald Keedwell, Matt Ollis and David Rees for their comments.

2 Finite abelian groups

In these notes, C_n denotes a cyclic group of order n (which is usually written multiplicatively), and $\mathbb{Z}_n$ denotes the integers modulo n (which is additively a cyclic group of order n but has a multiplicative structure as well).

The *Fundamental Theorem of Finite Abelian Groups* asserts that every such group can be written as a direct product of cyclic groups. This statement, however, needs refining, since the same group may be expressed in several different ways: for example, $C_6 \cong C_2 \times C_3$.

There are two commonly used *canonical forms* for finite abelian groups. Each of them has the property that any finite abelian group is isomorphic to exactly one group in canonical form, so that we can test the isomorphism of two groups by putting each into canonical form and checking whether the results are the same. We refer to Chapter 10 of Hartley and Hawkes [11] for further details.

2.1 Smith canonical form

Definition The expression

$$C_{n_1} \times C_{n_2} \times \cdots \times C_{n_r}$$

is in *Smith canonical form* if n_i divides n_{i+1} for $i = 1, \ldots, r-1$. Without loss of generality, we can assume that $n_1 > 1$; with this proviso, the form is unique; that is, if

$$C_{n_1} \times \cdots \times C_{n_r} \cong C_{m_1} \times \cdots \times C_{m_s}$$

where also m_j divides m_{j+1} for $j = 1, \ldots, s-1$, then $r = s$ and $n_i = m_i$ for $i = 1, \ldots, r$.

The numbers $n_1, \ldots, n_r$ are called the *invariant factors*, or *torsion invariants*, of the abelian group.

The algorithm for putting an arbitrary direct product of cyclic groups into Smith canonical form is as follows. Suppose that we are given the group $C_{l_1} \times \cdots \times C_{l_q}$, where $l_1, \ldots, l_q$ are arbitrary integers greater than 1. Define, for $i > 0$,

$$\prod_{j=1}^{i} n'_j = \mathrm{lcm}\left(\prod_{j=1}^{i} l_{k_j} : 1 \le k_1 < \cdots < k_i \le q \right).$$

If r is the least value such that $n'_{r+1} = 1$, then write the numbers $n'_1, \ldots, n'_r$ in reverse order:

$$n_i = n'_{r+1-i} \text{ for } i = 1, \ldots, r.$$

Then the Smith canonical form is

$$C_{n_1} \times C_{n_2} \times \cdots \times C_{n_r}.$$

For example, suppose that we are given $C_2 \times C_4 \times C_6$. We have

$$\begin{aligned} n'_1 &= \text{lcm}(2,4,6) = 12, \\ n'_1 n'_2 &= \text{lcm}(8,12,24) = 24, \\ n'_1 n'_2 n'_3 &= \text{lcm}(48) = 48, \end{aligned}$$

so that the Smith canonical form is $C_2 \times C_2 \times C_{12}$.

One feature of the Smith canonical form is that we can read off the *exponent* of an abelian group A, the least number m such that $x^m = 1$ for all $x \in A$; this is simply the number n_r, the largest invariant factor.

2.2 Primary canonical form

Using the fact that, if $n = p_1^{a_1} p_2^{a_2} \cdots p_r^{a_r}$, where $p_1, \ldots, p_r$ are distinct primes, then

$$C_n = C_{p_1^{a_1}} \times C_{p_2^{a_2}} \times \cdots \times C_{p_r^{a_r}},$$

we see that any finite abelian group can be written as a direct product of cyclic groups each of prime power order.

If we order the primes in increasing order, and then order the factors first by the prime involved and then by the exponent, the resulting expression is unique: this is the *primary canonical form*.

For example, the primary canonical form of $C_2 \times C_4 \times C_6$ is

$$C_2 \times C_2 \times C_4 \times C_3.$$

The exponent is given by taking the orders of the largest cyclic factors for each prime dividing the group order and multiplying these.

The orders of the factors in the primary canonical form are called the *elementary divisors* of the abelian group.

3 Möbius inversion

We sketch here the definition of the Möbius function and the Möbius inversion formula. These will be used several times without comment below. See Chapter 16 of Hardy and Wright [10].

Definition The *Möbius function* is the function μ defined on the positive integers by the rule

$$\mu(n) = \begin{cases} 1 & \text{if } n = 1; \\ (-1)^k & \text{if } n \text{ is the product of } k \text{ distinct primes;} \\ 0 & \text{if } n \text{ has a square factor greater than 1.} \end{cases}$$

The Möbius inversion formula is the following statement.

Theorem 3.1 *Let f and g be functions on the natural numbers. Then the following conditions are equivalent:*

(a) $g(n) = \sum_{m|n} f(m)$;

(b) $f(n) = \sum_{m|n} \mu(n/m)g(m)$.

For example, Euler's totient ϕ is the function on the natural numbers given by the rule that $\phi(n)$ is the number of integers $m \in [0, n-1]$ for which $\gcd(m,n) = 1$. (In other words, it is the order of the group $U(n)$ of units of $\mathbb{Z}_n$: see the next section.) Now, if $\gcd(m,n) = d$, then $\gcd(m/d, n/d) = 1$; there are $\phi(n/d)$ such integers m, for each divisor d of n. Thus we have

$$n = \sum_{d|n} \phi(n/d) = \sum_{m|n} \phi(m),$$

and so by Möbius inversion,

$$\phi(n) = \sum_{m|n} \mu(n/m)m = \sum_{d|n} \mu(d)n/d.$$

From here it is an exercise to derive the more familiar formula

$$\phi(n) = n \prod_{\substack{p \text{ prime} \\ p|n}} \left(1 - \frac{1}{p}\right).$$

4 The units modulo n

If x is an element of $\mathbb{Z}_n$ (that is, a residue class modulo n), and m is a divisor of n, then we may regard x also as a residue class modulo m. We usually denote this new residue class by the same symbol x. But really, we have a map from $\mathbb{Z}_n$ to $\mathbb{Z}_m$. This map θ is a ring homomorphism: that is, $\theta(x+y) = \theta(x) + \theta(y)$ and $\theta(xy) = \theta(x)\theta(y)$. We call this the *natural map* from $\mathbb{Z}_n$ to $\mathbb{Z}_m$.

The *Chinese remainder theorem* is crucial for what follows. It asserts that, if $n = n_1 \cdots n_r$, where $n_1, \ldots, n_r$ are pairwise coprime, and θ_i is the natural map from $\mathbb{Z}_n$ to $\mathbb{Z}_{n_i}$ for $i = 1, \ldots, r$, then the map

$$x \mapsto (\theta_1(x), \ldots, \theta_r(x))$$

from $\mathbb{Z}_n$ to $\mathbb{Z}_{n_1} \times \cdots \times \mathbb{Z}_{n_r}$ is a bijection: indeed, it is an isomorphism from $\mathbb{Z}_n$ to the direct sum of the rings $\mathbb{Z}_{n_i}$.

Let $U(n)$ denote the group (under multiplication mod n) of units of $\mathbb{Z}_n$ (the integers mod n). The units are the non-zero elements of $\mathbb{Z}_n$ which are coprime to n. The number of them is $\phi(n)$, where ϕ is Euler's totient function, defined in the preceding section.

The structure of the group $U(n)$ is given by the following well-known result. The first part follows immediately from the Chinese remainder theorem.

Theorem 4.1 *(a) Let $n = p_1^{a_1} p_2^{a_2} \cdots p_r^{a_r}$, where $p_1, \ldots, p_r$ are distinct primes and $a_1, \ldots, a_r > 0$. Then*

$$U(n) \cong U(p_1^{a_1}) \times U(p_2^{a_2}) \times \cdots \times U(p_r^{a_r}).$$

(b) If p is an odd prime and $a > 0$, then $U(p^a)$ is a cyclic group of order $p^{a-1}(p-1)$.

(c) $U(2)$ is the trivial group and, for $a > 1$, we have $U(2^a) \cong C_2 \times C_{2^{a-2}}$, where the generators of the two cyclic factors are -1 and 5.

Thus, if $n = p^a$ or $n = 2p^a$, where p is an odd prime, then $U(n)$ is a cyclic group. A generator of this group is called a *primitive root* of n.

For example,

$$U(18) = \{1, 5, 7, 11, 13, 17\}.$$

The successive powers $5^0, 5^1, \ldots \pmod{18}$ are

$$1, 5, 7, 17, 13, 11,$$

with $5^6 = 5^0 = 1$; so 5 is a primitive root of 18.

For $n > 4$, the converse is also true: if there is a primitive root of n, then n is an odd prime power or twice an odd prime power. This is because all the non-trivial cyclic factors given by Theorem 4.1 have even order, so if there are at least two of them, then $C_2 \times C_2$ is a subgroup of $U(n)$; this happens if n has two odd prime divisors, or if n is divisible by 4 and an odd prime, or if n is divisible by 8.

The elements of $U(n)$ can be divided into subsets called *power classes*: these are the equivalence classes of the relation $\sim$, where $x \sim y$ if $y = x^d$ for some d with $\gcd(d, \phi(n)) = 1$. (This relation is symmetric because, if $\gcd(d, \phi(n)) = 1$, then there exists e with $de \equiv 1 \pmod{\phi(n)}$; then $y^e = x^{de} = x$. It is easily seen to be reflexive and transitive.) Said otherwise, $x \sim y$ if and only if x and y generate the same cyclic subgroup of $U(n)$. If x has order m (a divisor of $\phi(n)$), then the size of the power class containing x is $\phi(m)$.

Note that all elements of a power class have the same multiplicative order mod n.

It follows from Theorem 5.2 (and is easy to prove directly) that, given any finite abelian group A, there are only a finite number of positive integers n such that $U(n) \cong A$.

Problem 1 Is it true that, in general, arbitrarily many values of n can be found for which the groups $U(n)$ are all isomorphic to one another?

For example, the groups $U(n)$ for $n = 35$, 39, 45, 52, 70, 78 and 90 are all isomorphic to $C_2 \times C_{12}$. There are ten values of n less than 1 000 000 for which $U(n) \cong U(n+1)$, namely 3, 15, 104, 495, 975, 22 935, 32 864, 57 584, 131 144 and 491 535. This is sequence A003276 in the *On-Line Encyclopedia of Integer Sequences* [15], where further references appear.

Problem 2 (a) Are there infinitely many values of n for which $U(n) \cong U(n+1)$?

(b) All the above examples except for $n = 3$ satisfy $n \equiv 4$ or 5 mod 10. Does this hold in general?

5 Carmichael's lambda-function

Euler's function ϕ has the property that $\phi(n)$ is the order of the group $U(n)$ of units of $\mathbb{Z}_n$. R. D. Carmichael [6] introduced the function λ:

Definition For a positive integer n, let $\lambda(n)$ be the exponent of $U(n)$ (the least m such that $a^m = 1$ for all $a \in U(n)$).

From the structure theorem for $U(n)$ (Theorem 4.1), we obtain the formula for $\lambda(n)$:

Proposition 5.1 *(a) If $n = p_1^{a_1} p_2^{a_2} \cdots p_r^{a_r}$, where $p_1, p_2, \ldots, p_r$ are distinct primes and $a_1, a_2, \ldots, a_r > 0$, then*

$$\lambda(n) = \mathrm{lcm}(\lambda(p_1^{a_1}), \lambda(p_2^{a_2}), \ldots, \lambda(p_r^{a_r})).$$

(b) If p is an odd prime and $a > 0$, then $\lambda(p^a) = \phi(p^a) = p^{a-1}(p-1)$.

(c) $\lambda(2) = 1$, $\lambda(4) = 2$, and, for $a \geq 3$, we have $\lambda(2^a) = 2^{a-2} = \phi(2^a)/2$.

The values of $\lambda(n)$ appear as sequence A002322 in the *On-Line Encyclopedia of Integer Sequences* [15]. The computer system GAP [9] has the function λ built-in, with the name `Lambda`.

Given m, what can be said about the values of n for which $\lambda(n) = m$? There may be no such values: this occurs, for example, for any odd number $m > 1$. (If $n > 2$, then the unit $-1 \in U(n)$ has order 2, so $\lambda(n)$ is even.) Also, there is no n with $\lambda(n) = 14$, as we shall see.

To get around this problem, we proceed as follows.

Theorem 5.2 *(a) If n_1 divides n_2, then $\lambda(n_1)$ divides $\lambda(n_2)$.*

(b) For any positive integer m, there is a largest n such that $\lambda(n)$ divides m. Denoting this value by $\lambda^*(m)$, we have that

(i) if $n \mid \lambda^*(m)$, then $\lambda(n) \mid m$;

(ii) $\lambda(n) = m$ if and only if n divides $\lambda^*(m)$ but n does not divide $\lambda^*(l)$ for any proper divisor l of m.

(c) The number of n such that $\lambda(n) = m$ is given by the formula

$$\sum_{l \mid m} \mu\left(\frac{m}{l}\right) d(\lambda^*(l)),$$

where $d(n)$ is the number of divisors of n.

Proof (a) Suppose that n_1 divides n_2. The natural map θ from $\mathbb{Z}_{n_2}$ to $\mathbb{Z}_{n_1}$ induces a group homomorphism from $U(n_2)$ to $U(n_1)$. We claim that θ is onto. It is enough to prove this in the case where n_2/n_1 is a prime p.

If p does not divide n_1, then $U(n_2) \cong U(n_1) \times U(p)$, and the conclusion is obvious. Suppose that $p \mid n_1$. Then if $0 < a < n_1$, we have $\gcd(a, n_1) = 1$ if and only if $\gcd(a, n_2) = 1$; so these elements of $U(n_2)$ are inverse images of the corresponding elements of $U(n_1)$.

Now, if $a^m = 1$ for all $a \in U(n_2)$, then $b^m = 1$ for all $b \in U(n_1)$ (since every such b has the form $\theta(a)$ for some $a \in U(n_2)$). So the exponent of $U(n_1)$ divides that of $U(n_2)$, as required.

(b) Suppose that m is given. If $\lambda(n)$ divides m, then $\lambda(p^a)$ divides m for each prime power factor p^a of n. In particular, if p is odd, then $p-1$ must divide m, so there are only finitely many possible prime divisors of n; and for each prime p, the exponent a is also bounded, since p^{a-1} or p^{a-2} must divide m. Hence there are only finitely many possible values of n, and so there is a largest value $\lambda^*(m)$.

By part (a), if $n \mid \lambda^*(m)$, then

$$\lambda(n) \mid \lambda(\lambda^*(m)) \mid m.$$

Conversely, the construction of $\lambda^*(m)$ shows that it is divisible by every n for which $\lambda(n)$ divides m.

(c) This follows from (b) by Möbius inversion.

Remark If $m > 2$ and m is even, then the summation in part (c) can be restricted to even values of l. For, if m is divisible by 4, then $\mu(m/l) = 0$ for odd l; and if m is divisible by 2 but not 4 and $m > 2$, then each odd value of l has $d(\lambda^*(l)) = 2$, and the contributions from such values cancel out.

The calculation of $\lambda^*(m)$ is implicit in the proof of the theorem. Explicitly, the algorithm is as follows. If m is odd, then $\lambda^*(m) = 2$. If m is even, then $\lambda^*(m)$ is the product of the following numbers:

(a) 2^{a+2}, where $2^a \mid\mid m$;

(b) p^{a+1}, for each odd prime p such that $p-1 \mid m$, where $p^a \mid\mid m$.

(Here the notation $p^a \mid\mid m$ means that p^a is the exact power of p dividing m.)

For example, when $m = 12$, the odd primes p such that $p-1 \mid 12$ are $3, 5, 7, 13$; and so

$$\lambda^*(12) = 2^4 \cdot 3^2 \cdot 5 \cdot 7 \cdot 13 = 65\,520.$$

For another example, let $m = 2q$, where q is a prime congruent to 1 mod 6. Then $2q+1$ is not prime, so the only odd prime p for which $p-1$ divides $2q$ is $p = 3$, and we have

$$\lambda^*(2q) = 2^3 \cdot 3 = 24 = \lambda^*(2).$$

Thus, there is no number n with $\lambda(n) = 2q$.

Other numbers which do not occur as values of the function λ include:

(a) $m = 2q_1q_2\cdots q_r$, where $q_1, q_2, \ldots, q_r$ are primes congruent to 1 mod 6 (they may be equal or distinct); for example, 98, 182, 266, ... ;

(b) $m = 2q^2$, where q is any prime greater than 3; for example, 50, 98, 242, ...

We do not have a complete description of such numbers.

Another observation is that, if q is a Sophie Germain prime (a prime such that $2q+1$ is also prime, see [5]), and q is greater than 3, then there are just eight values of n for which $\lambda(n) = 2q$, namely $n = (2q+1)f$, where f is a divisor of 24. We do not know whether other numbers m also occur just eight times as values of λ.

Sierpiński [14] remarks that the only numbers $n < 100$ which satisfy the equation $\lambda(n) = \lambda(n+1)$ are $n = 3$, 15 and 90. But this is not a rare property: a short GAP computation reveals that there are 143 numbers $n < 1\,000\,000$ for which the equation holds.

The formulae show up a couple of errors on p. 236 of [6], giving values of n for prescribed $\lambda(n)$. The entry 136 for $\lambda(n) = 6$ should read 126, and the value 528 is missing for $\lambda(n) = 20$.

Note that, for a fixed even exponent $m = \lambda(n)$, the maximum value $\lambda^*(m)$ of n also maximises the value of $\phi(n)$. For it is easily checked that, if n_1 is a proper divisor of n_2, then $\phi(n_1) \le \phi(n_2)$, with equality only if n_1 is odd and $n_2 = 2n_1$; but if m is even, then $\lambda^*(m)$ is divisible by 8.

For example, the numbers n with $\lambda(n) = 6$, and the corresponding values of $\phi(n)$, are given in the following table. (The function $\xi(n)$ is defined to be

$\phi(n)/\lambda(n)$.)

n	$\phi(n)$	$\xi(n)$
$7,9,14,18$	6	1
$21,28,36,42$	12	2
$56,72,84$	24	4
$63,126$	36	6
168	48	8
252	72	12
504	144	24

Note that the values of $\phi(n)$ are not monotonic in n for fixed $\lambda(n)$.

The order of magnitude of Carmichael's lambda-function was investigated by Erdős, Pomerance and Schmutz [8]. They showed, among other things, that for $x \geq 16$,

$$\frac{1}{x}\sum_{n\leq x}\lambda(n) = \frac{x}{\log x}\exp\left(\frac{B\log\log x}{\log\log\log x}(1+o(1))\right)$$

for some explicit constant B.

A composite positive integer m is called a *Carmichael number* if $\lambda(m)$ divides $m-1$. (For such numbers, a converse of the little Fermat theorem holds: $x^{m-1} \equiv 1 \pmod{m}$ for all residues x coprime to m.) The smallest Carmichael number is 561, with $\lambda(561) = 80$.

5.1 Denominators of Bernoulli numbers

The sequence $(24,240,504,480,264,\ldots)$ of values of $\lambda^*(2m)$ agrees with sequence A006863 in the *Encyclopedia of Integer Sequences* [15]. It is is described as "denominator of $B_{2m}/(-4m)$, where B_m are Bernoulli numbers".

The Bernoulli numbers arise in many parts of mathematics, including modular forms and topology as well as number theory. We won't try to give an account of all the connections here (but see the entry for "Eisenstein series" in MathWorld [16] for some of these); we simply prove that the formula given in the Encyclopedia agrees with the definition of $\lambda^*(2m)$.

The mth term a_m of the *Encyclopedia* sequence is the gcd of $k^L(k^{2m}-1)$, where k ranges over all natural numbers and L is "as large as necessary". To see how this works, consider the case $m = 3$. Taking $k = 2$, we see that a_3 divides $2^L(2^6-1)$, so a_3 is a power of 2 times a divisor of 63. Similarly, with $k = 3$, we find that a_3 is a power of 3 times divisor of 728. We conclude that a_3 divides

504. It is not yet clear, however, that 504 is the final answer, since in principle all values of k must be checked.

We show that a_m (as defined by this formula) is equal to $\lambda^*(2m)$. First, let $n = a_m$, and choose any k with $\gcd(k,n) = 1$. Then n divides $k^L(k^{2m}-1)$. Since k is coprime to n, we have $k^{2m} \equiv 1 \pmod{n}$. So the exponent of $U(n)$ divides $2m$, and n divides $\lambda^*(2m)$.

In the other direction, let $n = \lambda^*(2m)$; we must show that n divides $k^L(k^{2m}-1)$ for all k (with large enough L). Since

$$(k_1k_2)^L((k_1k_2)^{2m}-1) = (k_1k_2)^L k_1^{2m}(k_2^{2m}-1) + (k_1k_2)^L(k_1^{2m}-1),$$

it is enough to prove this when $k = p$ is prime. Write $n = p^a n_1$, where p does not divide n_1. Then $n_1 \mid \lambda^*(2m)$, so $\lambda(n_1) \mid 2m$ by Theorem 5.2; that is, $n_1 \mid p^{2m}-1$. So $n \mid p^a(p^{2m}-1)$, as required.

5.2 p-rank and p-exponent

Definition Let p be a prime. The *p-rank* of an abelian group A is the number of its elementary divisors which are powers of p, and the *p-exponent* is the largest of these elementary divisors.

The 2-rank and 2-exponent of the group of units mod n can be calculated as follows.

Suppose that $n = 2^a p_1^{a_1} \cdots p_r^{a_r}$, where $p_1, \ldots, p_r$ are odd primes, $a_1, \ldots, a_r > 0$, and $a \geq 0$. Then the 2-rank of $U(n)$ is equal to

$$\begin{cases} r & \text{if } a \leq 1, \\ r+1 & \text{if } a = 2, \\ r+2 & \text{if } a \geq 3. \end{cases}$$

The 2-exponent of $U(n)$ is the 2-part of $\lambda(n)$. It is the maximum of 2^b and the powers of 2 dividing $p_i - 1$ for $i = 1, \ldots, r$, where

$$b = \begin{cases} 0 & \text{if } a \leq 1, \\ 1 & \text{if } a = 2, \\ a-2 & \text{if } a \geq 3. \end{cases}$$

In particular, the 2-exponent of $U(n)$ is 2 if and only if

(a) the power of 2 dividing n is at most 2^3;

(b) all odd primes dividing n are congruent to 3 mod 4.

We leave as an exercise the description of the p-rank and p-exponent of $U(n)$ for odd p.

6 Primitive lambda-roots

Carmichael [6] defined primitive λ-roots as a generalisation of primitive roots, to cover cases where the latter do not exist.

Definition A primitive λ-root of n is an element of largest possible order (namely, $\lambda(n)$) in $U(n)$.

We also put $\xi(n) = \phi(n)/\lambda(n)$, where (as noted) $\phi(n)$ is the order of $U(n)$; thus there is a primitive root of n if and only if $\xi(n) = 1$. (Carmichael calls a primitive root a *primitive ϕ-root*.)

Since elements of a power class all have the same order, we see:

Proposition 6.1 *Every element in the power class of a primitive λ-root is a primitive λ-root.*

Proposition 6.2 *For any n, either $\xi(n) = 1$ or $\xi(n)$ is even.*

Proof Theorem 4.1 shows that $\xi(n) = 1$ if and only if $n = p^a$ or $n = 2p^a$, where p is an odd prime. Suppose that this is not the case. Then n is divisible by either two odd primes or a multiple of 4. In the first case, let $n = p^a q^b m$ where p and q are distinct odd primes not dividing m. Then $\phi(n) = \phi(p^a)\phi(q^b)\phi(m)$ and $\lambda(n) = \mathrm{lcm}\{\phi(p^a), \phi(q^b), \lambda(m)\}$; since $\phi(p^a)$ and $\phi(q^b)$ are both even, $\phi(n)/\lambda(n)$ is even. In the second case, if $a \geq 2$ then $\phi(2^a) = 2\lambda(2^a)$, and so $\phi(2^a m)/\lambda(2^a m)$ is even for any odd m.

For example, consider the case $n = 15$. We have $\phi(15) = \phi(3)\phi(5) = 8$, while $\lambda(15) = \mathrm{lcm}(\phi(3), \phi(5)) = 4$, and $\xi(15) = 2$. The group $U(15)$ consists of the elements $1, 2, 4, 7, 8, 11, 13, 14$, and their powers are given in the following table:

element x	powers of x
1	1
2	1, 2, 4, 8
4	1, 4
7	1, 7, 4, 13
8	1, 8, 4, 2
11	1, 11
13	1, 13, 4, 7
14	1, 14

The primitive λ-roots are thus $2,7,8,13$, falling into two power classes $\{2,8\}$ and $\{7,13\}$.

Corollary 6.3 *If $\lambda(n) > 2$, then the number of primitive λ-roots of n is even.*

Proof The number of PLRs in a power class is $\phi(\lambda(n))$; and $\phi(m)$ is even for $m > 2$.

Proposition 6.4 *The group $U(n)$ of units mod n is generated by primitive lambda-roots; the least number of PLRs required to generate the group is equal to the number of invariant factors.*

Proof We can write $U(n) = A \times B$, where A is a cyclic group of order $\lambda(n)$ generated by a primitive lambda-root a. Clearly every element of A lies in the subgroup generated by the primitive lambda-roots. For any $b \in B$, the element ab is a primitive lambda-root; for if m is a proper divisor of $\lambda(n)$, then $(ab)^m = a^m b^m$ and $a^m \neq 1$. So b is the product of the primitive lambda-roots a^{-1} and ab.

The number of generators of $U(n)$ is not less than the number of invariant factors. Suppose that $a_1, \ldots, a_r$ are generators of the invariant factors of $U(n)$, where a_1 is a PLR. Then the elements $a_1, a_1a_2, \ldots, a_1a_r$ are all PLRs and clearly generate $U(n)$.

How many primitive λ-roots of n are there? The answer is obtained by putting $m = \lambda(n)$ in the following result:

Theorem 6.5 *Let $A = C_{m_1} \times C_{m_2} \times \cdots \times C_{m_r}$ be an abelian group. Then, for any m, the number of elements of order m in A is*

$$\sum_{l|m} \mu\left(\frac{m}{l}\right) \prod_{i=1}^{r} \gcd(l, m_i).$$

Proof Let $a = (a_1, a_2, \ldots, a_r) \in A$. Then $a^m = 1$ if and only if $a_i^m = 1$ for $i = 1, \ldots, r$. The number of elements $x \in C_{m_i}$ satisfying $x^m = 1$ is $\gcd(m, m_i)$, so the number of elements $a \in A$ satisfying $a^m = 1$ is $g(m) = \prod_{i=1}^{r} \gcd(m, m_i)$. Now $a^m = 1$ if and only if the order of a divides m; so $g(m) = \sum_{l|m} f(l)$, where $f(l)$ is the number of elements of order l in A. Now the result follows by Möbius inversion.

For example, $U(65) \cong U(5) \times U(13) \cong C_4 \times C_{12}$, so that $\lambda(65) = 12$; and the number of primitive λ-roots is

$$\sum_{l|12} \mu(12/l)\gcd(4,l)\gcd(12,l).$$

The only non-zero terms in the sum occur for $l = 12, 6, 4, 2$, and the required number is

$$4 \cdot 12 - 2 \cdot 6 - 4 \cdot 4 + 2 \cdot 2 = 24.$$

Since $\phi(12) = 4$, there are $24/4 = 6$ power classes of primitive λ-roots; these are $\{2, 32, 33, 63\}$, $\{3, 22, 42, 48\}$, $\{6, 11, 41, 46\}$, $\{7, 28, 37, 58\}$, $\{17, 23, 43, 62\}$ and $\{19, 24, 54, 59\}$.

The following table gives the number of primitive λ-roots, and the smallest primitive λ-root, for certain values of n.

n	$\phi(n)$	$\lambda(n)$	# PLRs	Smallest PLR
15	8	4	4	2
24	8	2	7	5
30	8	4	4	7
35	24	12	8	2
63	36	6	24	2
65	48	12	24	2
91	72	12	32	2
105	48	12	16	2
117	72	12	32	2
143	120	60	32	2
168	48	6	20	5
189	108	18	54	2
275	200	20	96	2

We have $U(15) \cong U(30) \cong C_2 \times C_4$, and $U(91) \cong U(117) \cong C_6 \times C_{12}$, explaining the equal numbers and orders of primitive λ-roots in these cases. On the other hand, $\phi(65) = \phi(105)$, but $U(65) \cong C_4 \times C_{12}$, while $U(105) \cong C_2 \times C_4 \times C_6$; these groups are not isomorphic (the Smith canonical form of $U(105)$ is $C_2 \times C_2 \times C_{12}$). Note that, for $n = 143$, the proportion of units that are PLRs is less than $1/3$. In this connection, we have the following result and problem:

Proposition 6.6 *The proportion of units which are primitive λ-roots can be arbitrarily close to* 0.

Proof If $n = p$ is prime, then the proportion of units which are PLRs is

$$\phi(p-1)/(p-1) = \prod_{\substack{r \text{ prime} \\ r|p-1}} \left(1 - \frac{1}{r}\right).$$

Choosing p to be congruent to 1 modulo the product of the first k primes (this is possible, by Dirichlet's Theorem) ensures that the product on the right is arbitrarily small. In order to obtain proper PLRs, also choose $p \equiv 1 \pmod 4$; then the proportion for $4p$ is the same as for p.

Problem 3 Can the proportion of units which are primitive λ-roots be arbitrarily close to 1? Numbers n which are of the form $\lambda^*(m)$ seem to be particularly good for this problem. For example, if

$$\begin{aligned} n &= \lambda^*(53\,130) \\ &= 460\,765\,909\,369\,981\,425\,841\,156\,813\,418\,098\,240\,135\,472\,867\,831\,112, \end{aligned}$$

then the proportion of PLRs in the group of units differs from 1 by less than one part in two million.

Li [13] has considered the analogue for PLRs of Artin's conjecture for primitive roots, that is, the function $N_a(x)$ whose value is the number of positive integers $n \le x$ such that a is a PLR of n. This function is more erratic than the corresponding function for primitive roots: the lim inf of $\left(\sum_{1\le a\le x} N_a(x)\right)/x^2$ is zero, while the lim sup of this expression is positive.

6.1 Another formula

Here is another, completely different, method for calculating the number of primitive lambda-roots of n. This depends on knowing the elementary divisors of $U(n)$.

Theorem 6.7 *Let n be a positive integer. For any prime p dividing $\phi(n)$, let $p^{a(p)}$ be the largest p-power elementary divisor of $U(n)$, and let $m(p)$ be the number of elementary divisors of $U(n)$ which are equal to $p^{a(p)}$. Then the number of primitive lambda-roots of n is*

$$\phi(n) \prod_{p|\phi(n)} \left(1 - \frac{1}{p^{m(p)}}\right).$$

Proof Write $U(n) = P_1 \times \cdots \times P_r$, where P_i is the p_i-primary part of $U(n)$ (the product of all the cyclic factors of p_i-power order in the primary decomposition of $U(n)$). Now an element of $U(n)$ is a primitive lambda-root if and only if, for each i with $1 \leq i \leq r$, its projection into P_i is of maximum possible order $p_i^{a(p_i)}$. So we have to work out the fraction of elements of P which are of maximum possible order.

Dropping the subscripts, let $P = C_{p^a} \times \cdots \times C_{p^a} \times Q$, where there are m factors p^a, and Q is a product of cyclic p-groups of orders smaller than p^a. Then an element of P has order p^a if and only if its projection into $(C_{p^a})^m$ has order p^a. So the fraction of elements of maximal order in P is the same as in $(C_{p^a})^m$. Now the elements of the latter group of order less than p^a are precisely those lying in the subgroup $(C_{p^{a-1}})^m$, a fraction $1/p^m$ of the group. So a fraction $1 - 1/p^m$ have order equal to p^a.

This result has a curious corollary. If n is such that primitive roots of n exist (that is, if n is an odd prime power, or twice an odd prime power, or 4), then the number of primitive roots of n is $\phi(\phi(n))$. Now for any n, compare the formula in the theorem with the formula

$$\phi(\phi(n)) = \phi(n) \prod_{p \mid \phi(n)} \left(1 - \frac{1}{p}\right).$$

We see that the number of PLRs is at least $\phi(\phi(n))$, with equality if and only if $m(p) = 1$ for all p dividing $\phi(n)$. In other words:

Corollary 6.8 *For any n, the number of primitive lambda-roots of n is at least $\phi(\phi(n))$. Equality holds if and only if, for each prime p which divides $\phi(m)$, the largest p-power elementary divisor of $U(n)$ is strictly greater than all the other p-power elementary divisors of n. An equivalent condition is that the second largest invariant factor of $U(n)$ divides $\lambda(n)/\sigma(\lambda(n))$, where $\sigma(m)$ is the product of the distinct prime divisors of m.*

Proof The first part follows from the prefatory remarks. The equivalence of the last condition with the condition involving the elementary divisors is clear.

This raises a curious number-theoretic problem.

Problem 4 What proportion of numbers n have the property that the number of PLRs of n is equal to $\phi(\phi(n))$?

A computer search shows that nearly 60% of all numbers below 100 000 have this property (to be precise, 57 996 of them do).

The condition in this proposition comes up in a completely different context, namely, a relationship between the number of power classes of PLRs and the function $\xi(n) = \phi(n)/\lambda(n)$.

Proposition 6.9 *For any positive integer n, the number of power classes of PLRs of n is at least $\xi(n)$. Equality holds if and only if, for any prime divisor p of $\phi(n)$, the largest p-power elementary divisor is strictly greater than any other p-power elementary divisor.*

Proof We can write $U(n) = A \times B$, where A is a cyclic group of order $\lambda(n)$, generated by a (which is a PLR). Now, for each element $b \in B$, the product ab is a PLR. We claim that distinct elements of B give rise to distinct power classes. For suppose that ab_1 and ab_2 lie in the same power class. Then $ab_2 = (ab_1)^m$ for some m with $\gcd(\lambda(n), m) = 1$. This implies that $a = a^m$, so that $m \equiv 1 \pmod{\lambda(n)}$, from which it follows that $b_2 = b_1^m = b_1$. So there are at least as many power classes as elements of B. Since $|B| = \phi(n)/\lambda(n) = \xi(n)$, the inequality is proved.

Equality holds if and only if, whenever $a \in A$, $b \in B$, and ab is a PLR, it follows that a is a PLR. Suppose that the condition on elementary divisors holds. For any p dividing $\lambda(n)$, the p-elementary divisors of B divide $\lambda(n)/p$, and so $b^{\lambda(n)/p} = 1$. Hence $a^{\lambda(n)/p} = (ab)^{\lambda(n)/p} \neq 1$. Since this holds for all p, the order of a is $\lambda(n)$, and so a is a PLR. Conversely, suppose that the condition on elementary divisors fails, and suppose that the largest p-elementary divisor of B is p^r and is the p-part of $\lambda(n)$. Choose an element $b \in B$ of order p^r. Then $a^{p^r}b$ is a PLR, but a^{p^r} is not.

For another proof that the cases of equality in the two results coincide, note that $\phi(n)$ and $\lambda(n)$ have the same prime divisors, and so

$$\frac{\phi(\phi(n))}{\phi(n)} = \frac{\phi(\lambda(n))}{\lambda(n)},$$

so that $\xi(n) = \phi(\phi(n))/\phi(\lambda(n))$, whereas the number of power classes is the number of PLRs divided by $\phi(\lambda(n))$.

Example For $n = 360 = 2^3 \cdot 3^2 \cdot 5$, we have

$$U(n) \cong C_2 \times C_2 \times C_6 \times C_4 \cong C_4 \times C_2^3 \times C_3,$$

so

$$\begin{aligned} \#\text{PLRs} = \phi(\phi(n)) &= 32, \\ \#\text{PCs} = \xi(n) &= 8. \end{aligned}$$

For $n = 720 = 2^4 \cdot 3^2 \cdot 5$, we have

$$U(n) \cong C_2 \times C_4 \times C_6 \times C_4 \cong C_4^2 \times C_2^2 \times C_3,$$

so

$$\begin{aligned} \#\text{PLRs} = 96, \quad & \phi(\phi(n)) = 64, \\ \#\text{PCs} = 24 \quad & \xi(n) = 16. \end{aligned}$$

6.2 Fraternities

Definition Two PLRs x and y of n are said to be *fraternal* if $x^2 \equiv y^2 \pmod{n}$. This is an equivalence relation on the set of PLRs; its equivalence classes are called *fraternities*.

Recall the definition of 2-rank and 2-exponent from Subsection 5.2.

Proposition 6.10 *Suppose that $n \geq 2$. Let the 2-rank and 2-exponent of $U(n)$ be s and 2^e respectively. Then the size of a fraternity of PLRs of n is equal to*

$$\begin{cases} 2^s & \text{if } e > 1, \\ 2^s - 1 & \text{if } e = 1. \end{cases}$$

Proof Let $A = \{u \in U(n) : u^2 \equiv 1 \pmod{n}\}$. Clearly $|A| = 2^s$. Since $x^2 \equiv y^2$ if and only if $x = yu$ for some $u \in A$, each fraternity is the intersection of the set of PLRs with a coset of A.

Let a coset C of A contain an element of even order $2m$. If m is even, then every element of C has order $2m$. Suppose that m is odd. Then, for $u \in C$, $u^m \in A$, and $u \cdot u^m$ has order m; all other elements of C have order $2m$.

In particular, the number of PLRs in a coset of A is 2^r if $e > 1$, and is $2^r - 1$ if $e = 1$.

Remark We worked out in Subsection 5.2 the necesary and sufficient conditions for $e = 1$.

Proposition 6.11 *Suppose that $n > 2$, and let $\lambda(n) = 2m$. The intersection of the power class and the fraternity containing a PLR x of n is equal to $\{x\}$ if m is odd, and is $\{x, x^{m+1}\}$ if m is even. The number of fraternities is divisible by $\phi(\lambda(n))$ if m is odd, and by $\phi(\lambda(n))/2$ if m is even.*

Proof The elements of the power class of x have the form x^d, where $\gcd(d, \lambda(n)) = 1$. Now x and x^d are fraternal if and only if $x^{2(d-1)} \equiv 1$, which holds if and only if $d = 1 + \lambda(n)/2 = m + 1$. Now $\gcd(m+1, 2m) = 1$ if and only if m is even.

The last part follows from the fact that each power class has cardinality $\phi(\lambda(n))$.

Corollary 6.12 *The number of fraternities of PLRs is even, unless n divides 240, in which case there are three fraternities if $n = 80$ or $n = 240$, and 1 otherwise.*

Proof Suppose first that $\lambda(n) \equiv 2 \pmod 4$. Then either $\lambda(n) = 2$, or $\phi(\lambda(n))$ is even. In the first case, n divides 24, and every PLR satisfies $x^2 \equiv 1$, so there is just one fraternity. In the second, the number of fraternities meeting each power class is even.

Now suppose that $\lambda(n) \equiv 0 \pmod 4$. Then either $\lambda(n) = 4$, or $\phi(\lambda(n))$ is also divisible by 4. In the first case, n divides 240, and a finite amount of checking establishes the result. In the second, the number of fraternities meeting every power class is even.

Examples For $n = 40$ we have $s = 3$ and $e = 2$, so the size of a fraternity is $2^3 = 8$; all PLRs belong to a single fraternity

For $n = 56$, we have $s = 3$ and $e = 1$, so the size of a fraternity is $2^3 - 1 = 7$; the 14 PLRs fall into two fraternities. Since $\lambda(n) = 6$, one fraternity contains the inverses of the elements of the other.

For $n = 75$, we have $s = 2$ and $e = 2$, so the size of a fraternity is 4; the 16 PLRs fall into four fraternities.

7 Some special structures for the units

Theorem 7.1 *Suppose that the Smith canonical form of $U(n)$ is*

$$U(n) \cong C_{\lambda(n)} \times \cdots \times C_{\lambda(n)} \qquad \textit{(r factors)},$$

with $r > 1$. Then either

(a) $n = 8$, 12 or 24; or

(b) $n = p^a(p^a - p^{a-1} + 1)$ or $2p^a(p^a - p^{a-1} + 1)$, where p and $p^a - p^{a-1} + 1$ are odd primes.

In particular, $r \leq 3$, and $r = 3$ only in the case $n = 24$.

Proof Suppose first that $\phi(n)$ is a power of 2. Then $n = 2^a p_1 \cdots p_s$, where $p_1, \ldots, p_s$ are distinct Fermat primes, and $U(n) \cong U(2^a) \times C_{p_1-1} \times \cdots \times C_{p_s-1}$. Since all the cyclic factors have the same order, either $s = 0$, or $s = 1$, $p_1 = 3$; the cases where there are more than one cyclic factor are $n = 8$, 12 and 24.

Now suppose that $\phi(n)$ is not a power of 2; let n have s odd prime factors. The number of 2-power cyclic factors of $U(n)$ is s, plus one or two if the power of 2 dividing n is 4 or at least 8, respectively; the number of cyclic factors of odd prime power order is at most s. So n must be odd or twice odd; we may assume that n is odd. We have $s = r$.

Let $n = p_1^{a_1} \cdots p_r^{a_r}$. The decomposition

$$U(n) \cong U(p_1^{a_1}) \times \cdots \times U(p_r^{a_r})$$

must coincide with the Smith normal form of $U(n)$, so we must have

$$p_1^{a_1-1}(p_1 - 1) = \cdots = p_r^{a_r-1}(p_r - 1).$$

Clearly $a_i = 1$ can hold for at most one value of i. But, if $a_i > 1$, then p_i is the largest prime divisor of $p_i^{a_i-1}(p_i - 1)$. We conclude that $r = 2$ and that (assuming $p = p_1 < p_2$ and $a = a_1$) we have $p_2 = p^{a-1}(p-1) + 1$ and $a_2 = 1$.

The odd numbers $n < 1\,000\,000$ occurring in case (b) of the theorem are

$$\begin{aligned} 63 &= 9 \cdot 7, \\ 513 &= 27 \cdot 19, \end{aligned}$$

$$\begin{aligned} 2\,107 &= 49\cdot 43, \\ 12\,625 &= 125\cdot 101, \\ 26\,533 &= 169\cdot 157, \\ 39\,609 &= 243\cdot 163, \text{ and} \\ 355\,023 &= 729\cdot 487. \end{aligned}$$

There are various possibilities for the structure $U(n) \cong C_a \times C_{\lambda(n)} \times C_{\lambda(n)}$ with $a \mid \lambda(n)$; for example, for odd n, we have

$$\begin{aligned} n = 3\cdot 7^2\cdot 43, &\quad U(n) \cong C_2 \times C_{42} \times C_{42}; \\ n = 3^2\cdot 7^2\cdot 43, &\quad U(n) \cong C_6 \times C_{42} \times C_{42}; \\ n = 3\cdot 5^3\cdot 101, &\quad U(n) \cong C_2 \times C_{100} \times C_{100}; \\ n = 11\cdot 5^3\cdot 101, &\quad U(n) \cong C_{10} \times C_{100} \times C_{100}. \end{aligned}$$

For even n, the values $n = 4\cdot p^j\cdot(p^{j-1}(p-1)+1)$, where p and $p^{j-1}(p-1)+1$ are odd primes, give examples.

Problem 5 Can the multiplicity of $\lambda(n)$ as the order of an invariant factor of $U(n)$ be arbitrarily large? Again, numbers of the form $n = \lambda^*(m)$ are particularly fruitful here: for $n = \lambda^*(157\,080)$, a number with 122 digits, the multiplicity of $C_{157\,080}$ in the Smith normal form of $U(n)$ is 16.

8 Negating and non-negating PLRs

Suppose that x is a primitive λ-root. We can ask:

(a) Is $-x$ also a primitive λ-root?

(b) If so, is $-x$ in the same power class as x?

In an abelian group, the order of the product of two elements divides the lcm of the orders of the factors. Since $x = (-1)(-x)$, we see that, if x is a PLR, then the order of $-x$ must be either $\lambda(n)$ or $\lambda(n)/2$, and the latter holds only if $\lambda(n)/2$ is odd. Thus, we have:

Proposition 8.1 *Let x be a primitive λ-root of n, where $n > 2$. Then $-x$ is also a primitive λ-root if either n has a prime factor congruent to* $1 \pmod 4$, *or n is divisible by* 16.

Note that, if $-x$ has order $\lambda(n)/2$, then we have

$$\langle x \rangle = \langle -1 \rangle \times \langle -x \rangle,$$

so that -1 and $-x$ are both powers of x in this case. Conversely, if $\lambda(n)/2$ is odd and -1 is a power of x, then $-x$ is an even power of x and so has order $\lambda(n)/2$. Thus, in the cases excluded in the above Proposition, we see that $-x$ is a primitive λ-root if and only if -1 is not a power of x. Necessary and sufficient conditions for this are given in Subsection 8.3 below.

Definition The PLR x of n is *negating* if -1 is a power of x, and *non-negating* otherwise.

Now clearly $-x$ is a power of x if and only if x is negating.

Corollary 8.2 *Suppose that $\lambda(n)$ is twice an odd number (so that n is not divisible by 16 or by any prime congruent to $1 \pmod 4$).*

(a) If $n = 4$ or $n = 2p^a$ for some prime $p \equiv 3 \pmod 4$, then for every primitive λ-root x, we have that $-x$ is not a primitive λ-root.

(b) Otherwise, some primitive λ-roots x have the property that $-x$ is a primitive λ-root, and some have the property that it is not.

The PLR x is negating if and only if -1 belongs to the cyclic group generated by x; so we see:

Proposition 8.3 *If a primitive λ-root is negating, then so is every element of its power class.*

In the next two sections, after a technical result, we will determine for which n there exist negating PLRs, and count them. We conclude this section with some open problems.

Problem 6 Is it possible for -1 to be the only unit which is not a power of a PLR? More generally, which units can fail to be powers of PLRs?

Problem 7 For which values of n is it true that the product of two PLRs is never a PLR? (This holds for $n = 105$, for example.) For other values of n, can we characterise (or count) the number of pairs (x_1, x_2) of PLRs whose product is a PLR?

8.1 A refined canonical form

While the invariant factors and the elementary divisors of a finite abelian group are uniquely determined, the actual cyclic factors are not in general. This freedom is used in the following result, which is useful in the construction of terraces. This result lies at the opposite extreme from the negating PLRs we have considered; it shows that there is a unit generating a cyclic factor of $U(n)$ of smallest possible 2-power order which has -1 as a power.

Theorem 8.4 *Let 2^m be the smallest elementary divisor of $U(n)$ for the prime 2. Then $U(n) = A \times B$, where $A \cong C_{2^m}$ and $-1 \in A$. In particular,*

(a) $U(n)$ can be written in Smith canonical form so that the smallest cyclic factor contains -1;

(b) $U(n)$ can be written in primary canonical form so that the smallest cyclic factor of 2-power order contains -1.

Proof The case where n is divisible by 4 can be dealt with by a simple constructive argument. In this case, we have $2^m = 2$; all units are odd, and those congruent to 1 mod 4 form the subgroup B, while A is generated by -1.

Next, suppose that n is odd. In the decomposition of $U(n)$ into cyclic groups given by Theorem 4.1, the element -1 has order 2 in every factor. So, if we refine this decomposition to the primary canonical form, the element -1 has order 2 in every 2-power factor.

Let $C_{2^{m_1}} \times \cdots \times C_{2^{m_r}}$ be the 2-part of $U(n)$, where $m = m_1$. Let x_i be the generator of the ith factor. Then

$$-1 = x_1^{2^{m_1-1}} \cdots x_r^{2^{m_r-1}}.$$

Now replace x_1 by

$$y_1 = x_1 x_2^{2^{m_2-m_1}} \cdots x_r^{2^{m_r-m_1}}.$$

Then $y_1, x_2, \cdots x_r$ generate cyclic groups also forming the 2-part of the primary decomposition of $U(n)$; and we have

$$-1 = y_1^{2^{m_1-1}},$$

as required.

Finally, if n is odd, then $U(2n) \cong U(n)$, and the natural isomorphism maps -1 to -1. So the case where n is twice an odd number follows from the case where n is odd.

8.2 Generators differing by 1

As an example of the preceding result, consider $n = 275 = 5^2 \cdot 11$. The Smith canonical form of $U(n)$ is $C_{10} \times C_{20}$. If we take 139 and 138 as generators of the respective cyclic factors, then $139^5 = -1$. Is it just coincidence that the two generators differ by 1 in this case?

We cannot answer this question completely, but in some cases where $U(n)$ has just two cyclic factors, we can show that generators differing by 1 must exist, keeping the property that -1 lies in the smaller cyclic group.

We consider the case where $n = pq$, with p and q distinct odd primes. Then $U(n) \cong C_{\xi(n)} \times C_{\lambda(n)}$, where $\lambda(n)$ and $\xi(n)$ are the least common multiple and greatest common divisor, respectively, of $p-1$ and $q-1$. We have seen that it is possible to choose a generator x of the first factor such that -1 is a power of x (necessarily $-1 = x^{\xi(n)/2}$). Under suitable hypotheses, we can assume also that $x+1$ generates the second factor.

We consider first the case where $\xi(n) = 4$. In this case, both p and q must be congruent to 1 mod 4, and at least one must be congruent to 5 mod 8. Moreover, we have $x^2 \equiv -1 \pmod{pq}$.

Theorem 8.5 *Let p and q be primes congruent to $5 \pmod 8$, such that $\gcd(p-1, q-1) = 4$. Suppose that 2 is a primitive root of both p and q. Then there exists a number x such that*

$$U(pq) = \langle x \rangle \times \langle x+1 \rangle = \langle x \rangle \times \langle x-1 \rangle,$$

where the cyclic factors have orders $\xi(pq) = 4$ and $\lambda(pq) = (p-1)(q-1)/4$, and the first factor contains -1. There are two such values, one the negative of the other modulo pq.

Proof We have

$$2^{(p-1)(q-1)/8} = \left(2^{(p-1)/2}\right)^{(q-1)/4} \equiv (-1)^{\text{odd}} = -1 \pmod{p},$$

and similarly mod q; so

$$2^{(p-1)(q-1)/8} \equiv -1 \pmod{pq}.$$

Now there are four solutions of $x^2 \equiv -1 \pmod{pq}$, namely $\pm x_1$ and $\pm x_2$, where

$$\begin{aligned} x_1 &\equiv a \pmod{p}, & x_1 &\equiv b \pmod{q}, \\ x_2 &\equiv a \pmod{p}, & x_2 &\equiv -b \pmod{q}, \\ a^2 &\equiv -1 \pmod{p}, & b^2 &\equiv -1 \pmod{q}. \end{aligned}$$

So we can choose x such that $x^2 \equiv -1$ and $x \not\equiv \pm y \pmod{pq}$, where $y = 2^{(p-1)(q-1)/16}$.

Certainly x has order 4. Also we have

$$(x+1)^2 = x^2 + 2x + 1 \equiv 2x \pmod{pq},$$

and

$$(2x)^{(p-1)(q-1)/16} \equiv (\pm y)(\pm x) \pmod{pq},$$

whence $(2x)^{(p-1)(q-1)/8} \equiv 1 \pmod{pq}$. Clearly every odd divisor of $p-1$ or $q-1$ divides the order of $2x$, so $2x$ has order $(p-1)(q-1)/8$, and $x+1$ has order $(p-1)(q-1)/16$. Moreover, the subgroup generated by $x+1$ does not contain -1 (since its unique element of order 2 is $\pm xy$), so it is disjoint from the subgroup generated by x. Thus, these two subgroups generate their direct product, which (by considering order) is the whole of $U(pq)$.

The argument for $x-1$ is the same. Alternatively, note that we can replace x by $-x$ in the argument, giving

$$U(pq) = \langle -x \rangle \times \langle -x+1 \rangle = \langle x \rangle \times \langle x-1 \rangle.$$

The final statement in the theorem holds because if we chose $x = \pm y$, then $(2x)^{(p-1)(q-1)/16} \equiv \pm 1$, so that either the order of $x+1$ is too small, or $-1 \in \langle x \rangle \cap \langle x+1 \rangle$.

For example, 2 is a primitive root modulo 5, 13, 29, 37 and 53, so we can use any two of these primes in the Theorem. The table gives all instances with $pq < 300$.

n	x
$65 = 5 \cdot 13$	± 18
$145 = 5 \cdot 29$	± 12
$185 = 5 \cdot 37$	± 68
$265 = 5 \cdot 53$	± 83

A similar argument works in other cases, with some modification. If $q \equiv 1 \pmod{8}$, then 2 is a quadratic residue mod q, and cannot be a primitive root: its

order is at most $(q-1)/2$. For $q = 17, 41, \ldots$, it happens that the order of 2 mod q is $(q-1)/2$.

Consider, for example, the case $p = 5$, $q = 17$. Now 2 has order 4 mod 5 and 8 mod 17, so $2^8 \equiv 1 \pmod{85}$ but $2^4 \equiv 16 \pmod{85}$. So $2x$ has order 8, and $(x+1)$ has order 16, if x is any solution of $x^2 \equiv -1 \pmod{85}$. Thus all four such solutions $x = \pm 13, \pm 38$ have the required property.

On the other hand, 2 has order 20 mod 41, and so $2^{10} \equiv -1 \pmod{205}$. Thus $(2x)^{10} \equiv 1 \pmod{205}$, so in this case $x+1$ has order 20, rather than 40, and the construction fails.

In general, we have the following result, whose proof follows the same lines as the case $pq = 85$.

Theorem 8.6 *Let p and q be primes with $p \equiv 5 \pmod 8$ and $q \equiv 1 \pmod{16}$, such that $\gcd(p-1, q-1) = 4$. Suppose that 2 is a primitive root of p and has order $(q-1)/2$ modulo q. Then there exists a number x such that*

$$U(pq) = \langle x \rangle \times \langle x+1 \rangle = \langle x \rangle \times \langle x-1 \rangle,$$

where the cyclic factors have orders 4 and $\lambda(pq) = (p-1)(q-1)/4$, and the first factor contains -1. There are four such values of x modulo pq, falling into two pairs $\pm x$.

Examples with $pq < 300$ are given in the next table.

n	x
$85 = 5 \cdot 17$	$\pm 13, \pm 38$
$221 = 13 \cdot 17$	$\pm 21, \pm 47$

Similar results hold in the case where $\xi(pq) = 6$. In this case our condition is $x^3 \equiv -1$. This condition permits the possibility that $x \equiv -1$ modulo one of the primes; we exclude this, since then $x+1$ would not be a unit. Since $x^3 + 1 = (x+1)(x^2 - x + 1)$, this means that we require $x^2 - x + 1 \equiv 0$ modulo both p and q, so that this congruence holds modulo pq, Conversely, if $x^2 \equiv x - 1 \pmod{pq}$, then x has order 6 and $-1 \in \langle x \rangle$.

Theorem 8.7 *Let p and q be primes congruent to $7 \pmod{12}$, such that $\gcd(p-1, q-1) = 6$. Suppose that 3 is a primitive root modulo both p and q. Then there exists a number x such that*

$$U(pq) = \langle x \rangle \times \langle x+1 \rangle$$

where the cyclic factors have orders $\xi(pq) = 6$ and $\lambda(pq) = (p-1)(q-1)/6$, and the first factor contains -1.

Proof The proof is almost identical to that of the previous theorem. If $x^3 \equiv -1$, then $x^2 - x + 1 \equiv 0$, and so $(x+1)^2 \equiv 3x$.

Since 3 is a primitive root of 7, 19 and 31, the theorem gives the following values:

n	x
$133 = 7 \cdot 19$	$17, 75$
$217 = 7 \cdot 31$	$68, 150$

Problem 8 Find an analogous result in the case where $q \equiv 1 \pmod{12}$. We note that the conclusions of the theorem hold in several further cases, as in the next table.

n	x
$91 = 7 \cdot 13$	$17, 75$
$247 = 13 \cdot 19$	$69, 88, 160, 179$

There are also cases where the second factor is generated by $x - 1$ rather than $x + 1$:

n	x
$91 = 7 \cdot 13$	$12, 38$
$259 = 7 \cdot 37$	$73, 110$

Problem 9 (a) What happens for larger values of $\xi(pq)$?

(b) What happens for larger numbers of prime factors of n?

8.3 Existence of negating PLRs

The existence and number of negating PLRs of n depend on the structure of the *Sylow* 2*-subgroup S* of $U(n)$, the group of all units of 2-power order.

Definition An abelian group is *homocyclic* if it is the direct product of cyclic groups of the same order. The *rank* of a homocyclic abelian group is the number of cyclic factors in such a decomposition.

Theorem 8.8 *Let $n > 1$. There exists a negating PLR of n if and only if the Sylow 2-subgroup S of $U(n)$ is homocyclic. In this case, the proportion of PLRs which are negating is $1/(2^s - 1)$, where s is the rank of S.*

Proof Suppose first that S is not homocyclic. By Theorem 8.4, $U(n) = A \times B$, where A is cyclic and $-1 \in A$; and $\lambda(n)/|A|$ is even, so $a^{\lambda(n)/2} = 1$ for all $a \in A$. Thus no element of $U(n)$ has the property that its $\lambda(n)/2$ power is -1.

In the other direction, suppose that S is homocyclic. Then $U(n) = S \times T$, where T consists of the elements of odd order in $U(n)$; and a PLR of n is a product of elements of maximal order in S and T. In this case, the automorphism group of S acts transitively on the set of $2^s - 1$ elements of order 2 in S, so that each of them (and in particular, -1) occurs equally often as a power of an element of maximal order.

As a result, we see that every PLR is negating if and only if S is cyclic; this occurs if and only if $n = p^a$, $2p^a$ (for some odd prime p) or 4.

The next result, which follows immediately from the structure theorem for $U(n)$ (Theorem 4.1), thus describes when negating PLRs exist.

Theorem 8.9 *Let $n = 2^a m$ where m is odd, and let r be the number of distinct prime divisors of m. Then the Sylow 2-subgroup S of $U(n)$ is homocyclic if and only if one of the following holds:*

(a) $a \leq 1$ and, for any two primes p and q dividing m, the powers of 2 dividing $p-1$ and $q-1$ are equal. In this case the rank of S is r.

(b) $a = 2$ or $a = 3$, and every prime divisor of m is congruent to $3 \pmod 4$. In this case the rank of S is $r + a - 1$.

9 Inward and outward PLRs

Definition The PLR x of n is *inward* if $x-1$ is a unit, and *outward* otherwise.

Like the previous property, this one is a property of power classes. This follows from a more general observation.

Proposition 9.1 *Let $x, y \in U(n)$, and suppose that x and y belong to the same power class. Then $x-1 \in U(n)$ if and only if $y-1 \in U(n)$.*

Proof Let $y = x^d$. Since $\gcd(d, \phi(n)) = 1$, there exists e such that $x = y^e$. Now

$$y - 1 = x^d - 1 = (x-1)(x^{d-1} + \cdots + 1) = (x-1)a$$

for some $a \in \mathbb{Z}_n$. Similarly, $x-1 = (y-1)b$ for some $b \in \mathbb{Z}_n$. Thus $(x-1)ab = x-1$. If $x-1$ is a unit, this implies that $ab = 1$, so that a is a unit and $y-1 = (x-1)a$ is a unit; and conversely.

Corollary 9.2 *If a primitive λ-root is inward, then so is every element of its power class.*

Proposition 9.3 *(a) Every primitive λ-root of n is outward if and only if n is even.*

(b) If a primitive λ-root x is outward and negating, then n is even, and if n is divisible by 4 then $x \equiv 3 \pmod 4$.

Proof (a) If n is even, then every unit is odd, and so $x \in U(n)$ implies $x-1 \notin U(n)$.

Conversely, suppose that n is odd. Suppose first that n is a prime power, say $n = p^a$. If $x \equiv 1 \pmod p$, then the order of x mod n is a power of p, and x is not a PLR. Thus, every PLR is inward in this case.

In general, choose x congruent to a primitive root modulo every prime power divisor of n. Then x is a PLR, and by the preceding argument, $x-1$ is coprime to n. Thus, $x-1 \in U(n)$, and x is inward.

(b) If x is outward and negating, then $x^d = -1$ for some d, and $x-1$ divides $x^d - 1 = -2$. If n is odd, then -2 is a unit, and hence x is inward; so n is even. If n is divisible by 4, then x cannot be congruent to $1 \pmod 4$, since then 4 divides $x-1$ but 4 does not divide $x^d - 1$.

We remark that whether a PLR is inward or outward does not depend only on the group-theoretic structure of $U(n)$. For example,

$$U(21) \cong U(28) \cong U(42) \cong C_2 \times C_6;$$

each of these groups has six PLRs, falling into three power classes of size 2, as in the following table.

n	Power class	Type
21	2, 11	inward non-negating
	19, 10	outward non-negating
	5, 17	inward negating
28	11, 23	outward non-negating
	5, 17	outward non-negating
	3, 19	outward negating
42	11, 23	outward non-negating
	19, 31	outward non-negating
	5, 17	outward negating

A PLR x of n is outward if and only if x is congruent to 1 modulo some prime divisor of n. In principle, the number of inward PLRs can be calculated by inclusion-exclusion over the prime divisors of n. However, we do not have a concise formula.

For example, consider the case $n = 275 = 5^2 \cdot 11$. We have $\lambda(n) = 20$ and the number of PLRs of n is 96. A unit congruent to 1 mod 5 has order dividing 5 mod 5^2 and dividing 10 mod 11, and so cannot be a PLR. A unit congruent to 1 mod 11 is a PLR if and only if it is a primitive root of 25: there are 8 such elements. So there are $96 - 8 = 88$ inward PLRs of 275.

For a more complicated example, let $n = 189 = 3^3 \cdot 7$, with $\lambda(n) = 18$. An element congruent to 1 mod 3 has order dividing 9 mod 27; to be a PLR, its order must be 9 mod 27 and 2 or 6 mod 7. An element congruent to 1 mod 7 is a PLR mod 189 if and only if it is a PLR mod 27. So the number of inward PLRs is

$$54 - 6 \cdot 3 - 6 = 30.$$

Again, we end the section with an open problem.

Problem 10 What are necessary and sufficient conditions for n to have only inward PLRs? (If n is odd and squarefree, then a necessary and sufficient condition is that $\lambda(n/p) < \lambda(n)$ for every prime divisor p of n. There are many examples of this: $n = 35, 55, 77, 95, \ldots$)

10 Perfect, imperfect and aberrant PLRs

For convenience, in this section the term "primitive lambda-root" includes "primitive root".

Definition If $n = p_1^{a_1} p_2^{a_2} \cdots p_r^{a_r}$, then the PLR x of n is said to be

- *perfect* if x is a PLR of $p_i^{a_i}$ for all $i = 1, \ldots, r$;
- *imperfect* if x is a PLR of $p_i^{a_i}$ for at least one but not all $i = 1, \ldots, r$;
- *aberrant* if x is not a PLR of $p_i^{a_i}$ for any of the values $i = 1, \ldots, r$.

Trivially, if $r = 1$, then any PLR of n is perfect. From now on we assume that $r \geq 2$. Also, of course, if p_i is odd then a PLR of $p_i^{a_i}$ is simply a primitive root of $p_i^{a_i}$.

If n is odd, every unit mod $2n$ is congruent to 1 mod 2 and to a unit mod n, so there is a bijection between the units modulo n and $2n$. This bijection clearly preserves the properties of being a PLR and of being perfect, imperfect or aberrant. So the numbers of PLRs in each of these three categories are the same for $2n$ as for n.

The property of being a perfect PLR is equivalent to the apparently stronger property (b) in the following result.

Theorem 10.1 *Let x be a unit modulo n. Then the following are equivalent:*

(a) x is a perfect PLR of n;

(b) x is a PLR of m, for every divisor m of n;

(c) x is a perfect PLR of m, for every divisor m of n.

Proof Clearly (c) implies (b) and (b) implies (a). So suppose that (a) holds, with $n = p_1^{a_1} \cdots p_r^{a_r}$. Then x is a PLR of $p_i^{a_i}$, for each i.

We claim that x is a PLR of p_i^b, for all i and all b with $0 < b \leq a_i$. This is because the natural homomorphism from $U(p^c)$ to $U(p^{c-1})$ has kernel of order p if $c > 1$, so the order of x mod p^{c-1} is at least a fraction $1/p$ of its order mod p^c. (Compare the proof of Theorem 5.2(a).) Now "downward induction" establishes the claim.

But now, by definition, x is a perfect PLR of m for every divisor m of n, and we are done.

Perfect PLRs always exist: if x_i is a PLR of $p_i^{a_i}$ for $i = 1, \ldots, r$, then the Chinese Remainder Theorem guarantees us a solution of the simultaneous congruences $x \equiv x_i \pmod{p_i^{a_i}}$, and clearly x is a PLR of n. This argument allows us to count the number of perfect PLRs of n: this number is simply the product of the numbers of PLRs of $p_i^{a_i}$ for $i = 1, \ldots, r$.

Theorem 10.2 *Let n be odd. Then any perfect PLR of n is an inward PLR.*

Proof A number congruent to 1 mod p_i cannot be a PLR of $p_i^{a_i}$ for odd p_i, since its order is a power of p_i. Hence, if x is a PLR of n with n odd, then $x \not\equiv 1 \pmod{p_i}$ for $i = 1, \ldots, r$. This shows that $x-1$ is not divisible by any of $p_1, \ldots, p_r$, so that $x-1$ is a unit mod n. (This is the same as the proof of Proposition 9.3(a).)

Theorem 10.3 *If a PLR x of n is perfect, then so is every member of its power class. The same holds with "imperfect" or "aberrant" replacing "perfect".*

Proof Suppose that x is a perfect PLR of n, and let y belong to the power class of x. Then each of x and y is congruent to a power of the other mod n. It follows that each is a power of the other mod $p_i^{a_1}$, so that x and y have the same order mod $p_i^{a_i}$; thus, if one is a PLR of $p_i^{a_i}$, then so is the other.

Let $n = p_1^{a_1} p_2^{a_2} \cdots p_r^{a_r}$. We say that the prime power $p_i^{a_i}$ is *essential* in n if the following holds: for every prime power q^b such that q^b exactly divides $\lambda(p_i^{a_i})$, and for all $j \neq i$, it holds that q^b does not divide $\lambda(p_j^{a_j})$. If n is twice an odd number, then 2 is (vacuously) essential in n. Apart from this, there can be at most one essential prime power, since, if $p_i^{a_i} > 2$ is essential, then the power of 2 dividing $\lambda(p_i^{a_i})$ is higher than that dividing $\lambda(p_j^{a_j})$ for $j \neq i$.

If $p_i^{a_i}$ is essential in n, then any PLR of n is obviously a PLR of $p_i^{a_i}$, and conversely. Thus, we have the following result:

Theorem 10.4 *Every PLR of n is perfect if and only if n is a prime power or twice a prime power.*

In the following table, PLRs from different power classes are separated by semi-colons, and negating PLRs are asterisked.

n	perfect PLRs	imperfect PLRs	aberrant PLRs
15	2, 8	7, 13	—
21	5^*, 17^*	2, 11; 10, 19	—
35	3, 12, 17, 33	2, 18, 23, 32	—
63	5^*, 38^*; 47^*, 59^*	2, 32; 10, 19; 11, 23; 17^*, 26^*; 20^*, 41^*; 29, 50; 31, 61; 40, 52	13, 34; 44, 53

We turn now to the existence question for aberrant PLRs. The answer is somewhat elaborate and depends on the structure of an auxiliary coloured hypergraph, which we now construct.

Let $n = p_1^{a_1} p_2^{a_2} \cdots p_r^{a_r}$. The vertices of the hypergraph $H(n)$ are indexed by the primes $p_1, \ldots, p_n$. The edges (to be defined in a moment) are indexed by the prime divisors of $\lambda(n)$.

We say that a prime divisor q of $\lambda(n)$ *occurs maximally* in $\lambda(p_i^{a_i})$ if the largest power of q dividing $\lambda(p_i^{a_i})$ is the same as the largest power of q dividing $\lambda(n)$. Now we colour the vertices p_i with three colours as follows:

- p_i is red if every prime divisor of $\lambda(p_i^{a_i})$ occurs maximally there;
- p_i is green if some but not all prime divisors of $\lambda(p_i^{a_i})$ occurs maximally there;
- p_i is blue if no prime divisor of $\lambda(p_i^{a_i})$ occurs maximally there.

The edge indexed by the prime q is incident with all vertices p_i for which q occurs maximally in $\lambda(p_i^{a_i})$. Thus, the blue vertices are isolated. Note that an edge of the hypergraph may be incident with just one vertex.

For example, let $n = 63 = 9 \cdot 7$. We have $\lambda(63) = \lambda(9) = \lambda(7) = 6$; the graph $H(63)$ has two vertices labelled 3 and 7, both red, and two edges labelled 2 and 3, each incident with both the vertices. Since this graph is a cycle, the following theorem guarantees that aberrant PLRs exist for $n = 63$.

Theorem 10.5 *Let n be a positive integer. Then an aberrant PLR of n exists if and only if every connected component of the hypergraph $H(n)$ contains either a non-red vertex or a cycle.*

Proof Let x be a PLR of n. Then, for every prime q dividing $\lambda(n)$, there exists some p_i such that q occurs maximally in $\lambda(p_i^{a_i})$ and the order of x modulo $p_i^{a_i}$ is divisible by this maximal power of q. Thus, each edge q of the hypergraph must contain at least one representative vertex p_i for which this holds.

Suppose that the vertex p_i is blue. Choosing x to be congruent to a PLR mod $n/p_i^{a_i}$ and to 1 mod $p_i^{a_i}$, we see that x is aberrant mod n if and only if it is aberrant mod $n/p_i^{a_i}$. So we can ignore the blue primes.

Now suppose that a connected component contains either a green prime p_j, or a cycle $(p_{i_1}, q_1, p_{i_2}, \ldots, p_{i_m}, q_m, p_{i_1})$. In the case of the cycle, let p_{i_k} be the representative of q_k for $i = 1, \ldots, m$. Then choose a representative for all other

cycles which is at least distance to the green prime or the cycle in the hypergraph. Now choose x so that its order mod $p_i^{a_i}$ is the product of the appropriate powers of q for all edges q represented by p_i. Then the order of x is divisible by the correct power of each prime q indexing an edge of the component, but x is not a PLR of $p_i^{a_i}$ for any prime p_i in the component.

Now suppose that a component is acyclic and has only red vertices. We claim that, if a representative vertex is chosen for each edge, then some vertex must represent every edge containing it. For suppose we have a minimal counterexample. Choose a vertex lying on a single edge, and remove this vertex (by assumption, it is not the representative of its edge). By minimality, the hypergraph obtained by deleting this edge has a vertex which is the representative of every edge containing it, contrary to assumption.

Thus, if there is a component with this property, then every PLR of n must be a PLR of $p_i^{a_i}$ for some vertex p_i in this component, and x is not aberrant.

This completes the proof.

Corollary 10.6 *If $n = p^j(p^{j-1}(p-1)+1)$, where $j > 1$ and p and $p^{j-1}(p-1)+1$ are odd primes, then n has aberrant PLRs.*

For another example, let $n = 741 = 3 \cdot 13 \cdot 19$. In the graph $G(n)$, the prime 3 is blue while 13 and 19 are green; and the edges labelled 2 and 3 are incident with single vertices 13 and 19 respectively. Choosing x congruent to 1 mod 3, to an element of order 4 mod 13, and to an element of order 13 mod 19, we obtain an aberrant PLR of n.

Problem 11 Find families of integers n for which aberrant PLRs exist.

Problem 12 Count the aberrant PLRs of n. (This problem will not have a simple answer unless our characterisation of the values of n for which aberrant PLRs exist can be substantially improved!)

10.1 Deeply aberrant and nearly perfect PLRs

We can strengthen the concept of an aberrant PLR as follows.

Definition If $n = p_1^{a_1} p_2^{a_2} \cdots p_r^{a_r}$, then the PLR x of n is said to be *deeply aberrant* if x is not a PLR of p_i for any of the values $i = 1, \ldots, r$.

Thus, a deeply aberrant PLR is aberrant. Note that deeply aberrant PLRs cannot exist for even n.

Problem 13 Count the deeply aberrant PLRs of n.

We can also refine the notion of an imperfect PLR as follows.

Definition Let $n = p_1^{a_1} \cdots p_r^{a_r}$, and let x be a PLR of n which is not perfect. We say that x is *nearly perfect* if it is a PLR of p_i for all $i = 1, \ldots, r$.

Problem 14 Count the nearly perfect PLRs of n.

We note that, if n is even, then any unit is congruent to 1 mod 2, so the condition for the prime 2 is vacuous. Moreover, if n is squarefree, there are no nearly perfect PLRs of n. The proportion of units mod n which are congruent to primitive roots modulo each prime divisor of n is the product, over all prime divisors p of n, of the proportion of units mod p which are primitive roots. However, these elements may not all be PLRs.

For example, the number of perfect or nearly perfect PLRs of 63 is

$$\phi(63) \times \frac{1}{2} \times \frac{2}{6} = 6;$$

as we have seen, there are four perfect PLRs, and hence two nearly perfect PLRs. (In this case all such elements are PLRs, since $\lambda(63) = \lambda(7) = 6$.)

Proposition 10.7 *A nearly perfect PLR of n cannot be aberrant.*

Proof Suppose that n is a nearly perfect but aberrant PLR of n. Then each prime divisor of n must occur to a power higher than the first, since the requirements "not a PLR of $p_i^{a_i}$" and "a primitive root of p_i" conflict if $a_i = 1$. Let p be the largest prime divisor of n, and suppose that p^a exactly divides n. Suppose first that p is odd. Then p^{a-1} exactly divides $\lambda(n)$, so a PLR of n has order divisible by p^{a-1} mod p^a. But, if it is nearly perfect, then its order mod p^a is also divisible by $p-1$, and hence it is a primitive root mod p^a, and so is not aberrant. On the other hand, if $p = 2$, then n is a power of 2, and any PLR of n is perfect by definition.

Note also that, if n is odd, then any nearly perfect PLR of n is inward; in other words, Theorem 10.2 extends to nearly perfect PLRs, with the same proof.

The following table gives the nearly perfect PLRs of $n = 9p$ where p is prime and $\xi(n) = 6$ (that is, $p \equiv 1 \pmod 6$). They are negating if $p \equiv 3 \pmod 4$ and non-negating if $p \equiv 1 \pmod 4$.

n	nearly perfect PLRs
$63 = 3^2 \cdot 7$	$\{17, 26\}$
$117 = 3^2 \cdot 13$	$\{80, 71, 89, 98\}$
$171 = 3^2 \cdot 19$	$\{53, 116, 89, 98, 143, 71\}$
$279 = 3^2 \cdot 31$	$\{17, 260, 53, 251, 269, 179, 88, 197\}$

11 Further properties of PLRs

If x is an inward PLR of n, then the $2\lambda(n)$ differences

$$\pm(x^i - x^{i-1}), \quad (i = 1, 2, \ldots, \lambda(n)),$$

are all units, and consist of $2\lambda(n)$ different elements if x is non-negating, or $\lambda(n)$ elements each repeated twice if x is negating.

This property shows the importance (for constructions such as the motivating terrace in Section 1) of PLRs that are both inward and non-negating.

Definition The PLR x of n is *strong* if it is inward and non-negating. (Clearly this requires n to be odd, and not a prime power.)

It follows from Proposition 8.3 and Corollary 9.2 that, if a PLR is strong, then so is every PLR in the same power class.

Problem 15 Is it true that strong PLRs exist for all odd n with $\xi(n) > 1$, in other words, all odd numbers which are not prime powers?

This question has an affirmative answer for $n \leq 20\,000$.

Problem 16 Count the strong PLRs of n.

Problem 17 For which odd n such that $U(n) \cong C_{\lambda(n)} \times C_{\lambda(n)}$, can $U(n)$ be generated by two strong PLRs?

Note that the values of n for which $U(n) \cong C_{\lambda(n)} \times C_{\lambda(n)}$ are those given by Theorem 7.1(b), namely $n = p^a(p^a - p^{a-1} + 1)$, where p and $p^a - p^{a-1} + 1$ are odd primes and $a > 1$.

We give some examples. For $n = 63 = 9 \cdot 7$, $U_n \cong C_6 \times C_6$, and this group can be generated by the two PLRs 2 (which is strong) and 13 (which is outward and non-negating). However, it is not possible to choose two strong PLRs which generate the group.

For the next value of n, namely $n = 513 = 27 \cdot 19$, it is also not possible to find two strong PLRs generating $U(n)$, However, for $n = 2107 = 49 \cdot 43$, both 2 and 6 are strong PLRs, and they do generate $U(n)$.

Definition Let x be a strong PLR of n. Then x is called *self-seeking* if $x - 1 = \pm x^d$ for some integer d. Note that x is self-seeking if and only if the set $X = \{x^i : i = 0, 1, \ldots, \lambda(n) - 1\}$ of powers of x is equal to one of the two sets $A = \{x^i - x^{i-1} : i = 1, 2, \ldots, \lambda(n)\}$ or its negative $B = \{x^{i-1} - x^i : i = 1, 2, \ldots, \lambda(n)\}$. We say that x is *self-avoiding* otherwise.

Proposition 11.1 *If a self-avoiding strong PLR exists then* $\xi(n) > 2$.

Proof If x is strong then each of the sets X, A, B consists of units; X is the subgroup generated by x, and A and B are cosets of X. Clearly, if $\xi(n) = 1$, there are only $\lambda(n)$ units, so all three sets must be equal. Since x is strong, -1 is not a power of x, so the sets A and B are disjoint (for $x^i - x^{i-1} = x^{j-1} - x^j$ implies $x^{i-j} = -1$); so one of them must be equal to X if $\xi(n) = 2$.

Unlike what we have seen for other properties of PLRs, it is possible for all, some, or none of the elements of a power class of PLRs to be self-seeking. For $n = 65$, the powers of the PLRs ± 3 are:

3	1	3	9	27	16	48	14	42	61	53	29	22
-3	1	62	9	38	16	17	14	23	61	12	29	43

Thus the power class $\{3, 48, 42, 22\}$ consists of self-avoiding elements, while the power class $\{62, 17, 23, 43\}$ consists of self-seeking elements. (For example, $61 = 62^8$.)

For $n = 91$, the strong PLRs 2 and 32 come from the same power-class; successive powers are:

2	1	2	4	8	16	32	64	37	74	57	23	46
32	1	32	23	8	74	2	64	46	16	57	4	37

The power class is $\{2, 32, 37, 46\}$; 2 and 46 are self-seeking but the other two are self-avoiding.

Problem 18 What conditions must hold for the product of two strong PLRs of n to be a PLR of n? If $\xi(n) > 2$, is it possible for both, one or neither of the PLRs to be self-seeking?

Problem 19 Under what circumstances can the product of two strong PLRs of n be itself a strong PLR of n? Is it possible for both, one or neither of the PLRs to be self-seeking?

The smallest value of n for which this can occur is $n = 455$, where 18, 19 and $18 \cdot 19 = 342$ are all strong PLRs. None of these three is self-seeking.

For the value $n = 1771$, the numbers 39, 1768 and $39 \cdot 1768 = 1654$ are all self-seeking PLRs. This is the smallest value of n for which this can occur.

12 Tables of PLRs

We conclude with tables giving information about the smallest PLRs.

12.1 PLRs for composite odd multiples of 3

Combinatorics of Non-Crossing Configurations

F. Cazals, August 1997

Generalities

Non-Crossing configurations

Take n points equally spaced on the unit circle, and draw chords between these points with the constraint that no two chords cross one-another. The resulting configuration is called a **non-crossing configuration** and the study of such entities originates in the work of Euler and Segner in 1753 for counting triangulations of a n-gon. Since then several types of such configurations have been defined, and for example the presence/absence of cycles and the number of connected components in a given configuration define the classes of trees and forests, connected graphs and general graphs. In addition to be of combinatorial interest per se, these configurations are also important for algorithmic problems arising in computer graphics or computational geometry where they provide simple models for real-world situations.

If historically the study of these configurations has been carried out one at a time, it turns out that they all fit in the model of algebraic and analytic combinatorics and are thus amenable to a unified treatment. More precisely, they can be defined in terms of grammars, from which the generating functions can automatically be obtained and used to asymptotically analyse the number of configurations, the number of connected components, etc.

The goal of this worksheet is to present this chain, from the grammars specification using combstruct, to the asymptotics of algebraic functions using some features of gfun, together with some plots of random configurations and of the singularities determining the asymptotic behaviour. The reader is referred to [FlaNo97] for the details.

The worksheet is organized as follows. In the rest of this section we define a few functions of null combinatorial interest but that we shall need to plot random configurations. In section two we present the grammar specifications for 6 of the main non-crossing configurations together with some plots of random configurations. And section three is devoted to the asymptotic machinery used to count the number of configurations of a given size, as well as a comparison between the asymptotic estimates and the exact values.

But to begin with, we first load the combstruct, gfun and plots libraries:

```
> with(combstruct):with(gfun):with(plots):
```

Appendix

Again, we define here a few functions we shall need to plot NC configurations. The first one returns the number of atoms in a structure, that is its size:

```
> size:=proc(t) convert(map(size, t), `+`) end:size(Epsilon):=0: size(Z):=1:
```

Since a configuration is defined by edges drawn between points equally spaced on the unit circle, we first show how to retrieve these pairs of indices from the grammars to be defined in the next section:

Collecting the edges of a NC-tree

Since a tree T satisfies T=Product (Z, Sequence(Butterflies)), to plot it we just have to collect its edges which are pairs of indices in 0..n-1:

```
> plotTree:= proc(aTree) local r, nbVertices;
#--op returns the Sequence; 0 is the index of the root on the circle;
#--1 indicates that the butterflies attached to the root are counted as a
#--right wing
r:=getTreeEdges(op(2, aTree), 0, 1);
nbVertices:=size(aTree);

plotSetOfEdges(r, nbVertices)
end:
```

The parameters of getTreeEdges are the following: aSeqOfBtf is a sequence of butterflies; rootIdx is the index of the vertex this sequence is attached to; leftRight (-1 or +1) indicates if this sequence is a left/right wing of the bug. The algorithm works as follows:

1.We first compute the indices of the apex vertices of the butterflies

2.For a given butterfly, we recurse on the 2 wings and attach its apex to the rootIdx parameter

```
> getTreeEdges:=proc(aSeqOfBtf, rootIdx, leftRight)
```

```
local i, a, eL, currentBtf, cumul;

if aSeqOfBtf = Epsilon then {}
else
cumul := rootIdx;
if leftRight=1 then #--we are processing a right wing
for i to nops(aSeqOfBtf) do
currentBtf := op(i, aSeqOfBtf);
a[i] := cumul + size(op(1, currentBtf)) + 1;
cumul := cumul + size(currentBtf)
od;
else #--and here a left one
for i from nops(aSeqOfBtf) by -1 to 1 do
currentBtf := op(i, aSeqOfBtf);
a[i] := cumul - size(op(3, currentBtf)) - 1;
cumul := cumul - size(currentBtf);
od;
fi;

#-- recurses for each Prod(?, Z, ?) in the sequence, with ? = E or Seq()
eL := {};
for i from 1 to nops(aSeqOfBtf) do
currentBtf := op(i, aSeqOfBtf);
eL := eL union getTreeEdges(op(1, currentBtf), a[i], -1);
eL := eL union {[a[i], rootIdx]};
eL := eL union getTreeEdges(op(3, currentBtf), a[i], 1);
od;

#--returns the result
eL;
fi;
end:
```

Collecting the edges of a NC-graph

This first procedure recursively collects the edges of an EA, and is a straightforward application of the EA definition above. The parameter ori stands for the index of the lefmost point of the arch:

```
> getArchEdges:=proc(arch, ori) local i, offset, res;

if (arch=Epsilon) then res:={}
else
#--we first add the `roof' of the arch
res := {[ori, ori+size(arch)]};

#-----Prod(Z, Seq1, Seq2)
if (op(1,arch)=Z) then
res := res union getArchEdges(op(2,arch), ori);
res := res union getArchEdges(op(3,arch), ori+1+size(op(2,arch)))
else #--Sequence of arches
offset:=0;
#--let's process all the arches in this sequence
for i from 1 to nops(arch) do
res := res union getArchEdges(op(i, arch), ori+offset);
offset := offset + size(op(i,arch))
od
fi
fi;
res;
end:
```

Same thing but to a sequence of arches:

```
> getArchesSeqEdges:=proc(archesSeq, ori)
local i, arch, offset, res;
res:={}; offset:=0;

for i from 1 to nops(archesSeq) do
arch:= op(i, archesSeq);
res:= res union getArchEdges(arch, ori+offset);
offset := offset+size(arch)
od;
#--returns the setOfEdges and the new origin
res,ori+offset;
end:
```

And now the main procedure which collects the edges of a Non-Crossing graph:

```
> getNCGraphEdges:=proc(aNCGraph)
local res, ori, edges,
i, j,
seqOfSeqOrProd, seqOrProd;

#--first, the right ear which is a Seq(EA)
ori:=1;
res:=getArchesSeqEdges(op(3,aNCGraph), ori);
edges:=res[1]; ori := res[2];

edges := edges union {[0, ori]};

#--then the EAs inbetween two successive childs of v_1
seqOfSeqOrProd := op(5,aNCGraph);

for i from 1 to nops(seqOfSeqOrProd) do
seqOrProd:=op(i, seqOfSeqOrProd);
#--2 connected graphs
if (op(1, seqOrProd)=Z) then
res:=getArchesSeqEdges(op(2, seqOrProd), ori);
edges:= edges union res[1]; ori := res[2];

res:=getArchesSeqEdges(op(3, seqOrProd), 1+ori);
edges:= edges union res[1]; ori := res[2]

#--a Sequence
else
res:=getArchesSeqEdges(seqOrProd, ori);
edges:= edges union res[1]; ori := res[2]
fi;

#--we need to add the current child to the graph root
edges := edges union {[0, ori]};
od;

#--and the left ear
res:=getArchesSeqEdges(op(4,aNCGraph), ori);
edges:= edges union res[1]; ori := res[2];

#--returns the result
edges
end:
```

To plot a NC Graph, we just collect the edges and pass them to the plotSetOfEdges procedure:

```
> plotNCGraph:=proc(aNCGraph);
plotSetOfEdges(getNCGraphEdges(aNCGraph), size(aNCGraph))
end:
```

Now, given pairs of indices in 0,...,nbVertices-1 on the unit circle, the following procedure draws the corresponding chords
assuming that the k-th point has coordinates ((cos((2 Pi k)/nbVertices), sin((2 Pi k)/nbVertices))):

```
> plotSetOfEdges:=proc(aSetOfEdges, nbVertices) local pointsOnCircle;

pointsOnCircle:= expand(map(`*`, aSetOfEdges,2*Pi/nbVertices));
plot([op(map2(map,[cos,sin], pointsOnCircle))],color=blue,axes=NONE)
end:
```

Counting and drawing non-crossing configurations

Trees and forests

Trees

A Tree is a sequence of butterflies attached to a root, a Butterfly being an ordered pair of trees whose roots have been merged into a single node. Since this merge step cannot be specified by an operation such as B = Prod(T, Z, T)/Z in combstruct, it is more convenient to express a butterfly as the product of 2 forests, a Forest being a sequence of butterflies. Indeed, we now just have to attach the roots of all the trees of the two forests to a newly added node:

```
> tbf:={T=Prod(Z, Sequence(B)), F=Sequence(B), B=Prod(F,Z,F)};
```

$$tbf := \{T = \mathrm{Prod}(Z, \mathrm{Sequence}(B)), F = \mathrm{Sequence}(B), B = \mathrm{Prod}(F, Z, F)\}$$

Standard functionalities of Combstruct consist in counting the number of entities of a given type:

```
> seq(count([T,tbf], size=i),i=1..10);
```

$$1, 1, 3, 12, 55, 273, 1428, 7752, 43263, 246675$$

```
> seq(count([F,tbf], size=i),i=1..10);
```

$$1, 3, 12, 55, 273, 1428, 7752, 43263, 246675, 1430715$$

```
> seq(count([F,{F=Sequence(B), B=Prod(F,Z,F)}],size=i),i=0..10);
```

$$1, 1, 3, 12, 55, 273, 1428, 7752, 43263, 246675, 1430715$$

And randomly generating all the configurations of a given size:

```
> allstructs([T,tbf],size=2);
```

$$[\mathrm{Prod}(Z, \mathrm{Sequence}(\mathrm{Prod}(E, Z, E)))]$$

```
> expleT:=draw([T, tbf], size=20);
```

$$expleT := \mathrm{Prod}(Z, \mathrm{Sequence}(\mathrm{Prod}(\mathrm{Sequence}(\mathrm{Prod}(E, Z, \mathrm{Sequence}(\mathrm{Prod}(\mathrm{Sequence}(\mathrm{Prod}(E, Z, \mathrm{Sequence}(\mathrm{Prod}(\mathrm{Sequence}(\mathrm{Prod}(\mathrm{Sequence}(\mathrm{Prod}(E, Z, \mathrm{Sequence}(\mathrm{Prod}(\mathrm{Sequence}(\mathrm{Prod}(E, Z, \mathrm{Sequence}(\mathrm{Prod}(E, Z, \mathrm{Sequence}(\mathrm{Prod}(E, Z, E)))), Z, E))), \mathrm{Prod}(\mathrm{Sequence}(\mathrm{Prod}(E, Z, E)), \mathrm{Prod}(E, Z, E)), Z, E))))))), Z, E), \mathrm{Prod}(\mathrm{Sequence}(\mathrm{Prod}(E, Z, \mathrm{Sequence}(\mathrm{Prod}(E, Z, E)))), Z, \mathrm{Sequence}(\mathrm{Prod}(E, Z, E)))), Z, E)))), Z, E)))$$

We can also use gfseries to retrieve the first terms of the generating functions:

```
> Order:=10:gfseries(tbf,unlabelled,z);
```

$$\mathrm{table}([$$

$$F(z) = 1 + z + 3z^2 + 12z^3 + 55z^4 + 273z^5 + 1428z^6 + 7752z^7 + 43263z^8 + 246675z^9 + O(z^{10})$$

$$B(z) = z + 2z^2 + 7z^3 + 30z^4 + 143z^5 + 728z^6 + 3876z^7 + 21318z^8 + 120175z^9 + O(z^{10})$$

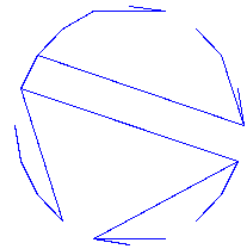
$$T(z) = z + z^2 + 3z^3 + 12z^4 + 55z^5 + 273z^6 + 1428z^7 + 7752z^8 + 43263z^9 + O(z^{10})$$

$$Z(z) = z$$

$$])$$

And here is an example of random tree:

```
> plotTree(draw([T,tbf],size=20));
```



```
>
```

Forests

In order to dissociate the trees in a forest, let us substitute to each vertex of a tree another vertex together with a forest

```
> fo:={B=Prod(Sequence(B),V,Sequence(B)),
V=Union(Prod(Z, F)),
```

```
F=Union(Epsilon, Prod(V, Sequence(B)))};
```

$$fo := \{B = \mathrm{Prod}(\mathrm{Sequence}(B), V, \mathrm{Sequence}(B)), V = \mathrm{Union}(\mathrm{Prod}(Z, F)), F = \mathrm{Union}(E, \mathrm{Prod}(V, \mathrm{Sequence}(B)))\}$$

```
> seq(count([F, fo], size=i), i=1..10);
```

$$1, 2, 7, 33, 181, 1083, 6854, 45111, 305629, 2117283$$

Connected and general graphs

Connected graphs

To see how nc-graphs are built, consider the set of childs $v_i, v_{i+1}, \ldots, v_j$ attached to the root v_1. The graphs built on $v_2, \ldots, v_i$ and $v_j, \ldots, v_{n-1}$ are connected by hypothesis, while between any two other vertices v_k and v_{k+1} one can have either one connected graph or two connected graphs.

But any graph built from a sequence of successive vertices of the circle is a system of arches since the arcs which are chords are not allowed to cross. The endpoints of these arches are shared by the graphs built to the left and to the right of a given v_k, so that we shall say that the size of an arch built on n points is $n-1$. At last, we are interested here in Elementary Arches, that is arches that always contain an arc between the firt and last points. General arches are easily obtained by sequencing EAs.

From this discussion we derive the Combstruct specification of NC graphs containing at least 2 vertices. In particular, the 5 arguments of a C entity are as follows:

1.first Z: the root of the graph

2.second Z: the lefmost point of the first EA

3 and 4. the two EAs built on $v_2, \ldots, v_i$ and $v_j, \ldots, v_{n-1}$

5.the sequence of EAs found between two consecutive childs of v_1. The first term corresponds to one EA,

and the second one to two EAs. For the latter case, the Z in the Prod stands for the lefmost point of the secong EA.

```
> ar:={EA = Union(Sequence(EA, card >= 2),
Prod(Z, Sequence(EA), Sequence(EA))
),
C=Union(Z,
Prod(Z,Z,Sequence(EA), Sequence(EA),
Sequence(Union(Sequence(EA,card>=1), Prod(Z,Sequence(EA),Sequence(EA))))))};
```

$$ar := \{EA = \mathrm{Union}(\mathrm{Sequence}(EA, 2 \le card), \mathrm{Prod}(Z, \mathrm{Sequence}(EA), \mathrm{Sequence}(EA))), C = \mathrm{Union}(Z, \mathrm{Prod}(Z, Z, \mathrm{Sequence}(EA), \mathrm{Sequence}(EA), \mathrm{Sequence}(\mathrm{Union}(\mathrm{Sequence}(EA, 1 \le card), \mathrm{Prod}(Z, \mathrm{Sequence}(EA), \mathrm{Sequence}(EA))))))\}$$

We can now count the number of elementary arches of a given size. The sequence found is not in [Sloa95]:

```
> seq(count([EA,ar], size=i),i=1..20);
```

$$1, 3, 16, 105, 768, 6006, 49152, 415701, 3604480, 31870410, 286261248, 2604681690, 23957864448, 222399744300, 2080911654912, 19604537460045, 185813170126848, 1770558814528770, 16951376923852800, 162984598242674670$$

```
> allstructs([EA,ar],size=2);
```

$$[\mathrm{Sequence}(\mathrm{Prod}(Z, E, E)), \mathrm{Prod}(Z, E, E)), \mathrm{Prod}(Z, \mathrm{Sequence}(\mathrm{Prod}(Z, E, E)), E), \mathrm{Prod}(Z, E, \mathrm{Sequence}(\mathrm{Prod}(Z, E, E)))]$$

We can also count the number of NC-graphs. The corresponding sequence turns out to be M3594 in [Sloa95] and gives the reverse

of the g.f. for squares:

```
> seq(count([C,ar], size=i),i=1..10);
```

$$1, 1, 4, 23, 156, 1162, 9192, 75819, 644908, 5616182$$

As usual, we can get all the structures of a given size, or just draw some of them:

```
> allstructs([C,ar],size=3);
```

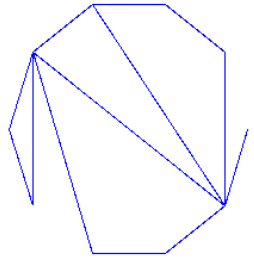
$$[\mathrm{Prod}(Z, Z, E, E, \mathrm{Sequence}(\mathrm{Sequence}(\mathrm{Prod}(Z, E, E)))), \mathrm{Prod}(Z, Z, E, E, \mathrm{Sequence}(\mathrm{Prod}(Z, E, E))),$$
$$\mathrm{Prod}(Z, Z, E, \mathrm{Sequence}(\mathrm{Prod}(Z, E, E)), E), \mathrm{Prod}(Z, Z, \mathrm{Sequence}(\mathrm{Prod}(Z, E, E)), E, E)]$$

```
> draw([EA,ar],size=10);
```

$$\mathrm{Sequence}(\mathrm{Sequence}(\mathrm{Prod}(Z, E, E),$$
$$\mathrm{Prod}(Z, E, \mathrm{Sequence}(\mathrm{Prod}(Z, E, \mathrm{Sequence}(\mathrm{Prod}(Z, E, \mathrm{Sequence}(\mathrm{Prod}(Z, E, E)))))))), \mathrm{Prod}(Z, E, E)),$$
$$\mathrm{Sequence}(\mathrm{Sequence}(\mathrm{Prod}(Z, E, E), \mathrm{Prod}(Z, E, E), \mathrm{Prod}(Z, E, E)), \mathrm{Prod}(Z, E, E)))$$

And an example of random graph:

```
> plotNCGraph(draw([C,ar],size=10));
```



>

General graphs

As observed in [FlaNo97], a general graph is obtained from a connected one by the substitution Z -> Prod(Z, G). So that we just have to rewrite the previous grammar by adding a new symbol which makes this substitution. Notice however that the decomposition of a connected graph misses a configuration for general graphs: the one where vertex v_1 does not have any child, which we therefore add:

```
> br:={EA = Union(Sequence(EA, card >= 2),
Prod(V, Sequence(EA), Sequence(EA))
),
V=Union(Prod(Z, G)),
G=Union(Epsilon,
Prod(Z, G),
Prod(V,V,Sequence(EA), Sequence(EA),
Sequence(Union(Sequence(EA,card>=1), Prod(V,Sequence(EA),Sequence(EA)))))
)
};
```

$$br := \{EA = \mathrm{Union}(\mathrm{Sequence}(EA, 2 \le card), \mathrm{Prod}(V, \mathrm{Sequence}(EA), \mathrm{Sequence}(EA))), V = \mathrm{Union}(\mathrm{Prod}(Z, G)), G =$$
$$\mathrm{Union}(E, \mathrm{Prod}(Z, G), \mathrm{Prod}(V, V, \mathrm{Sequence}(EA), \mathrm{Sequence}(EA),$$
$$\mathrm{Sequence}(\mathrm{Union}(\mathrm{Sequence}(EA, 1 \le card), \mathrm{Prod}(V, \mathrm{Sequence}(EA), \mathrm{Sequence}(EA)))))))\}$$

The number of graphs is given by the following sequence, not to be found in [Sloa95]:

```
> ggSeq:=[seq(count([G, br], size=i), i=0..20)];
```

$$ggSeq := [1, 1, 2, 8, 48, 352, 2880, 25216, 231168, 2190848, 21292032, 211044352, 2125246464, 21681954816,$$
$$223623069696, 2327818174464, 24424842461184, 258054752698368, 2742964283768832, 29312424612462592,$$
$$314739971287154688]

In this case, it also turns out that the differential equation verified by y is of order 1:

```
> ggDiffEq:=listtodiffeq(ggSeq,y(x));
```

$$ggDiffEq := \left[\{y(0) = 1, -1 + 18x + (1 - 18x + 8x^2)\,y(x) + (12x^2 - 4x^3 - x)\left(\frac{\partial}{\partial x}y(x)\right)\}, ogf\right]$$

From this equation and the condition $\mathrm{coeff}(y(x), x, 1) = 1$, we get the following closed form:

```
> closedForm:=dsolve(ggDiffEq[1],y(x));
subs(_C1=-1/2,closedForm);
```

$$closedForm := y(x) = 1 + \frac{3}{2}x - x^2 + x\sqrt{-12x + 4x^2 + 1}\_C1$$

$$y(x) = 1 + \frac{3}{2}x - x^2 - \frac{1}{2}x\sqrt{-12x + 4x^2 + 1}$$

As shown in [FlaNo97], this corresponds to the general term:

```
> cn:=proc(n)
local k,l;
sum((-1)^k*product(2*l-1,l=1..n-k-1)/(factorial(k)*factorial(n-2*k))*3^(n-2*k)*2^(-k-2), k=0..iquo(n,2))
end:
```

```
> gn:=proc(n) 2^n*cn(n-1) end;
```

$$gn := \mathbf{proc}(n)\ 2^n * \mathrm{cn}(n-1)\ \mathbf{end}$$

```
> seq(gn(i), i=3..10);
```

$$8, 48, 352, 2880, 25216, 231168, 2190848, 21292032$$

Dissections and partitions

Dissections

A dissection of a convex polygon $P_n = \{v_1, \ldots, v_n\}$ is a partition of the polygon into polygonal regions by means of non-crossing diagonals. If the polygonal region containing the edge $v_1 v_2$ has $r+1$ sides, one gets a bigger dissection by replacing the r edges by a dissection. So that a dissection is either an edge connecting two vertices or a sequence of dissections. The tricky point in sequencing 2 dissections consists in not counting the same vertex twice, as for the connected graphs above. When sequencing dissections, we therefore assume that each dissection provides its rightmost point while the lefmost one is the rightmost point of the dissection to the left in the sequence. With this convention, the number of dissections of size i actually counts the number of dissections of a polygon with $i+1$ vertices, and the grammar is:

```
> dissG:={Di=Union(Z, Sequence(Di, card >= 2))};
```

$$dissG := \{Di = \mathrm{Union}(Z, \mathrm{Sequence}(Di, 2 \le card))\}$$

The corresponding sequence, M2898 in [Sloa95] and related to Schroeder's second problem is:

```
> seq(count([Di, dissG], size=i), i=1..10);
```

$$1, 1, 3, 11, 45, 197, 903, 4279, 20793, 103049$$

Partitions

A non-crossing partition of size n is a partition of [n]={1,2,...,n} such that if a<b<c<d and a block contains a and c, then no block contains b and d. Given a partition block, possibly empty, one gets a bigger partition by subsituting to each vertex the product between Z and another partition. So that:

```
> partG:={P=Sequence(V), V = Prod(Z,P)};
```

$$partG := \{P = \mathrm{Sequence}(V), V = \mathrm{Prod}(Z, P)\}$$

We get the sequence of Catalan numbers, which can be checked in terms of generating functions:

> **seq(count([P, partG], size=i), i=1..10);**

$$1, 2, 5, 14, 42, 132, 429, 1430, 4862, 16796$$

> **gfsolve(partG, unlabelled, z);**

$$\{Z(z) = z, V(z) = \frac{1}{2} - \frac{1}{2}\sqrt{1 - 4z}, P(z) = \frac{1}{2}\frac{1 - \sqrt{1 - 4z}}{z}\}$$

Univariate asymptotics

Asymptotic counting: algorithm

Outline

As shown in [FlaNo97] for the six NC configurations we are interested in, the generating function $y(z)$ satisfies an algebraic equation. In the case of NC forests for example, we have:

> **eq:=y^3+(-z+z^2-3)*y^2+(z+3)*y-1;**

$$eq := y^3 + (-z + z^2 - 3)y^2 + (z + 3)y - 1$$

Like in many implicitely defined functions [Dr97, HaPa73], we expect *a priori* $y(z)$ to have locally an expansion of the square-root type, that is:

$$y(z) = c_0 + c_1\sqrt{1 - \frac{z}{\rho}} + c_2\left(1 - \frac{z}{\rho}\right) + O\left(\left(1 - \frac{z}{\rho}\right)^{\left(\frac{3}{2}\right)}\right)$$

By a singularity analysis at the dominant singularity ρ and denoting $\gamma = -\frac{c_1}{2}$, we get:

$$[z^n]\,y(z) = \frac{c_1\,\rho^{(-n)}\left(1 + O\left(\frac{1}{n}\right)\right)}{\Gamma\left(-\frac{1}{2}\right)\sqrt{n^3}} \quad \text{or} \quad y_n = \frac{\gamma\,\rho^{(-n)}\left(1 + O\left(\frac{1}{n}\right)\right)}{\sqrt{\pi\,n^3}}$$

We now examplify this method for the class of NC-forests. The singulatities sought may arise at those points z such that E(z,y)=0 and $\frac{\partial}{\partial y}E(z, y) = 0$. In order to get the candidates z satisfyning these conditions, we just have to eliminate y between the two previous equations through a resultant computation:

> **res_y:=resultant(eq,diff(eq,y),y);**
res_y:=expand(normal(res_y/gcd(res_y,diff(res_y,z))));
Omega[0]:=normal(res_y/z^ldegree(res_y));

$$res\_y := -4z^3 + 32z^4 + 8z^5 - 5z^6$$

$$res\_y := -4z + 32z^2 + 8z^3 - 5z^4$$

$$\Omega_0 := -4 + 32z + 8z^2 - 5z^3$$

And the singularities sought are the solutions of the previous equation whose modulus is smaller than 1. If the set

found has cardinality one, we are done. It actually turns out that this is the case for all our configurations but the connected graphs where a `ghost' singularity has to be elimanated by an external argument --see [FlaNo97]. In our case:

```
> rhonums:=[fsolve(Omega[0],z,complex)];
Omega[1]:=map(proc(x) if abs(x)<1 then x fi end,rhonums);
```

$$rhonums := [-1.930283307,\ .1215851069,\ 3.408698200]$$

$$\Omega_1 := [.1215851069]$$

And a convenient way to represent our singularity both in symbolic and numerical form is:

```
> rho_symb:=RootOf(Omega[0], z, op(Omega[1]));
```

$$rho\_symb := \mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3,\ .1215851069)$$

Since in our case the dominant coefficient of the equation in y does not vanish, the function remains finite at its singularity. Its value $\tau = \lim_{z \to \rho} y(z)$ is also the quantity c_0 defined above. Since the point $P(\rho, \tau)$ is a singularity, we have $E(\rho, \tau) = 0$ and $\left(\frac{\partial}{\partial y} E(z, y)\right)_{\rho, \tau} = 0$. Candidate values for τ are therefore obtained as follows:

```
> deq:=subs(z=rho_symb, diff(eq,y));
print(`Candidate values for function at singularity`);
tau_vals:=[fsolve(deq,y)];
print(tau_vals);
```

$$deq := 3y^2 + 2\left(-\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3,\ .1215851069) + \mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3,\ .1215851069)^2 - 3\right)y + \mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3,\ .1215851069) + 3$$

Candidate values for function at singularity

$$tau\_vals := [.8568817020,\ 1.214319744]$$

$$[.8568817020,\ 1.214319744]$$

Plugging back these candidates into the equation eq, we could get the correct one from a carefully controlled numerical analysis:

```
> eTau:=subs(z=rho_symb, eq);
[seq( evalf(subs(y=tau_vals[i], eTau)), i=1..nops(tau_vals))];
```

$$eTau := y^3 + \left(-\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3,\ .1215851069) + \mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3,\ .1215851069)^2 - 3\right)y^2 + \left(\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3,\ .1215851069) + 3\right)y - 1$$

$$[.02283349037,\ -.69\ 10^{-9}]$$

To get the constant c_1 we are missing, let us just compute the Puiseux expansions verified by $y(z)$ with the algeqtoseries procedure from the gfun package:

```
> all_puis:=algeqtoseries(subs(z=rho_symb*(1-t^2),eq),t,y,6);
```

$$
\begin{aligned}
&all\_puis := \Bigg[\\
&\left(\frac{25}{37} + \frac{1}{37}\,\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069) - \frac{2}{37}\,\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069)^2\right) \\
&- \left(-2.5 - \mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069) + 2\,\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069)^2\right) \\
&\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069)\Big(-12 - 49\,\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069) \\
&- 4\,\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069)^2 + 4\,\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069)^3\Big) \\

\end{aligned}
$$

$$
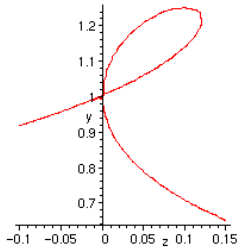
\mathit{Constant}, [-.1493185566]
$$

Should we have found several expansions containing a t term, the right one could have been selected from the formula $c_1 = -\sqrt{\frac{2\,\rho\,p_{1,0}}{p_{0,2}}}$ and $p_{i,j} = \frac{\mathrm{Diff}(eq, z\$i, y\$j)_{\rho,\tau}}{i!\,j!}$. Also note that the minus sign has to be adopted for c_1 since the generating function increases with its argument.

We can locally plot the algebraic curve in the neighborhood of the singularity:

```
> implicitplot(eq, z=-.1..0.15, y=-1..1.3, numpoints=5000);
```



Putting everything together, we get the following procedure which we apply to the remaining NC configurations.

Implementation

We first look for the singularity(ies) of smallest modulus(i):

```
> locateDominantSing := proc(eq, y, z)
local res_y, Omega, rhonums,
rho_symb;

#--we look for the z such that eq and diff(eq,y) have a common root y
res_y:=resultant(eq,diff(eq,y),y);
res_y:=expand(normal(res_y/gcd(res_y,diff(res_y,z))));
Omega[0]:=normal(res_y/z^ldegree(res1_y));
rhonums:=[fsolve(Omega[0],z,complex)];

#--we are just interested in roots of modulus < 1
Omega[1]:=map(proc(x) if abs(x)<1 then x fi end,rhonums);
if nops(Omega[1])<>1 then
ERROR(`More than one root of modulus < 1: not implemented!`) fi;

rho_symb:=RootOf(Omega[0], z, op(Omega[1]));
print(`Singularity is`); print(rho_symb);

rho_symb
end:
```

And then the asymptotic expansion. The values returned are:

1.the symbolic expressions for the c_1 constant

2.the dominant singularity ρ

3.the Puiseux expansion

```
> singExpansion:=proc(eq, y, z)
local rho_symb,
deq, tau_vals,
all_puis, all_puis_s, c1;

#--numerical and symbolic representation of the singularities
rho_symb:=locateDominantSing(eq, y, z);

#--values of the function at the singularity
deq:=subs(z=rho_symb, diff(eq,y));
print(`Candidate values for function at singularity`);
tau_vals:=[fsolve(deq,y)];
print(tau_vals);
```

```
#--Puiseux expansion; we expect a single exp. to have a t term
all_puis:=algeqtoseries(subs(z=rho_symb*(1-t^2),eq),t,y,6);

#--convert into series i.e. remove the O()
all_puis_s:=map(eval, map2(subs, O=0, all_puis));
#--collect the coeff in t and select the non-null one(s)
c1:=map(proc(x) if x<>0 then x fi end, map(coeff, all_puis_s, t, 1));

if nops(c1)<>1 then
print(`Problem in singular expansion`); print(all_puis); RETURN(FAIL)
else
c1:=op(c1); if evalf(c1)>0 then c1:=-c1 fi
fi;

#--returns the constant c1 and the singularity in symbolic forms
print(`c1 constant`, c1,evalf(c1,20));
[c1,rho_symb, my_puis]
end:
```

Applications to non-crossing configurations

We now present the whole chain that goes from the grammars specification to the asymptotic machinery. More precisely, for each of the NC configurations studied above, we:

1.call Combstruct[gfeqns] to retrieve the system of equations verified by the generating functions associated with the grammar,

2.compute the algebraic equation verified by a given generating function with gfun[algfuntoalgeq],

3.feed this equation to the asymptotic machinery developped above.

Trees

Generating functions associated with the grammar:

```
> gfeqns(tbf, unlabelled, z);
```

$$\left[B(z) = F(z)^2 Z(z), F(z) = \frac{1}{1 - B(z)}, Z(z) = z, T(z) = \frac{Z(z)}{1 - B(z)}\right]$$

```
> treesSys:=gfsolve(tbf, unlabelled, z);
```

$$treesSys := \left\{F(z) = \text{RootOf}(\_Z + \_Z^3 z + 1), T(z) = -\frac{z}{2}, B(z) = \text{RootOf}(\_Z + \_Z^3 z + 1)^2 z, Z(z) = z\right\}$$

Algebraic equation:

```
> trees:=algfuntoalgeq(subs(treesSys,T(z)), y(z));
```

$$trees := -y z + z^2 + y^3$$

Asymptotic machinery:

```
> resTrees:=singExpansion(trees, y, z):
```

Singularity is

$$\frac{4}{27}$$

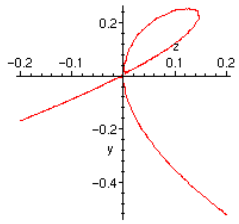
Candidate values for function at singularity

$$[-.2222222222, .2222222222]$$

$$c1\ constant, \mathrm{RootOf}(-4 + 243\_Z^2), -.12830005981991683656$$

Plot of the singularity:

> **implicitplot(trees, z=-0.2..0.2, y=-1..1, numpoints=5000);**



Forests

> **forests:=y^3+(-z+z^2-3)*y^2+(z+3)*y-1;**

$$forests := y^3 + (-z + z^2 - 3)y^2 + (z + 3)y - 1$$

> **resForests:=singExpansion(forests, y, z):**

Singularity is

$$\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069)$$

Candidate values for function at singularity

$$[.8568817020, 1.214319744]$$

$$c1\ constant, \mathrm{RootOf}\left(1369\_Z^2 + 5290\,\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069)^2 - 228 + 981\,\mathrm{RootOf}(4 - 32\_Z - 8\_Z^2 + 5\_Z^3, .1215851069)\right), -.14931855684380904697$$

Connected graphs

Generating functions associated with the grammar:

> **CGSys:=gfsolve(ar, unlabelled, z);**

$$CGSys := \left\{ Z(z) = z,\ EA(z) = \mathrm{RootOf}(\_Z - 3\_Z^2 + 2\_Z^3 - z),\ C(z) = -\frac{z\left(1 - 3\,\mathrm{RootOf}(\_Z - 3\_Z^2 + 2\_Z^3 - z) + 2\,\mathrm{RootOf}(\_Z - 3\_Z^2 + 2\_Z^3 - z)^2\right)}{-1 + 3\,\mathrm{RootOf}(\_Z - 3\_Z^2 + 2\_Z^3 - z) - 2\,\mathrm{RootOf}(\_Z - 3\_Z^2 + 2\_Z^3 - z)^2 + z} \right\}$$

Algebraic equation:

> **CG:=algfuntoalgeq(subs(CGSys,C(z)), y(z));**

$$CG := y^3 + y^2 - 3yz + 2z^2$$

Asymptotic machinery:

> **resCG:=singExpansion(CG, y, z):**

Error, (in locateDominantSing) More than one root of modulus < 1: not implemented!

As observed in [FlaNo97], due to the two singularities found, we need additional information to select the right one. Eliminating the negative value and performing the previous computations yields the following c_1 and ρ :

> **resCG[1]:=-RootOf(54*_Z^2-7+72*RootOf(-1+108*_Z^2,.962250448649376274 18e-1));**

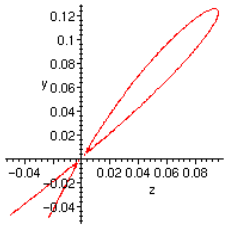
$$resCG_1 := -\text{RootOf}(54\_Z^2 - 7 + 72\,\text{RootOf}(-1 + 108\_Z^2, .096225044864937627418))$$

> **resCG[2]:=RootOf(-1+108*_Z^2,.962250448649376274 18e-1);**

$$resCG_2 := \text{RootOf}(-1 + 108\_Z^2, .096225044864937627418)$$

Plot of the singularity:

> **implicitplot(CG, z=-0.05..0.15, y=-.05..0.2, numpoints=10000);**



General graphs

Generating functions associated with the grammar:

> **GGSys:=gfsolve(br, unlabelled, z);**

$$GGSys := \{EA(z) = \frac{1}{4} - \frac{1}{2}z - \frac{1}{4}\sqrt{1 - 12z + 4z^2}, V(z) = z\left(1 + z + 2\left(\frac{1}{4} - \frac{1}{2}z - \frac{1}{4}\sqrt{1 - 12z + 4z^2}\right)z\right),$$
$$G(z) = 1 + z + 2\left(\frac{1}{4} - \frac{1}{2}z - \frac{1}{4}\sqrt{1 - 12z + 4z^2}\right)z, Z(z) = z\}$$

Algebraic equation:

> **GG:=algfuntoalgeq(subs(GGSys,G(z)), y(z));**

$$GG := y^2 + (-2 - 3z + 2z^2)y + 1 + 3z$$

Asymptotic machinery:

> **resGG:=singExpansion(GG, y, z):**

Singularity is

$$\text{RootOf}(1 - 12\_Z + 4\_Z^2, .08578643763)$$

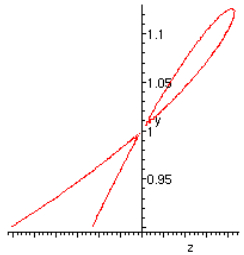
Candidate values for function at singularity

$$[1.121320344]$$

$$c1\ constant, \mathrm{RootOf}(8\_Z^2 + 198\,\mathrm{RootOf}(1 - 12\_Z + 4\_Z^2, .08578643763) - 17), -.042257173759048982037$$

Plot of the singularity:

```
> implicitplot(GG, z=-0.2..0.1, y=0.9..1.2, numpoints=10000);
```



Dissections

```
> dissSys:=gfsolve(dissG, unlabelled, z);
```

$$dissSys := \{\mathrm{Di}(z) = \frac{1}{4} + \frac{1}{4}z - \frac{1}{4}\sqrt{1 - 6z + z^2}, \mathrm{Z}(z) = z\}$$

```
> diss:=algfuntoalgeq(subs(dissSys,Di(z)), y(z));
```

$$diss := 2y^2 + (-1 - z)y + z$$

```
> resDiss:=singExpansion(diss, y, z):
```

Singularity is

$$\mathrm{RootOf}(1 - 6\_Z + \_Z^2, .1715728753)$$

Candidate values for function at singularity

$$[.2928932168]$$

$$c1\ constant, \mathrm{RootOf}(8\_Z^2 + 3\,\mathrm{RootOf}(1 - 6\_Z + \_Z^2, .1715728753) - 1), -.24629285775235400967$$

It should be noticed that the equation obtained in the paper and stated below in slightly different.But remember that z^i counts here the number of dissections of a polygon with $i + 1$ vertices. Of course, we still have the same singularity:

```
> diss2:=2*y^2-z*(1+z)*y+z^3:
```

```
> resDiss2:=singExpansion(diss2, y, z):
```

Singularity is

$$\mathrm{RootOf}(1 - 6\_Z + \_Z^2, .1715728753)$$

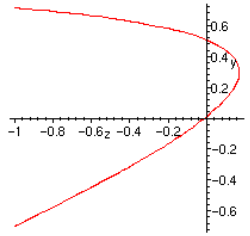
Candidate values for function at singularity

$$[.05025253170]$$

$$c1\ constant, \mathrm{RootOf}(8\_Z^2 + 99\,\mathrm{RootOf}(1 - 6\_Z + \_Z^2, .1715728753) - 17), -.042257173759048980558$$

Plot of the singularity:

> **implicitplot(diss, z=-1..1, y=-1..1, numpoints=1000);**



Partitions

> **partsSys:=gfsolve(partG, unlabelled, z);**

$$partsSys := \{Z(z) = z, V(z) = \frac{1}{2} - \frac{1}{2}\sqrt{1-4z}, P(z) = \frac{1}{2}\frac{1-\sqrt{1-4z}}{z}\}$$

> **parts:=algfuntoalgeq(subs(partsSys,P(z)), y(z));**

$$parts := 1 + y^2 z - y$$

> **resParts:=singExpansion(parts, y, z);**

Singularity is

$$\frac{1}{4}$$

Candidate values for function at singularity

[2.]

Problem in singular expansion

$$[2 - 2t + 2t^2 - 2t^3 + O(t^{7/2}), 2 + 2t + 2t^2 + 2t^3 + O(t^{7/2})]$$

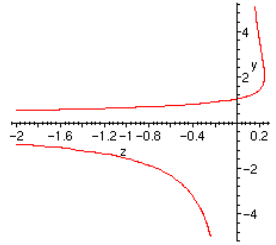
resParts := FAIL

Here we are in trouble since there are 2 Puiseux expansions with $t^{\frac{7}{2}}$ terms. But only the first one makes sense since the generating function increases with its argument. So that:

> **resParts[1]:=2: resParts[2]:=1/4:**

Plot of the singularity:

> **implicitplot(parts, z=-2..1, y=-5..5, numpoints=1000);**



Exact and estimated values: comparisons

We have already seen that an estimate of the number of objects of size n is given by:

```
> nbEnt:=proc(c1,rho, n)
evalf(c1*rho^(-n)/(2*sqrt(Pi*n^3)))
end;
```

$$nbEnt := \mathbf{proc}(c1, \rho, n)\ \mathrm{evalf}(1 / 2*c1*\rho\hat{}(-n) / \mathrm{sqrt}(\pi*n\hat{}3))\ \mathbf{end}$$

Comparisons with the exact values are as follows. It is interesting to observe that these values are within about 2% in any case:

Trees

```
> exactTr:=evalf(count([T,tbf], size=100));
```

$$exactTr := .31112294248977312479\ 10^{79}$$

```
> estimTr:=nbEnt(resTrees[1],resTrees[2],100);
```

$$estimTr := .30831823414949327377\ 10^{79}$$

```
> exactTr/estimTr;
```

$$1.0090967968469874574$$

Forests

```
> exactFo:=evalf(count([F,fo], size=100));
```

$$exactFo := .13843759166925326460\ 10^{88}$$

```
> estimFo:=nbEnt(resForests[1], resForests[2], 100);
```

$$estimFo := .13692122170039683439\ 10^{88}$$

```
> exactFo/estimFo;
```

$$1.0110747621882491234$$

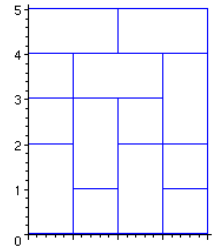
MonoDiMer.mws

Monomer-Dimer Tilings

F. Cazals, December 1997.

A fundamental problem in lattice statistics is the monomer-dimer problem, in which the sites of a regular lattice are covered by non-overlapping monomers and dimers, that is squares and pairs of neighbor squares. An example of such a tiling for a $m \times n$ chessboard with $m = 4$ and $n = 5$ is depicted below. The relative number of monomers and dimers can be arbitrary or may be constrained to some density p, and the problem can be generalized to any fixed dimension d. This model was introduced long ago to investigate the properties of adsorbed diatomic molecules on a crystal surface [Rob35], and its three-dimensional version occurs in the theory of mixtures of molecules of different sizes [Gug52] as well as the cell cluster theory of the liquid state [CoAl55]. Practically, most of the thermodynamic properties of these physical systems can be derived from the number of ways a given lattice can be covered, so that a considerable attention has been devoted to this counting question. For any fixed dimension d and any monomer density p, a *provably good polynomial time approximation algorithm* is exposed in [KenAl95]. But exact counting results are still unknown even in dimension two.



The goal of this worksheet is to show that these questions are amenable to an automated computer algebra treatment which goes from the specifications of the coverings constructions in terms of Combstruct grammars, to the asymptotics using rational generating functions and the numeric-symbolic method exposed in [GoSa96]. In particular we shall be interested in enumerating the tilings for a vertical strip of constant width m in terms of multivariate rational generating functions, from which the average number of pieces or the expected proportions of the three types of pieces in a random tiling are easily derived.

This will also enable us to establish a *provably good* sequence of upper and lower bounds for the connectivity constant $\tau = \lim_{n \to \infty} g(n)^{\left(\frac{1}{n^2}\right)}$ where $g(n)$ counts the number of ways to tile an $n \times n$ cheesboard.

But before getting started, we need to load the Combstruct library, as well as the piece of code doing the asymptotics of rational fractions:

```
> with(combstruct): with(gfun): read `ratasympt.mpl`;read `./gfsolve.mpl`;
```

A step-by-step example

We first observe that the number T_n counting the different tilings of a vertical slice of width 1 has a well known expression: since height n can be reached from height $n-1$ by adding a monomer and from height $n-2$ with a vertical dimer, we have $T_n = T_{n-1} + T_{n-2}$ with $T_0 = 1, T_1 = 1$, that is the Fibonacci recurrence. This can be checked directly with Combstruct:

```
> TGr:={T=Sequence(Union(monomer,dimer)),monomer=Z,dimer=Prod(Z,Z)};
```

$$TGr := \{T = \mathrm{Sequence}(\mathrm{Union}(monomer, dimer)), monomer = Z, dimer = \mathrm{Prod}(Z, Z)\}$$

And we can retrieve the corresponding rational Generating Function with gfsolve:

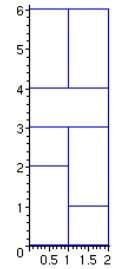
```
> gfsolve(TGr,unlabelled, z);
```

$$\{Z(z) = z, \mathrm{monomer}(z) = z, \mathrm{dimer}(z) = z^2, T(z) = -\frac{1}{-1 + z + z^2}\}$$

More interesting is the case m=2 which we examine examine now.

Tiling a slice of width $m = 2$

An example covering of a 2x6 lattice is depicted below. If we draw a horizontal line at height 0, it turns out that we do not `cut' any piece, which we encode by MM. At height 1, we cut the lefmost vertical dimer but just touch the monomer topmost side, which we encode by PM. At height 2 the leftmost P turned into an M since we now touch the dimer boundary, while on the right side we added a dimer and have a P. More generally, we shall *assign to each height of the construction containing a monomer or dimer boundary* a word of length m on the alphabet $\{M, P\}$ as follows: the i th digit of the word is P if an horizontal line at this particular height splits a vertical domino located in the i th column, and M otherwise. To summarize our example we therefore have MM, PM, MP, MM, MM,MM at the heights 0,1,2,3,4,6. (BTW, M stands for Minus and P for Plus!)



This encoding is not one-to-one since whenever we find two consecutive Ms, we do not know wether they are on top of two monomers or of a horizontal dimer. But it is sufficient to incrementally build all the possible configurations by recording the status of the *fringe*. If $m = 2$, the possible fringes are MM,MP,PM and each of them can be derived from a combination of the others and of monomers and dimers. For example, the configuration MM can be reached in 5 different ways by:

-stacking a horizontal dimer H, two monomers C,C, or two vertical dimers V,V on top of a MM configuration,

-adding a monomer C to the right column of a PM configuration or to the left one of a MP.

The remaining transitions follow similar rules. And in order to characterize the ordinate reached by the construction, we can mark the height reached by the bottommost piece whose elevation gain is 1 or 2 at each step of the construction. Putting everything together and associating the symbols H, V, C and S to the number of horizontal dimers, vertical dimers, monomers and the height yields the following Combstruct grammar:

```
> Gr2:={MM=Union(Epsilon,Prod(S, MM, H), Prod(S, MM, C,C),
Prod(S,PM, C),Prod(S,MP, C),Prod(S,S,MM,V,V)),
PM=Union(Prod(S,MM, V, C), Prod(S,MP,V)),
MP=Union(Prod(S,MM, C, V), Prod(S,PM,V)),
H=Epsilon,V=Epsilon,C=Epsilon,S=Atom}:
```

The ordinary generating functions can be derived by Combstruct[gfsolve]:

```
> GF2Sys:=gfsolve(Gr2, unlabelled, z, [[h,H], [v,V], [c,C]]);
```

$$GF2Sys := \{\mathrm{PM}(z,h,v,c) = \frac{z\,v\,c}{-z\,v+1+h\,z^2\,v-z\,h-z^2\,c^2\,v-z\,c^2+z^3\,v^3-z^2\,v^2},$$
$$\mathrm{MP}(z,h,v,c) = \frac{z\,v\,c}{-z\,v+1+h\,z^2\,v-z\,h-z^2\,c^2\,v-z\,c^2+z^3\,v^3-z^2\,v^2},$$
$$\mathrm{MM}(z,h,v,c) = -\frac{z\,v-1}{-z\,v+1+h\,z^2\,v-z\,h-z^2\,c^2\,v-z\,c^2+z^3\,v^3-z^2\,v^2}, \mathrm{C}(z,h,v,c) = c, \mathrm{H}(z,h,v,c) = h,$$
$$\mathrm{V}(z,h,v,c) = v, \mathrm{S}(z,h,v,c) = z\}$$

Furthermore we can isolate the GF corresponding to the MM fringes; the coefficient of $z^n h^i v^j c^l$ in this GF counts the number of ways to tile a chessboard $2 \times n$ with respectively j, k and l horizontal and vertical dimers and monomers:

```
> GF2:=subs(GF2Sys,MM(z,h,v,c));
```

$$GF2 := -\frac{z\,v-1}{-z\,v+1+h\,z^2\,v-z\,h-z^2\,c^2\,v-z\,c^2+z^3\,v^3-z^2\,v^2}$$

The number of configurations up to a given height independently of the number and kind of pieces used can be retrieved by erasing the dimers and monomers markers followed by a Taylor expansion:

```
> GF2h:=subs([h=1,v=1,c=1],GF2);series(GF2h,z=0,11);
```

$$GF2h := -\frac{z-1}{-3\,z+1-z^2+z^3}$$

$$1+2\,z+7\,z^2+22\,z^3+71\,z^4+228\,z^5+733\,z^6+2356\,z^7+7573\,z^8+24342\,z^9+78243\,z^{10}+O(z^{11})$$

This sequence does not appear in [Sloa95]. It can be checked that these values match those computed directly from the grammer by Combstruct[count]:

```
> seq(count([MM,Gr2], size=i), i=0..10);
```

$$1, 2, 7, 22, 71, 228, 733, 2356, 7573, 24342, 78243$$

Another way to compute the exact number of tilings for large values of n is through the recurrence equation satisfied by the Taylor coefficients and computed by gfun[diffeqtorec]:

```
> diffeqtorec(y(z)-GF2h,y(z),u(n));
```

$$\{u(n) - u(n+1) - 3\,u(n+2) + u(n+3), u(0) = 1, u(1) = 2, u(2) = 7\}$$

```
> p2:=rectoproc('',u(n)):
```

```
> for i from 1 to 10 do i,p2(i) od;
```

$$1, 2$$

$$2, 7$$

$$3, 22$$

$$4, 71$$

$$5, 228$$

$$6, 733$$

$$7,2356$$

$$8,7573$$

$$9,24342$$

$$10,78243$$

For example:

> **p2(1000);evalf(");**

```
81588806641560701690695240411230759515151275968774848493613419585169068227333558126428001382175\

```

$$.8158880664\ 10^{507}$$

But as we shall see now, asymptotic estimates can be derived much faster.

Asymptotic estimates of the number of tilings

We have just seen that the number of configurations is encoded by the rational generating function GF2h(z). An elegant way to access its Taylor coefficients is therefore through a full partial fraction decomposition yielding linear denominators:

> **fpf:=convert(GF2h,fullparfrac,z);**

$$fpf := \sum_{\_\alpha = \mathrm{RootOf}(-3\_Z + 1 - \_Z^2 + \_Z^3)} \frac{-\frac{8}{37}\_\alpha + \frac{7}{74}\_\alpha^2 - \frac{11}{74}}{z - \_\alpha}$$

The term in z^n comes from the contributions of the roots of $Z^3 - Z^2 - 3Z + 1 = 0$ in the expansion of

> **el:=op(1,fpf);**

$$el := \frac{-\frac{8}{37}\_\alpha + \frac{7}{74}\_\alpha^2 - \frac{11}{74}}{z - \_\alpha}$$

and since there are 3 singularities, the main asymptotic contribution comes from the one with smallest modulus:

> **fsolve(-3*_Z+1+_Z^3-_Z^2,_Z);**

$$-1.481194304, .3111078175, 2.170086487$$

> **root1:=RootOf(-3*_Z+1+_Z^3-_Z^2,.3111078175);**
root2:=RootOf(-3*_Z+1+_Z^3-_Z^2,-1.481194304);
root3:=RootOf(-3*_Z+1+_Z^3-_Z^2,2.170086487);

$$root1 := \mathrm{RootOf}(-3\_Z + 1 - \_Z^2 + \_Z^3, .3111078175)$$

$$root2 := \mathrm{RootOf}(-3\_Z + 1 - \_Z^2 + \_Z^3, -1.481194304)$$

$$root3 := \mathrm{RootOf}(-3\_Z + 1 - \_Z^2 + \_Z^3, 2.170086487)$$

On this example the dominant pole is clearly $.31$ so that the main contribution is encoded by:

```
> el1:=subs(_alpha=root1,el);
```

$$ell := \frac{-\frac{8}{37}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.3111078175)+\frac{7}{74}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.3111078175)^2-\frac{11}{74}}{z-\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.3111078175)}$$

```
> evalf(");
```

$$-\frac{.2067595751}{z-.3111078175}$$

Extracting the term in z^n in the previous expression produces the estimate:

```
> es2:=n->.2067595751*(1/.3111078175)^(n+1);
```

$$es2 := n \to .2067595751\,3.214319743^{(n+1)}$$

```
> seq(es2(i),i=1..10);
```

2.136209208, 6.866459431, 22.07099612, 70.94323855, 228.0342523, 732.9749992, 2356.016011, 7572.988780, 24342.00736, 78242.99481

To sum up, from the rational generating function we have:

-performed a full partial fraction decomposition,

-computed the singularities and sorted them by increasing moduli,

-extracted the contribution of the singularity with smallest modulus.

The key step consists in deciding which are the singularity (ies) with smallest modulus (i), and can be performed numerically using properties of polynomials with integer coefficients --see [GoSa96]. This is implemented by the **ratasympt** function --whose optional 4 th argument corresponds to the number of singularity layers the user wants to take into account. In particular to retrieve the main contribution, one writes:

```
> layer1:=ratasympt(GF2h,z,n,1);nbCfs1:=evalf(layer1);
```

$$layer1 := -\frac{-\frac{8}{37}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)+\frac{7}{74}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^2-\frac{11}{74}}{\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^{(n+1)}}$$

$$nbCfs1 := \frac{.2067595751}{.3111078175^{(n+1.)}}$$

And to take into account all the layers:

```
> layers:=ratasympt(GF2h,z,n);nbCfs:=evalf(layers);
```

$$layers := -\frac{-\frac{8}{37}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)+\frac{7}{74}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^2-\frac{11}{74}}{\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^{(n+1)}}-$$

$$\left(-\frac{8}{37}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,-1.48119430409)+\frac{7}{74}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,-1.48119430409)^2-\frac{11}{74}\right)^{(n+1)}\Big/\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,-1.48119430409)$$

$$-\left(-\frac{8}{37}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,2.17008648663)+\frac{7}{74}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,2.17008648663)^2-\frac{11}{74}\right)^{(n+1)}\Big/\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,2.17008648663)$$

$$nbCfs := \frac{.2067595751}{.3111078175^{(n+1.)}} - \frac{.3791441193}{(-1.481194304)^{(n+1.)}} + \frac{.1723845440}{2.170086487^{(n+1.)}}$$

We can check that the second approximation is more accurate:

> **evalf(seq(subs(n=i, layer1), i=1..10));**

2.136209208, 6.866459430, 22.07099611, 70.94323856, 228.0342523, 732.9749992, 2356.016012, 7572.988781, 24342.00735, 78242.99482

> **evalf(seq(subs(n=i, layers), i=1..10));**

2.000000000, 6.999999995, 21.99999998, 70.99999995, 227.9999998, 732.9999991, 2355.999997, 7572.999991, 24341.99996, 78242.99989

> **seq(p2(i),i=1..10);**

2, 7, 22, 71, 228, 733, 2356, 7573, 24342, 78243

The proportion of monomers and dimers

We now address the computation of the average number of pieces in a random tiling. From the multivariate generating function $GF2(z,h,v,c)$ we can merge the three types of pieces as follows:

> **GF2;stij:=subs([h=t,v=t,c=t], GF2);**

$$-\frac{z\,v-1}{-z\,v+1+h\,z^2\,v-z\,h-z^2\,c^2\,v-z\,c^2+z^3\,v^3-z^2\,v^2}$$

$$stij := -\frac{z\,t-1}{-2\,z\,t+1-z^2\,t^3-z\,t^2+z^3\,t^3}$$

The coefficient of $z^i\,t^j$ in $stij$ counts the number of tilings at height i with exactly j pieces of any type. To get the total number of pieces we just have to compute the derivative with respect to t and substitute $t=1$:

> **sstij:=subs(t=1, diff(stij,t));**

$$sstij := \frac{(z-1)\,(-4\,z-3\,z^2+3\,z^3)}{(-3\,z+1-z^2+z^3)^2}-\frac{z}{-3\,z+1-z^2+z^3}$$

For example, the total number of dimers and monomers used in all the configurations tilling the square $2x2$ is 20:

> **series(",z=0,5);**

$$3\,z+20\,z^2+94\,z^3+402\,z^4+O(z^5)$$

As before, we can compute an estimate of the total number of pieces in all the configurations at a given height:

```
> ratasympt(sstij,z,n,1);
```

$$\left(\frac{7}{74}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^2+\frac{5}{37}-\frac{13}{74}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)\right)^{(n+1)}\Big/\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^{(n+2)}-\left(-\frac{376}{1369}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)+\frac{551}{2738}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^2-\frac{1035}{2738}\right)\Big/\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^{(n+1)}-\frac{\frac{39}{74}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)-\frac{12}{37}\,\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^2+\frac{43}{74}}{\mathrm{RootOf}(-3\_Z+1-\_Z^2+\_Z^3,.311107817466)^{(n+1)}}$$

```
> nBDPiecesN:=evalf(");
```

$$nBDPiecesN := .08963668765\,\frac{n+1.}{.3111078175^{(n+2.)}}-\frac{.2696705336}{.3111078175^{(n+1.)}}$$

So that the average number of pieces is asymptotically equivalent to:

```
> avNbD:=expand(nBDPiecesN/nbCfs1);
```

$$avNbD := 1.393507288\,n+.08923621157$$

And the average number of pieces per layer in a tiling of height n is therefore:

```
> asympt("/n,n);
```

$$1.393507288+\frac{.08923621157}{n}$$

The number of occurrences and the proportions of dimers and monomers can be computed in the same way by erasing the irrelevant indeterminates:

```
> pieceProportion:=proc(MGF, keptPiece)
local forSubs, stij, sstij, nbp;

forSubs:={h=1,v=1,c=1} minus {keptPiece=1};
stij:=subs([op(forSubs)], MGF);
sstij:=subs(keptPiece=1, diff(stij,keptPiece));
nbp:=evalf(ratasympt(sstij,z,n,1));
asympt(nbp/nBDPiecesN,n,2)
end:
```

And we end up with:

```
> nbh:=pieceProportion(GF2,h);
nbv:=pieceProportion(GF2,v);
nbc:=pieceProportion(GF2,c);
```

$$nbh := .1483735155+O\left(\frac{1}{n}\right)$$

$$nbv := .2868539972+O\left(\frac{1}{n}\right)$$

$$nbc := .5647724884 + O\left(\frac{1}{n}\right)$$

Plotting routines archive

The figures above were plotted with the following functions:

```
> dominoH:=proc(x,y) [[x,y], [x+2,y], [x+2,y+1], [x,y+1], [x,y]] end:
dominoV:=proc(x,y) [[x,y], [x+1,y], [x+1,y+2], [x,y+2], [x,y]] end:
dominoC:=proc(x,y) [[x,y], [x+1,y], [x+1,y+1], [x,y+1], [x,y]] end:

> plot([dominoV(0,0), dominoC(0,2),dominoC(0,3),
dominoC(1,0),dominoV(1,1),dominoH(1,3),
dominoV(2,0),dominoC(2,2),
dominoC(3,0),dominoC(3,1),dominoV(3,2),
dominoH(0,4),dominoH(2,4)],scaling=constrained,color=blue);

>

> plot([dominoV(0,0), dominoC(1,0),dominoV(1,1),dominoC(0,2),dominoH(0,3),dominoV(0,4),dominoV(1,4)],
scaling=constrained,color=blue);
```

Automatic counting in a slice of width m

Computing the generating functions

We now show how to automate the previous computations for any integer m. The first task consists in generating the $2^m - 1$ words on the binary alphabet $\{M, P\}$, and this is easily done with a Combstruct grammar as follows:

```
> allMPWords:=proc(m::integer)
local i, MPGr, mps1, mps2, Pm;

MPGr:={AllMP=Sequence(MP), MP=Union(M,P), M=Atom, P=Atom};
mps1:=allstructs([AllMP, MPGr], size=m);
mps2:=convert(map(proc(x) cat(op(x)) end, mps1), set);
Pm:=cat(seq(P,i=1..m));
[op(mps2 minus {Pm})]
end:
```

For example if $m = 3$:

```
> allMPWords(3);
```

$$[PMM, MMP, MMM, PPM, MPP, MPM, PMP]$$

More interesting is the generation of the transitions between these words. Let $pattern$ be one of them and suppose we want to figure out all the fringes $pattern$ can be derived from. Suppose for example the i th letter of $pattern$ is a P ; this means that the i th letter of the fringe $pattern$ was derived from was M and that a vertical dimer was put on top of this M . Similar rules applies if the i th digit is a M . And since the letter of a given fringe are independent --except for two consecutive M s that may come from an horizontal dimer, it suffices to recursively examine the digits from left to right as follows:

```
> #--pattern is the fringe to be built, e.g. MMPMM
recComesFrom:=proc(pattern::string, idx::integer, prefix::string, mul::list, result::table)
local prodRes, m, Mm, Pm;

if (idx>length(pattern)) then #--stores the result into an indexed table
prodRes:=Prod(S,prefix, op(mul));
if not assigned(result[pattern]) then result[pattern]:={prodRes}
else result[pattern]:=result[pattern] union {prodRes}
fi
else
#--we examine the idx^{th} letter of the target
if substring(pattern,idx)=P then
recComesFrom(pattern, idx+1, cat(prefix,M), [op(mul), V], result)
else #target=M
recComesFrom(pattern, idx+1, cat(prefix,P), mul, result);
```

```
recComesFrom(pattern, idx+1, cat(prefix,M), [op(mul), C], result);

#--we may have MM=Prod(MM,H)
if (length(pattern)>idx) and (substring(pattern,idx+1)=M) then
recComesFrom(pattern, idx+2, cat(prefix,M,M), [op(mul), H], result)
fi
fi
fi;

#--some extra work for M^m
m:=length(pattern);
Mm:=cat(seq(M,i=1..m));
if pattern=Mm then
Pm:=cat(seq(P,i=1..m));
result[Mm]:=result[Mm] minus {Prod(S,Pm)}
union {Epsilon,Prod(S,S,Mm,seq(V,i=1..m))}
fi
end:
```

Here is the table for $m = 3$:

```
> table3:=table():for i in allMPWords(3) do recComesFrom(i, 1, ``, [], table3) od:print(table3);
```

```
table([
MPM = {Prod(S, PMP, V), Prod(S, MMM, C, V, C), Prod(S, MMP, C, V), Prod(S, PMM, V, C)}
MMM = {E, Prod(S, S, MMM, V, V, V), Prod(S, PPM, C), Prod(S, PMM, C, C), Prod(S, PMP, C), Prod(S, MPM, C, C),
Prod(S, MPP, C), Prod(S, PMM, H), Prod(S, MMP, C, C), Prod(S, MMM, C, C, C), Prod(S, MMM, C, H),
Prod(S, MMP, H), Prod(S, MMM, H, C)}
PMP = {Prod(S, MMM, V, C, V), Prod(S, MPM, V, V)}
PPM = {Prod(S, MMM, V, V, C), Prod(S, MMP, V, V)}
PMM = {Prod(S, MPP, V), Prod(S, MPM, V, C), Prod(S, MMM, V, C, C), Prod(S, MMM, V, H), Prod(S, MMP, V, C)}
MPP = {Prod(S, MMM, C, V, V), Prod(S, PMM, V, V)}
MMP = {Prod(S, PMM, C, V), Prod(S, MPM, C, V), Prod(S, MMM, C, C, V), Prod(S, MMM, H, V), Prod(S, PPM, V)}
])
```

The tables entries are merged as follows:

```
> setGrammarFromTable:=proc(aTable)
local aList, transitions, x;
aList:=op(op(aTable));#--[a={Prod(...), Prod(...)}, ...]
transitions:=seq(op(1,x)=Union(op(op(2,x))), x=aList);
{transitions} union {H=Epsilon,V=Epsilon,C=Epsilon,S=Atom}
end:
```

This yields the grammar:

```
> Gr3:=setGrammarFromTable(table3);
```

```
Gr3 := {MMP =
Union(Prod(S, PMM, C, V), Prod(S, MPM, C, V), Prod(S, MMM, C, C, V), Prod(S, MMM, H, V), Prod(S, PPM, V)), PMM
 = Union(Prod(S, MPP, V), Prod(S, MPM, V, C), Prod(S, MMM, V, C, C), Prod(S, MMM, V, H), Prod(S, MMP, V, C)),
MPP = Union(Prod(S, MMM, C, V, V), Prod(S, PMM, V, V)),
PMP = Union(Prod(S, MMM, V, C, V), Prod(S, MPM, V, V)),
PPM = Union(Prod(S, MMM, V, V, C), Prod(S, MMP, V, V)),
MPM = Union(Prod(S, PMP, V), Prod(S, MMM, C, V, C), Prod(S, MMP, C, V), Prod(S, PMM, V, C)), MMM = Union(E,
Prod(S, S, MMM, V, V, V), Prod(S, PPM, C), Prod(S, PMM, C, C), Prod(S, PMP, C), Prod(S, MPM, C, C),
Prod(S, MPP, C), Prod(S, PMM, H), Prod(S, MMP, C, C), Prod(S, MMM, C, C, C), Prod(S, MMM, C, H),
Prod(S, MMP, H), Prod(S, MMM, H, C)), H = E, V = E, C = E, S = Atom}
```

This is solved as usual:

```
> MM3GFSys:=gfsolve(Gr3, unlabelled, z, [[h,H], [v,V], [c,C]]);
MM3GF:=subs(MM3GFSys,MMM(z,h,v,c));
```

$$MM3GFSys := \{\mathrm{PMM}(z,h,v,c) = z\,v\,(-z\,c\,v^2 - c^2 - h + z^3 v^5 c + z^2 v^3 h - z\,c^3 v) \,/\, (-1 + 3 z^2 v^3 + 5 z^2 c^2 v^2$$

Putting everything together, we end up with a procedure which takes m as entry and returns the grammar:

```
> getGrammar:=proc(m::integer)
local i, MPTable;

MPTable:=table();
for i in allMPWords(m) do recComesFrom(i,1,``,[],MPTable) od;
setGrammarFromTable(MPTable)
end:

getMmGFun:=proc(m::integer)
local i, MPTable,Grm,MMmGFSys;

Grm:=getGrammar(m);
MMmGFSys:=gfsolve(Grm, unlabelled, z, [[h,H], [v,V], [c,C]]);
subs(MMmGFSys,cat(seq(M,i=1..m))(z,h,v,c));
end:
```

The computation to be carried out being quite heavy for 4-variate generating functions, we can alleviate it be keeping only the markers for the total number of pieces and the height:

```
> getMmGFunZ:=proc(m::integer)
local i, MPTable,Grm,GrmM,MMmGFSys;

MPTable:=table();
for i in allMPWords(m) do recComesFrom(i,1,``,[],MPTable) od;
Grm:=setGrammarFromTable(MPTable);
MMmGFSys:=gfsolve(Grm, unlabelled, z);
subs(MMmGFSys,cat(seq(M,i=1..m))(z));
end:
```

Asymptotics

We can now compute the generating functions for small values of m :

```
> gf:='gf':
```

```
> for i from 1 to 5 do i,time(assign(gf[i],getMmGFunZ(i))),gf[i] od;
```

$$1,\ .553,\ -\frac{1}{-1+z^2+z}$$

$$2,\ .554,\ -\frac{z-1}{-3z+1-z^2+z^3}$$

$$3,\ 3.593,\ -\frac{z^4+z^3-4z^2-z+1}{14z^2-1+4z+z^6-10z^4}$$

$$4,\ 16.026,\ -\frac{1-4z-15z^2+20z^3+z^7-11z^5-2z^6+10z^4}{z^9-z^8-23z^7+29z^6+91z^5-111z^4-41z^3+41z^2+9z-1}$$

$$5,\ 87.973,\ -(z^{18}+2z^{17}-45z^{16}-68z^{15}+654z^{14}+870z^{13}-3820z^{12}-4700z^{11}+9255z^{10}+9448z^9 - 11175z^8-7532z^7+6956z^6+1994z^5-1794z^4-88z^3+113z^2+6z-1) \Big/ (z^{20}+2z^{19}-65z^{18}-140z^{17} + 1281z^{16}+2538z^{15}-10366z^{14}-17604z^{13}+38553z^{12}+50158z^{11}-73623z^{10}-60482z^9+74665z^8 + 26564z^7-35106z^6-898z^5+4757z^4+16z^3-229z^2-14z+1)$$

For bigger ones, the grammar size, that is 2^m-1 , inherently yields a linear system $(2^m-1)\times(2^m-1)$ with large coefficients whose resolution is very much time consuming. So that for $6\le m$, a better alternative to running getMmGFunZ(m) is to retrieve the result in the archive below!

From these generating functions we can easily isolate the main contribution to the asymptotic equivalent with the ratasympt procedure:

```
> asGf:='asGf':
```

```
> for i from 1 to 6 do assign(asGf[i],ratasympt(gf[i],z,n,1)),evalf(asGf[i]) od;
```

$$\frac{.4472135955}{.6180339887^{(n+1.)}}$$

$$\frac{.2067595751}{.3111078175^{(n+1.)}}$$

$$\frac{.08874224656}{.1609769304^{(n+1.)}}$$

$$\frac{.03918944864}{.08292494619^{(n+1.)}}$$

$$\frac{.01715071699}{.04274350262^{(n+1.)}}$$

$$\frac{.007526396801}{.02203003755^{(n+1.)}}$$

It should be observed that these estimates correspond to huge expressions. For $m = 5$ for example:

> **asGf[5];**

$$-\left(-\frac{463179910739189981217205522586809325329255884518202099022030107003962817186192851341989823243890 As observed in [Fin97], if $g(n)$ denotes the number of tilings of a $n \times n$ chessboard, an interesting value for the physical applications is $\tau = \lim_{n \to \infty} g(n)^{\left(\frac{1}{n^2}\right)}$.

No exact expression for this limit is known, although the approximation 1.940215531 is generally agreed on. The first terms of the sequence can be computed from the previous approximations and are consistent with 1.94:

```
> nn:='nn':

> for i from 1 to 6 do assign(nn[i],coeff(series(gf[i],z=0,i+1),z,i)),evalf((nn[i])^(1/(i*i))) od;
```

1.

1.626576562

1.718906945

1.778412706

1.811142170

1.833198802

But more interesting is the following observation. Suppose for example n is a multiple of 6. To tile a $n \times n$

chessboard we can put side by side $\frac{n}{6}$ slices of width 6. In this case $\tau = \alpha^{\left(\frac{1}{6}\right)}$ with α the singularity of smallest modulus of the denominator of gf_6. If n is not a multiple of 6, it suffices to complete with at most 5 vertical stripes of width 1, but this does not change the limit. The interest in using as many slices of maximal width is to minimize the number of joints where the overlaps are not taken into account. The sequence $\left\{\alpha_i^{\left(\frac{1}{i}\right)}, i = 1..6\right\}$ therefore provides lower bounds for the constant τ. An upper bound can be obtained in the same way by having slices of width 6 overlap on a position, and the corresponding sequence is $\left\{\alpha_i^{\left(\frac{1}{i-1}\right)}, i = 2..6\right\}$.

```
> for i from 2 to 6 do i,(1/op(1,denom(evalf(asGf[i]))))^(1./i),(1/op(1,denom(evalf(asGf[i]))))^(1./(i-1)) od;
```

6, 1.888704987, 2.144850135

At last a trick we can use to try to guess the value of τ is Romberg's convergence acceleration. Let u_n be a sequence known to converge to l. If the rate of convergence is of the form $u_n = l + \frac{\alpha_1}{n} + O\left(\frac{1}{n^2}\right)$, then $2u_{2n} - u_n$ is $l + O\left(\frac{1}{n^2}\right)$. On our example, although the upper bound does not make sense due to too erroneous initial values, after a single step the lower bound gets close to the commonly accepted value:

```
> u[2]:=1.792852404:u[4]:=1.863497010:
v[2]:=3.214319743:v[4]:=2.293180643:
2*u[4]-u[2],2*v[4]-v[2];

u[3]:=1.838281935:u[6]:=1.888704987:
v[3]:=2.492402505:v[6]:=2.144850135:
2*u[6]-u[3],2*v[6]-v[3];
```

Conclusion

We showed that various parameters related to dimer-monomer tilings such as the average number of pieces or the relative

numbers of horizontal dimers and monomers in a random tiling of height n in a strip of width m can be computed very easily using Combstruct and ratasympt. More precisely Combstruct is used to define the grammars the tilings are derived from, and ratasympt is used to perform asymptotic expansions on rational fractions with rational coeficients.

About the number $g(n)$ of different tilings of a $n \times n$ chessboard, altough the method presented here is limited due to the exponential growth of the grammar describing these tilings, the very first terms computed provide *provably good upper and lower bounds* for the connectivity constant $g(n)^{\left(\frac{1}{n^2}\right)}$. More precisely:

Theorem . The connectvity constant for two dimensional monomer-dimer tilings satisfies

$$1.888 \leq \tau \quad \text{and} \quad \tau \leq 2.144$$

Structures arborescentes : problèmes algorithmiques et combinatoires

Cedric Chauve

Thèse de doctorat en informatique - LaBRI, Université Bordeaux I

Directeur : Serge Dulucq

Résumé. La première partie de ce mémoire est consacrée à l'énumération de diverses familles de structures arborescentes, en général selon le nombre de sommets. Les trois premiers chapitres sont consacrés à l'étude des arborescences de Cayley telles que la racine est inférieure à ses fils et des arborescences alternantes. La plupart de nos résultats sont prouvés bijectivement. Nous nous intéressons ensuite aux arborescences coloriées, et plus particulièrement à la formule d'inversion de séries formelles multivariées de Good-Lagrange. Nous donnons une nouvelle preuve bijective d'une variante de cette formule et utilisons cette preuve pour prouver combinatoirement diverses formules d'énumération de structures arborescentes et en déduire des algorithmes de génération aléatoire pour ces structures (notamment les cactus planaires). Nous concluons cette première partie par un chapitre consacré aux constellations : en combinant notre preuve de la formule de Good-Lagrange et la conjugaison d'arborescences (due à Bousquet-Mélou et Schaeffer), nous prouvons bijectivement une formule (nouvelle) pour l'énumération de constellations selon le nombre de sommets et de faces.

Dans la seconde partie, nous étudions le problème de la recherche de motifs dans une arborescence, en utilisant une structure de données classique pour les mots : l'arborescence des suffixes. Nous proposons notamment un algorithme de recherche de motifs dans une arborescence, basé sur un codage d'une arborescence par des mots et sur l'utilisation de l'arborescence des suffixes d'un de ces mots, qui semble avoir de bonnes propriétés expérimentales. Nous concluons en étendant la notion d'arborescence des suffixes des mots aux arborescences et en décrivant un algorithme de construction pour cette structure.

Mémoire :

Daniel Chavarría-Miranda, Alain Darte, Robert Fowler, and John Mellor-Crummey. On efficient parallelization of line-sweep computations. Research Report 2001-45, Laboratoire de l'Informatique du Parallélisme, École Normale Supériore de Lyon, November 2001. [ps], [pdf]

Multipartitioning is a strategy for partitioning multi-dimensional arrays among a collection of processors so that line-sweep computations can be performed efficiently. With multipartitioning, computations that require solving 1D recurrences along each dimension of a multidimensional array can be parallelized effectively. Previous techniques for multipartitioning yield efficient parallelizations over 3D domains only when the number of processors is a perfect square. This paper considers the general problem of computing optimal multipartitionings for *d*-dimensional data volumes on an arbitrary number of processors. We describe an algorithm that computes an optimal multipartitioning for this general case, which enables efficient parallelizations of line-sweep computations under arbitrary conditions. Finally, we describe a prototype implementation of generalized multipartitioning in the Rice dHPF compiler and performance results obtains when using ti to parallelize a line-sweep computation for different numbers of processors.

Keywords: loop parallelization, array mapping, generalized latin squares, High Performance Fortran.

1. INTRODUCTION

A composition of n consists of an ordered sequence of positive integers whose sum is n. A palindromic composition (or palindrome) is one for which the sequence reads the same forwards and backwards. We derive results for the number of "+" signs, summands, levels (a summand followed by itself), rises (a summand followed by a larger one), and drops (a summand followed by a smaller one) for both compositions and palindromes of n. This generalizes a paper by Alladi and Hoggatt [1], where summands were restricted to be only 1s and 2s.

Some results by Alladi and Hoggatt can be generalized to compositions with summands of all possible sizes, but the connections with the Fibonacci sequence are specific to compositions with 1s and 2s. However, we will establish a connection to the Jacobsthal sequence [8], which arises in many contexts: tilings of a 3 x n board [7], meets between subsets of a lattice [3], and alternating sign matrices [4], to name just a few. Alladi and Hoggatt also derived results about the number of times a

particular summand occurs in all compositions and palindromes of n, respectively. Generalizations of these results are given in [2].

In Section 2 we introduce the notation that will be used, methods to generate compositions and palindromes, as well as some easy results on the total numbers of compositions and palindromes, the numbers of "+" signs and the numbers of summands for both compositions and palindromes. We also derive the number of palindromes into i parts, which form an "enlarged" Pascal's triangle.

Section 3 contains the harder and more interesting results on the numbers of levels, rises and drops for compositions, as well as interesting connections between these quantities. In Section 4 we derive the corresponding results for palindromes. Unlike the case of compositions, we now have to distinguish between odd and even n. The final section contains generating functions for all quantities of interest.

2. NOTATION AND GENERAL RESULTS

We start with some notation and general results. Let

C_n, P_n	=	the number of compositions and palindromes of n, respectively
C_n^+, P_n^+	=	the number of "+" signs in all compositions and palindromes of n, respectively
C_n^{s}, P_n^{s}	=	the number of summands in all compositions and palindromes of n, respectively
$C_n(x)$	=	the number of compositions of n ending in x
$C_n(x, y)$	=	the number of compositions of n ending in $x + y$
r_n, l_n, d_n	=	the number of rises, levels, and drops in all compositions of n, respectively
$\tilde{r}_n$, $\tilde{l}_n$, $\tilde{d}_n$	=	the number of rises, levels, and drops in all palindromes of n, respectively.

We now look at ways of creating compositions and palindromes of n. Compositions of $n + 1$ can be created from those of n by either appending '+1' to the right

end of the composition or by increasing the rightmost summand by 1. This process is reversible and creates no duplicates, hence creates all compositions of $n+1$. To create all palindromes of n, combine a middle summand of size m (with the same parity as n, $0 \leq m \leq n$) with a composition of $\frac{n-m}{2}$ on the left and its mirror image on the right. Again, the process is reversible and creates no duplicates (see Lemma 2 of [2]). We will refer to these two methods as the *Composition Creation Method* (*CCM*) and the *Palindrome Creation Method* (*PCM*), respectively. Figure 1 illustrates the PCM.

6	7
1 4 1	1 5 1
2 2 2	2 3 2
1 1 2 1 1	1 1 3 1 1
3 3	3 1 3
1 2 2 1	1 2 1 2 1
2 1 1 2	2 1 1 1 2
1 1 1 1 1 1	1 1 1 1 1 1 1

Figure 1: Creating palindromes of $n = 6$ and $n = 7$

We can now state some basic results for the number of compositions, palindromes, "+" signs and summands.

Theorem 1 *1.* $C_n = 2^{n-1}$ *for* $n \geq 1$, $C_0 := 1$.

2. $P_{2k} = P_{2k+1} = 2^k$ *for* $k \geq 0$.

3. $C_n^+ = (n-1)2^{n-2}$ *for* $n \geq 1$, $C_0^+ := 0$.

4. $P_{2k+1}^+ = k2^k$ *for* $k \geq 0$, $P_{2k}^+ = (2k-1)2^{k-1}$ *for* $k \geq 1$, $P_0^+ := 0$.

5. $C_n^s = (n+1)2^{n-2}$, *for* $n \geq 1$, $C_0^s := 1$.

6. $P^s_{2k+1} = (k+1)2^k$ *for* $k \geq 0$, $P^s_{2k} = (2k+1)2^{k-1}$ *for* $k \geq 1$, $P^s_0 := 1$.

Proof: 1. The number of compositions of n into i parts is $\binom{n-1}{i-1}$ (see Section 1.4 in [5]). Thus, for $n \geq 1$,

$$C_n = \sum_{i=1}^{n} \binom{n-1}{i-1} = 2^{n-1}.$$

2. Using the PCM as illustrated in Figure 1, it is easy to see that

$$P_{2k} = P_{2k+1} = \sum_{i=0}^{k} C_i = 1 + (1 + 2 + \cdots + 2^{k-1}) = 2^k.$$

3. A composition of n with i summands has $i-1$ "+" signs. Thus, the number of "+" signs can be obtained by summing according to the number of summands in the composition:

$$\begin{aligned} C^+_n &= \sum_{i=1}^{n}(i-1)\cdot\binom{n-1}{i-1} = \sum_{i=2}^{n}(i-1)\cdot\frac{(n-1)!}{(i-1)!(n-i)!} \\ &= (n-1)\sum_{i=2}^{n}\binom{n-2}{i-2} = (n-1)\cdot 2^{n-2}. \end{aligned} \tag{1}$$

4. The number of "+" signs in a palindrome of $2k+1$ is twice the number of "+" signs in the associated composition, plus two "+" signs connecting the two compositions with the middle summand.

$$\begin{aligned} P^+_{2k+1} &= \sum_{i=1}^{k}(2C_i + 2C^+_i) = \sum_{i=1}^{k}(2\cdot 2^{i-1} + 2(i-1)2^{i-2}) \\ &= \sum_{i=1}^{k}(i+1)2^{i-1} = k2^k, \end{aligned}$$

where the last equality is easily proved by induction. For palindromes of $2k$, the same reasoning applies, except that there is only one "+" sign when a composition of k is combined with its mirror image. Thus,

$$\begin{aligned} P^+_{2k} &= \sum_{i=1}^{k-1}(2C_i + 2C^+_i) + (C_k + 2C^+_k) = \sum_{i=1}^{k}(2C_i + 2C^+_i) - C_k \\ &= k2^k - 2^{k-1} = (2k-1)2^{k-1}. \end{aligned}$$

5. & 6. The number of summands in a composition or palindrome is one more than the number of "+" signs, and the results follows by substituting the previous results into $C_n^S = C_n^+ + C_n$ and $P_n^S = P_n^+ + P_n$. □

Part 4 of Theorem 4 could have been proved similarly to part 1, using the number of palindromes of n into i parts, denoted by P_n^i. These numbers exhibit an interesting pattern which will be proved in Lemma 2.

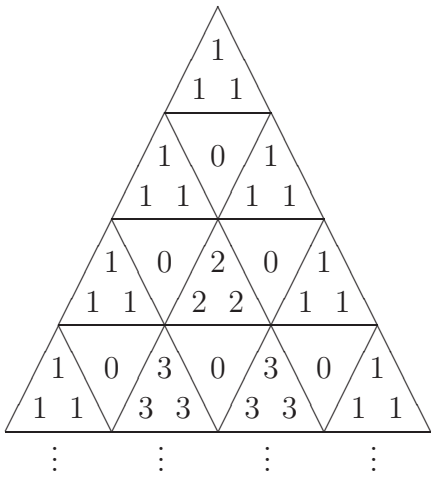

Figure 2: Palindromes with i parts

Lemma 2 $P_{2k-1}^{2j} = 0$ *and* $P_{2k-1}^{2j-1} = P_{2k}^{2j-1} = P_{2k}^{2j} = \binom{k-1}{j-1}$ *for* $j = 1, ..., k, k \geq 1$.

Proof: The first equality follows from the fact that a palindrome of an odd number n has to have an odd number of summands. For the other cases we will interpret the palindrome as a tiling where cuts are placed to create the parts. Since we want to create a palindrome, we look only at one of the two halves of the tiling and finish the other half as the mirror image. If $n = 2k-1$, to create $2j-1$ parts we select $\frac{(2j-1)-1}{2} = j-1$ positions out of the possible $\frac{(2k-1)-1}{2} = k-1$ cutting positions.

If $n = 2k$, then we need to distinguish between palindromes having an odd or even number of summands. If the number of summands is $2j-1$, then there cannot be a cut directly in the middle, so only $\frac{2k-2}{2} = k-1$ cutting positions are available, out of which we select $\frac{(2j-1)-1}{2} = j-1$. If the number of summands is $2j$, then the number of palindromes corresponds to the number of compositions of k, with half the number of summands ($=j$), which equals $\binom{k-1}{j-1}$ □

3. LEVELS, RISES AND DROPS FOR COMPOSITIONS

We now turn our attention to the harder and more interesting results for the numbers of levels, rises and drops in all compositions of n.

Theorem 3 *1.* $l_n = \frac{1}{36}\left((3n+1)2^n + 8(-1)^n\right)$ *for* $n \geq 1$ *and* $l_0 = 0$.

2. $r_n = d_n = \frac{1}{9}\left((3n-5)2^{n-2} - (-1)^n\right)$ *for* $n \geq 3$ *and* $r_0 = r_1 = r_2 = 0$.

Proof: 1. In order to obtain a recursion for the number of levels in the compositions of n, we look at the right end of the compositions, as this is where the CCM creates changes. Applying the CCM, the levels in the compositions of $n+1$ are twice those in the compositions of n, modified by any changes in the number of levels that occur at the right end. If a 1 is added, an additional level is created in all the compositions of n that end in 1, i.e., a total of $C_n(1) = \frac{1}{2}C_{n-1}$ additional levels. If the rightmost summand is increased by 1, one level is lost if the composition of n ends in $x+x$, and one additional level is created if the composition of n ends in $x+(x-1)$. Thus,

$$l_{2k+1} \;=\; 2l_{2k} + \frac{1}{2}C_{2k} - \sum_{x=1}^{k} C_{2k}(x,x) + \sum_{x=2}^{k} C_{2k}(x,x-1)$$

$$
\begin{aligned}
&= 2l_{2k} + 2^{2k-2} - \sum_{x=1}^{k} C_{2k-2x} + \sum_{x=2}^{k} C_{2k-(2x-1)} \\
&= 2l_{2k} + 2^{2k-2} - (2^{2k-3} + 2^{2k-5} + \cdots + 2^1 + 1) + (2^{2k-4} + \cdots + 1) \\
&= 2l_{2k} + (2^{2k-2} - 2^{2k-3} + 2^{2k-4} - \cdots - 2 + 1) - 1 \\
&= 2l_{2k} + \frac{2^{2k-1} - 2}{3},
\end{aligned}
$$

while

$$
\begin{aligned}
l_{2k} &= 2l_{2k-1} + \frac{1}{2}C_{2k-1} - \sum_{x=1}^{k-1} C_{2k-1}(x,x) + \sum_{x=2}^{k} C_{2k-1}(x,x-1) \\
&= 2l_{2k-1} + 2^{2k-3} - (2^{2k-4} + 2^{2k-6} + \cdots + 2^2 + 1) + (2^{2k-5} + \cdots + 2^1 + 1) \\
&= 2l_{2k-1} + (2^{2k-3} - 2^{2k-4} + 2^{2k-5} - \cdots + 2 - 1) + 1 \\
&= 2l_{2k-1} + \frac{2^{2k-2} + 2}{3}.
\end{aligned}
$$

Altogether, for all $n \geq 2$,

$$
l_n = 2l_{n-1} + \tfrac{2^{n-2}+2(-1)^n}{3}. \tag{2}
$$

The homogeneous and particular solutions, $l_n^{(h)}$ and $l_n^{(p)}$, respectively, are given by

$$
l_n^{(h)} = c \cdot 2^n \quad \text{and} \quad l_n^{(p)} = A \cdot (-1)^n + B \cdot n2^n.
$$

Substituting $l_n^{(p)}$ into Eq. (2) and comparing the coefficients for powers of 2 and -1, respectively, yields $A = \frac{2}{9}$ and $B = \frac{1}{12}$. Substituting $l_n = l_n^{(h)} + l_n^{(p)} = c \cdot 2^n + \frac{2}{9}(-1)^n + \frac{1}{12} \cdot n \cdot 2^n$ into Eq. (2) and using the initial condition $l_2 = 1$ yields $c = \frac{1}{36}$, giving the equation for l_n for $n \geq 3$. (Actually, the formula also holds for $n \geq 1$).

2. It is easy to see that $r_n = d_n$, since for each nonpalindromic composition there is one which has the summands in reverse order. For palindromic compositions, the symmetry matches each rise in the first half with a drop in the second half and vice versa. Since $C_n^+ = r_n + l_n + d_n$, it follows that $r_n = \frac{C_n^+ - l_n}{2}$. □

Table 1 shows values for the quantities of interest. In Theorem 4 we will establish the patterns suggested in this table.

n	1	2	3	4	5	6	7	8	9	10	11	12
C_n^+	0	1	4	12	32	80	192	448	1024	2304	5120	11264
l_n	0	1	2	6	14	34	78	178	398	882	1934	4210
$r_n = d_n$	0	0	1	3	9	23	57	135	313	711	1593	3527

Table 1: Values for C_n^+, l_n and r_n

Theorem 4 *1.* $r_{n+1} = r_n + l_n$ *and more generally,* $r_n = \sum_{i=2}^{n-1} l_i$ *for* $n \geq 3$.

2. $C_n^+ = r_n + r_{n+1}$.

3. $C_n^+ = 4 \cdot (l_{n-1} + l_{n-2}) = 4 \cdot (r_n - r_{n-2})$.

4. $l_n - r_n = a_{n-1}$, *where* a_n *is the* n^{th} *term of the Jacobsthal sequence.*

Proof: 1. The first equation follows by substituting the formulas of Theorem 3 for r_n and l_n and collecting terms. The general formula follows by induction.

2. This follows from part 1, since $C_n^+ = r_n + l_n + d_n$ and $r_n = d_n$.

3. The first equality follows by substituting the formula in Theorem 3 for l_{n-1} and l_{n-2}. The second equality follows from part 1.

4. The sequence of values for $f_n = l_n - r_n$ is given by $1, 1, 3, 5, 11, 21, 43, \ldots$. This sequence satisfies several recurrence relations, for example $f_n = 2f_{n-1} + (-1)^n$ or $f_n = 2^n - f_{n-1}$, both of which can be verified by substituting the formulas given in Theorem 3. These recursions define the Jacobsthal sequence (A001045 in [8]), and comparison of the initial values shows that $f_n = a_{n-1}$. □

4. LEVELS, RISES AND DROPS FOR PALINDROMES

We now look at the numbers of levels, rises and drops for palindromes. Unlike the case for compositions, there is no single formula for the number of levels, rises and drops, respectively. Here we have to distinguish between odd and even values of n, as well as look at the remainder of k when divided by 3.

Theorem 5 *For $k \geq 1$,*

1. $\tilde{l}_{2k} = \frac{2}{9}(-1)^k + 2^k\left(\frac{53}{126} + \frac{k}{3}\right) + \begin{cases} \frac{6}{7} & k \equiv 0 \ mod\ (3) \\ \frac{-2}{7} & k \equiv 1 \ mod\ (3) \\ \frac{-4}{7} & k \equiv 2 \ mod\ (3) \end{cases}$

$\tilde{l}_{2k+1} = \frac{2}{9}(-1)^k + 2^k\left(\frac{22}{63} + \frac{k}{3}\right) + \begin{cases} \frac{-4}{7} & k \equiv 0 \ mod\ (3) \\ \frac{6}{7} & k \equiv 1 \ mod\ (3) \\ \frac{-2}{7} & k \equiv 2 \ mod\ (3) \end{cases}$

2. $\tilde{r}_{2k} = \tilde{d}_{2k} = -\frac{1}{9}(-1)^k - 2^{k-1}\left(\frac{58}{63} - \frac{2k}{3}\right) + \begin{cases} \frac{-3}{7} & k \equiv 0 \ mod\ (3) \\ \frac{1}{7} & k \equiv 1 \ mod\ (3) \\ \frac{2}{7} & k \equiv 2 \ mod\ (3) \end{cases}$

$\tilde{r}_{2k+1} = \tilde{d}_{2k+1} = -\frac{1}{9}(-1)^k - 2^{k-1}\left(\frac{22}{63} - \frac{2k}{3}\right) + \begin{cases} \frac{2}{7} & k \equiv 0 \ mod\ (3) \\ \frac{-3}{7} & k \equiv 1 \ mod\ (3) \\ \frac{1}{7} & k \equiv 2 \ mod\ (3) \end{cases}$

Proof: We use the PCM, where a middle summand $m = 2l$ or $m = 2l + 1$ ($l \geq 0$) is combined with a composition of $k - l$ and its mirror image, to create a palindrome of $n = 2k$ or $n = 2k + 1$, respectively. The number of levels in the palindrome is twice the number of levels of the composition, plus any additional levels created when the compositions are joined with the middle summand.

We will first look at the case where n (and thus m) is even. If $l = m = 0$, a composition of k is joined with its mirror image, and we get only one additional level. If $l > 0$, then we get two additional levels for a composition ending in m, for $m = 2l \leq k - l$. Thus,

$$\tilde{l}_{2k} \;=\; 2 \cdot \sum_{l=0}^{k} l_{k-l} + C_k + 2 \cdot \sum_{l=1}^{\lfloor k/3 \rfloor} C_{k-l}(2l) = s_1 + 2^{k-1} + s_2. \qquad (3)$$

Since $l_0 = l_1 = 0$, the first summand reduces to

$$\begin{aligned} s_1 &= \frac{1}{18} \cdot \sum_{i=2}^{k} \left\{ (3i+1)2^i + 8(-1)^i \right\} = \frac{2}{9} \sum_{i=2}^{k} 2^{i-2} + \frac{1}{3} \sum_{i=2}^{k} i \cdot 2^{i-1} + \frac{4}{9} \sum_{i=0}^{k} (-1)^i \\ &= \frac{2}{9} \cdot (2^{k-1} - 1) + \frac{1}{3} \left(\frac{\mathrm{d}}{\mathrm{dx}} \sum_{i=2}^{k} x^i \right) \Bigg|_{x=2} + \frac{2}{9}((-1)^k + 1) \\ &= \frac{1}{9} 2^k + \frac{1}{3} \left\{ (k+1)2^k - 2^{k+1} \right\} + \frac{2}{9}(-1)^k = \frac{2}{9}(-1)^k + \left(\frac{k}{3} - \frac{2}{9} \right) 2^k. \end{aligned} \tag{4}$$

To compute s_2, note that $C_n(i) = C_{n-1}(i-1) = ... = C_{n-i+1}(1) = \frac{1}{2} C_{n-i+1} = 2^{n-i-1}$ for $i < n$ and $C_n(n) = 1$. The latter case only occurs when $k = 3l$. Let $k := 3j + r$, where $r = 1, 2, 3$. (This somewhat unconventional definition allows for a unified proof.) Thus, with $\mathcal{I}_A$ denoting the indicator function of A,

$$\begin{aligned} s_2 &= 2 \cdot \sum_{l=1}^{\lfloor k/3 \rfloor} C_{k-l}(2l) = 2 \cdot \sum_{l=1}^{j} 2^{3j+r-l-2l-1} + 2 \cdot \mathcal{I}_{\{r=3\}} \\ &= 2^r \cdot \sum_{l=1}^{j} \left(2^3 \right)^{j-l} + 2 \cdot \mathcal{I}_{\{r=3\}} = 2^r \left(\frac{(2^3)^j - 1}{7} \right) + 2 \cdot \mathcal{I}_{\{r=3\}} \\ &= \frac{2^k - 2^r}{7} + 2 \cdot \mathcal{I}_{\{r=3\}} = \begin{cases} \frac{2^k+6}{7} & k \equiv 0 \bmod (3) \\ \frac{2^k-2^r}{7} & k \equiv r \bmod (3), \text{ for } r = 1, 2. \end{cases} \end{aligned} \tag{5}$$

Combining Equations (3), (4) and (5) and simplifying gives the result for $\tilde{l}_{2k}$.

For $n = 2k + 1$, we make a similar argument. Again, each palindrome has twice the number of levels of the associated composition, and we get two additional levels whenever the composition ends in m, for $m = 2l + 1 \leq k - l$. Thus,

$$\tilde{l}_{2k+1} = 2 \cdot \sum_{l=0}^{k} l_{k-l} + 2 \cdot \sum_{l=0}^{\lfloor (k-1)/3 \rfloor} C_{k-l}(2l+1) =: s_1 + s_3.$$

With an argument similar to that for s_2,we derive

$$s_3 = \begin{cases} \frac{2^{k+2}-4}{7} & k \equiv 0 \bmod (3) \\ \frac{2^{k+2}+6}{7} & k \equiv 1 \bmod (3) \\ \frac{2^{k+2}-2}{7} & k \equiv 2 \bmod (3) \end{cases} \tag{6}$$

Combining Equations (4) and (6) and simplifying gives the result for $\tilde{l}_{2k+1}$. Finally, the results for $\tilde{r}_n$ and $\tilde{d}_n$ follow from the fact that $\tilde{r}_n = \tilde{d}_n = \frac{P_n^+ - \tilde{l}_n}{2}$. □

5. GENERATING FUNCTIONS

Let $G_{a_n}(x) = \sum_{k=0}^{\infty} a_k x^k$ be the generating function of the sequence $\{a_n\}_0^\infty$. We will give the generating functions for all the quantities of interest.

Theorem 6 *1.* $G_{C_n}(x) = \frac{1-x}{1-2x}$ *and* $G_{P_n}(x) = \frac{1+x}{1-2x^2}$.

2. $G_{C_n^+}(x) = \frac{x^2}{(1-2x)^2}$ *and* $G_{P_n^+}(x) = \frac{x^2+2x^3+2x^4}{(1-2x^2)^2}$.

3. $G_{C_n^S}(x) = \frac{1-3x+3x^2}{(1-2x)^2}$ *and* $G_{P_n^S}(x) = \frac{1+x-x^2+2x^4}{(1-2x^2)^2}$.

4. $G_{l_n}(x) = \frac{x^2(1-x)}{(1+x)(1-2x)^2}$ *and* $G_{r_n}(x) = G_{d_n}(x) = \frac{x^3}{(1+x)(1-2x)^2}$.

5. $G_{\tilde{l}_n}(x) = \frac{x^2(1+3x+4x^2+x^3-x^4-4x^5-6x^6)}{(1+x^2)(1+x+x^2)(1-2x^2)^2}$ *and*
$G_{\tilde{r}_n}(x) = G_{\tilde{d}_n}(x) = \frac{x^4(1+3x+4x^2+4x^3+4x^4)}{(1+x^2)(1+x+x^2)(1-2x^2)^2}$.

Proof: 1. & 2. The generating functions for $\{C_n\}_0^\infty$, $\{P_n\}_0^\infty$ and $\{C_n^+\}_0^\infty$ are straightforward using the definition and the formulas of Theorem 1. We derive $G_{P_n^+}(x)$, as it needs to take into account the two different formulas for odd and even n. From Theorem 1, we get

$$\begin{aligned} G_{P_n^+}(x) &= \sum_{k=1}^{\infty} P_{2k-1}^+ x^{2k-1} + \sum_{k=1}^{\infty} P_{2k}^+ x^{2k} \\ &= \sum_{k=1}^{\infty} (k-1)2^{k-1}x^{2k-1} + \sum_{k=1}^{\infty} (2k-1)2^{k-1}x^{2k} \end{aligned} \tag{7}$$

Separating each sum in Eq. (7) into terms with and without a factor of k, and recombining like terms across sums leads to

$$\begin{aligned} G_{P_n^+}(x) &= \frac{1+2x}{4} \sum_{k=1}^{\infty} 4xk(2x^2)^{k-1} - (x+x^2) \sum_{k=1}^{\infty} (2x^2)^{k-1} \\ &= \frac{1+2x}{4} \cdot \frac{\mathrm{d}}{\mathrm{dx}} \left(\frac{1}{1-2x^2}\right) - \frac{x+x^2}{1-2x^2} = \frac{x^2+2x^3+2x^4}{(1-2x^2)^2}. \end{aligned}$$

3. Since $C_n^{\mathrm{S}} = C_n + C_n^+$, $G_{C_n^{\mathrm{S}}}(x) = G_{C_n}(x) + G_{C_n^+}(x)$; likewise for $G_{P_n^{\mathrm{S}}}(x)$.

4. The generating function for l_n can be easily computed using Mathematica or Maple, using either the recursive or the explicit description. The relevant Mathematica commands are

```
<<DiscreteMath‘RSolve‘

GeneratingFunction[{a[n+1]==2a[n]+(2/3)*2^(n-2)+(-2/3)*(-1)^(n-2),
   a[0]==0,a[1]==0},a[n],n,z][[1,1]]

PowerSum[((1/36) + (n/12))*2^n + (2/9)*(-1)^n,{z,n,1}]
```

Furthermore, $G_{r_n}(x) = G_{d_n}(x) = \frac{1}{2}\left(G_{C_n^+}(x) - G_{l_n}(x)\right)$, since $r_n = d_n = \frac{C_n^+ - l_n}{2}$.

5. In this case we have six different formulas for $\tilde{l}_n$, depending on the remainder of n with respect to 6. Let $G_i(x)$ denote the generating function of $\left\{\tilde{l}_{6k+i}\right\}_{k=0}^{\infty}$. Then, using the definition of the generating function and separating the sum according to the remainder (similar to the computation in part 2), we get

$$G_{\tilde{l}_n}(x) = G_0(x^6) + x \cdot G_1(x^6) + x^2 \cdot G_2(x^6) + \cdots + x^5 \cdot G_5(x^6).$$

The functions $G_i(x)$ and the resulting generating function $G_{\tilde{l}_n}(x)$ are derived using the following Mathematica commands:

```
<<DiscreteMath‘RSolve‘

g0[z_]=PowerSum[(1/126)((126(n)+53)* 2^(3n)+108+28(-1)^(n)),{z,n,1}]

g1[z_]=PowerSum[(1/63)((63n+22)* 2^(3n)-36+14(-1)^n),{z,n,1}]

g2[z_]=PowerSum[(1/63)((126n+95)* 2^(3n)-18-14(-1)^n),{z,n,0}]

g3[z_]=PowerSum[(1/63)((126n+86)* 2^(3n)+54-14(-1)^n),{z,n,0}]

g4[z_]=PowerSum[(1/63)((252n+274)* 2^(3n)-36+14(-1)^n),{z,n,0}]

g5[z_]=PowerSum[(1/63)((252n+256)* 2^(3n)-18+14(-1)^n),{z,n,0}]

genfun[z]:= g0[z^6]+z g1[z^6]+z^2 g2[z^6]+z^3 g3[z^6]+z^4 g4[z^6]+z^5 g5[z^6]
```

Finally, $G_{\tilde{r}_n}(x) = G_{\tilde{d}_n}(x) = \frac{1}{2}\left(G_{P_n^+}(x) - G_{\tilde{l}_n}(x)\right)$, since $\tilde{r}_n = \tilde{d}_n = \frac{P_n^+ - \tilde{l}_n}{2}$. □

Abstract

A composition of a positive integer n consists of an ordered sequence of positive integers whose sum is n. A palindromic composition is one for which the sequence is the same from left to right as from right to left. This paper shows various ways of generating all palindromic compositions, counts the number of times each integer appears as a summand among all the palindromic compositions of n, and describes several patterns among the numbers generated in the process of enumeration.

Keywords: Compositions, palindromes, tilings.
A.M.S. Classification Number: 05A99

1 Introduction

A *composition* of a positive integer n consists of an ordered sequence of positive integers whose sum is n. It is well-known that there are 2^{n-1} compositions of n (see for example [3]). A *palindromic composition* is one for which the sequence is the same from left to right as from right to left. For the remainder of this paper we will refer to such compositions by the short-hand term *palindrome*. Compositions can also be thought of as tilings of a 1 x n board, with 1 x k tiles of integer length k, $1 \leq k \leq n$. In this setting, a composition of n with j summands or parts is created by making $j-1$ vertical cuts on the 1 x n board. This viewpoint allows for easy combinatorial proofs of certain facts and will be used when advantageous.

The question concerning the number of times a particular summand k occurs in all compositions of n has been answered by one of the authors in [3]. Furthermore, Chinn et al. showed that the number of times k appears as a summand in compositions of n is equal to the number of times $k+1$ appears in compositions of $n+1$. Alladi and Hoggatt enumerated the number of times the summands 1 and 2 occur in all compositions and palindromes containing only these two summands [1]. Grimaldi has investigated compositions with odd summands, and expressed the number of times a 1 occurs in all compositions of n with odd summands as a specific linear combination of Lucas and Fibonacci numbers [4]. Furthermore, the occurrence of the number $2k+1$ in all compositions of n with odd summands equals the number of 1s in all compositions of $n-2k$ with odd summands. We will show a somewhat similar result for palindromes, namely that the number of times the summand k occurs in a palindrome of a specific size can sometimes be reduced to the number of 1s in all palindromes of a certain smaller size. In addition, the sequence of values of occurences of 1s in palindromes of even and odd values of n, respectively, matches known sequences (A057711 and A001792 in [7]).

Section 2 contains notation and a few basic observations that will be used throughout the rest of the paper. In Section 3, we describe two methods of generating palindromes, and give a formula for the total number of palindromes. Section 4 contains explicit formulas for $R_n(k)$, the number of times the number k occurs as a summand among all the palindromes of n. We conclude in Sections 5 and 6 by discussing the various patterns found within the table of values for $R_n(k)$, and give combinatorial or analytical proofs for these patterns.

2 Notation and General Observations

Before deriving specific results, we will define our notation, and state a remark which will be used in later sections. Let

C_n = the number of compositions of n, where $C_0 := 1$

P_n = the number of palindromes of n, where $P_0 := 1$

$R_n(k)$ = the number of repetitions of the integer k in all palindromes of n.

Remark 1 *1. A palindrome of an odd integer n always has an odd number of summands, and the middle summand must be an odd integer.*

2. A palindrome of an even integer n can have an odd number of summands with an even summand in the center or an even number of summands and no middle summand.

We will refer to a palindrome of the latter type as having an *even split*.

3 Generating Palindromes

Palindromes can be created in a number of ways, each of which is useful for some of the proofs in this section. In addition, these different creation methods illustrate the multiple ways of thinking about palindromes. The first method creates palindromes using compositions, whereas the second method creates palindromes recursively. We start by describing the explicit method of palindrome creation, which consists of combining all possible middle summands with a composition of an appropriate positive integer to the left, and with its mirror image on the right. This method will be referred to as the *Explicit Palindrome Creation Method* (EPCM):

> To create a palindrome of $n = 2k$ ($n = 2k + 1$), combine the middle summand $m = 2l$ ($m = 2l + 1$), for $l = 0, ..., k$, with a composition of $\frac{n-m}{2} = k - l$ on the left and its mirror image on the right. For those palindromes that result from $l = 0$, delete the middle summand of 0.

The second method creates palindromes recursively; to seed this method, we define a palindrome of $n = 0$, namely 0. We will refer to this method as

the *Recursive Palindrome Creation Method* (RPCM):

> Before applying the algorithm, create a middle summand for palindromes with an even number of summands by replacing the "+" sign in the center of the palindrome by "+0+". (This artifice simplifies the algorithm and allows the treatment of palindromes having an odd and even number of summands, respectively, using the same instructions.)
>
> 1. **Creating palindromes of $2k+1$ from those of $2k$**: Increase the middle summand by 1.
> 2. **Creating palindromes of $2k+2$ from those of $2k$**: Create one palindrome by increasing the middle summand by 2, and another one by replacing the middle summand m by $\left(\frac{m}{2}+1\right)+\left(\frac{m}{2}+1\right)$.

Lemma 2 *Both the EPCM and the RPCM create all palindromes of n for $n \geq 1$.*

Proof: Clearly, the EPCM creates all palindromes of n, without duplicates or omissions. For the RPCM, we need to work a little harder to show that indeed no duplicates are created, and also that all possible palindromes are created by the algorithm. For easier readability we will refer to the middle summand(s) of a palindrome of n as m_n. Furthermore, we will only concentrate on the middle summands, as all other summands remain unchanged when creating the palindromes of $2k+1$ and $2k+2$, respectively, from those of $2k$.

• Palindromes of $2k+1$: Every palindrome of $2k+1$ with middle summand m_{2k+1} corresponds to a palindrome of $2k$ whose middle summand is $m_{2k+1}-1$. (If $m_{2k+1}=1$, then the corresponding palindrome of $2k$ is the one where the dummy 0 summand is deleted.)

• Palindromes of $2k+2$: No duplicates are created as distinct palindromes of $2k$ lead to distinct palindromes of $2k+2$ for each instruction. Furthermore, the first instruction creates palindromes with an odd number of summands, whereas the second instruction creates palindromes with an even number of summands. Thus, if a palindrome of $2k+2$ has an odd number of summands, then it is created from the palindrome of $2k$ whose middle summand is $m_{2k+2}-2$. If, on the other hand, the palindrome of $2k+2$ has an even number of summands, then it is created from the palindrome of $2k$ whose middle summand is $2\cdot(m_{2k+2}-1)$. (If $m_{2k}=0$, then delete the dummy 0 summand.)

• Initial conditions: This algorithm creates the one palindrome of $n = 1$, namely 1, and the two palindromes of $n = 2$, namely 2 and $1 + 1$, from the initial condition. □

The recursive method immediately shows some of the structure within the palindromes.

Remark 3 *1. The first rule of the RPCM demonstrates that half of the palindromes of an odd integer n have a 1 as the middle summand (since half of the palindromes of $n - 1$ had a dummy zero summand).*

2. The second rule of the RPCM illustrates that half of all the palindromes of an even integer n have an even number of summands.

Using either the RPCM or the EPCM, we can easily determine the total number of palindromes of n.

Theorem 4 *For $k \geq 0$, $P_{2k} = P_{2k+1} = 2^k$, where $P_0 := 1$.*

Proof: In the RPCM, the number of palindromes stays the same when creating the palindromes of $2k + 1$ from those of $2k$, and the number of palindromes doubles when creating the palindromes of $2k + 2$. Thus,

$$P_{2k+1} = P_{2k} \quad \text{and} \quad P_{2k} = 2P_{2(k-1)} = 2^2 P_{2(k-2)} = ... = 2^{k-1} P_2 = 2^k$$

which completes the proof. □

4 The Frequency of k in Palindromes of n

The question regarding how many times the summand k appears among all the palindromes of n is motivated by the comparable question regarding compositions as explored in [3]. The following theorem is proved in that paper.

Theorem 5 *The number of repetitions of the integer k in all of the compositions of n is $(n - k + 3) \cdot 2^{n-k-2}$ for $n > k$ and 1 for $n = k$.*

The following theorem states the corresponding result for palindromes. We need to consider different cases according to whether or not n and k have the same parity, and also according to the relative size of n and k. In particular, we get a different pattern when n is too small to accommodate two summands of k within a single palindrome.

Theorem 6 *For $n < k$, $R_n(k) = 0$. If n and k have different parity, then*

$$R_n(k) = \begin{cases} 0 & k < n < 2k \\ 2^{\lfloor n/2 \rfloor - k}(2 + \lfloor \frac{n}{2} \rfloor - k) & n \geq 2k \end{cases} .$$

If n and k have the same parity, then

$$R_n(k) = \begin{cases} 1 & n = k \\ 2^{(n-k)/2-1} & k < n < 2k \\ 2^{\lfloor n/2 \rfloor - k}(2 + \lfloor \frac{n}{2} \rfloor - k + 2^{\lfloor \frac{k+1}{2} - 1 \rfloor}) & n \geq 2k \end{cases} .$$

Proof: Let $n = 2i$ or $n = 2i + 1$, and $k = 2j$ or $2j + 1$, respectively. For $n < k$, the palindrome cannot contain the summand k. If $n = k$, then there is exactly one palindrome that contains the summand k, namely just k by itself. If $k < n < 2k$, then the summand k can occur at most once in any palindrome, and hence has to occur in the center. This is only possible if n and k have the same parity (by Remark 1), which implies that $R_n(k) = 0$ if n and k have different parity. If they have the same parity, then the palindromes that have the summand k in the center can be created using the explicit method. Thus, the number of repetitions of k is given by the number of compositions of size $\left(\frac{n-k}{2}\right) = i - j$, which gives $R_n(k) = 2^{i-j-1}$.

If $n \geq 2k$, then the summand k can occur in the center, or in symmetric pairs at other positions within the palindrome. To count the different cases, we will think of the palindrome as a 1 x n board as illustrated in Figure 1.

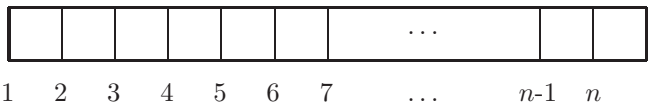

Figure 1: Palindrome as a 1 x n board

We will count according to whether a tile of length k starts at position s, for $1 \leq s \leq i - k + 1$, as we will only look at the left half of the tiling. Tilings that contain a tile of size k starting at position s can be created by combining the tile of size k with any tiling (i.e., composition)

of length $s-1$ on the left, and a symmetric tiling (i.e., palindrome) of length $n-2(s-1)-2k$ on the right, and then completing the remainder of the tiling symmetrically. If n and k have the same parity, we also get occurrences of k in the center.

We look first at the case where n and k have different parity:

$$\begin{aligned} R_n(k) &= 2 \cdot \sum_{s=1}^{i-k+1} C_{s-1} \cdot P_{n-2(s+k-1)} = 2 \cdot \sum_{s=1}^{i-k+1} C_{s-1} \cdot P_{2(i-s-k+1)} \\ &= 2 \cdot C_0 \cdot P_{2(i-k)} + 2 \cdot \sum_{s=2}^{i-k+1} 2^{s-2} \cdot 2^{i-s-k+1} \\ &= 2 \cdot 1 \cdot 2^{i-k} + 2 \cdot 2^{i-k-1} \cdot (i-k) = 2^{i-k}(2+i-k) \end{aligned} \tag{1}$$

which gives the formula for $R_n(k)$ for $n \geq 2k$ where n and k have different parity.

Lastly, we consider the case where n and k have the same parity and $n \geq 2k$. In this case, the number of occurrences of k is given by off-center ones (as counted in Eq. (1)), plus those that occur in the center. The latter is given by $C_{i-j} = 2^{i-j-1}$ (see the case $k < n < 2k$). Altogether,

$$\begin{aligned} R_n(k) &= 2^{i-k}(2+i-k) + 2^{i-j-1} \\ &= \begin{cases} 2^{i-k}(2+i-k+2^{j-1}) & \text{if } k = 2j \\ 2^{i-k}(2+i-k+2^{j}) & \text{if } k = 2j+1 \end{cases} \end{aligned}$$

which proves the formula for the case $n \geq 2k$ where n and k have the same parity. These two cases can be written using a single formula by noting that $\lfloor \frac{k+1}{2} - 1 \rfloor$ gives the correct powers of $j-1$ and j, respectively. □

Table 1 displays the values of $R_n(k)$ that arise from the formulas given in Theorem 6. Examining the values in Table 1 led the authors to observe a variety of patterns. Some of these follow from combinatorial arguments while others just seem to be consequences of the formulas given in Theorem 6. In Section 5 we will present those patterns that hold across the table, and give combinatorial proofs for them. Patterns that hold only for specific columns will be discussed in Section 6. As before, we let $n = 2i$ or $n = 2i+1$, and $k = 2j$ or $k = 2j+1$, respectively.

5 General Patterns in the Repetitions of k in all Palindromes of n

The most striking pattern in the table is the equality of certain diagonally adjacent entries. Furthermore, diagonal sequences that start in column 1

$n\backslash k$	1	2	3	4	5	6	7	8	9	10
1	1									
2	2	1								
3	3	0	1							
4	6	3	0	1						
5	8	2	1	0	1					
6	16	8	2	1	0	1				
7	20	6	4	0	1	0	1			
8	40	20	6	4	0	1	0	1		
9	48	16	10	2	2	0	1	0	1	
10	96	48	16	10	2	2	0	1	0	1
11	112	40	24	6	6	0	2	0	1	0
12	224	112	40	24	6	6	0	2	0	1
13	256	96	56	16	14	2	4	0	2	0
14	512	256	96	56	16	14	2	4	0	2
15	576	224	128	40	32	6	10	0	4	0
16	1152	576	224	128	40	32	6	10	0	4
17	1280	512	288	96	72	16	22	2	8	0
18	2560	1280	512	288	96	72	16	22	2	8
19	2816	1152	640	224	160	40	48	6	18	0
20	5632	2816	1152	640	224	160	40	48	6	18
21	6144	2560	1408	512	352	96	104	16	38	2
22	12288	6144	2560	1408	512	352	96	104	16	38

Table 1: The number of occurrences of k among all palindromes of n

for $n = 2i$ are repeated on the diagonal that starts in row $2i + 2$, with two new entries inserted at the beginning of the lower diagonal. Note also that the values that occur on these diagonals are comprised of the values for even rows in column 1 (above the starting row for the diagonal), in reverse order.

Theorem 7
a) $R_{2i+1}(2j) = R_{2i+2}(2j + 1)$ *for* $i \geq j \geq 1$.
b) $R_{2i}(2j - 1) = R_{2i+3}(2j)$, *for* $i \geq j \geq 1$.
c) $R_{2i+2l}(2l + 1) = R_{2i-2l}(1)$ *for* $l \geq 1$.

Proof: a) To show the first equality, note that a palindrome of an odd integer n must have an odd middle summand; thus, no copy of $2j$ occurs in the center. For $i \geq j$, pairs of $(2j)$s can occur. For each pair of symmetrically located occurrences of $2j$ in a palindrome of $2i + 1$, there is a

corresponding palindrome of $2i+2$ which has a pair of symmetrically located occurrences of $2j+1$ and whose middle summand is decreased by one. Since a palindrome of an even integer n cannot have $2j+1$ as the middle summand, the number of occurrences of $2j$ in the palindromes of $2i+1$ equals the number of occurrences of $2j+1$ in the palindromes of $2i+2$.

b) To show the second equality, which together with part a) leads to the repeated diagonals, we make a similar argument. Since a palindrome of an even integer n must have an even middle summand (possibly 0), no copy of $2j-1$ occurs in the center. For $i \geq j$, pairs of $(2j-1)$s can occur. For each pair of symmetrically located occurrences of $2j-1$ in a palindrome of $2i$, there is a corresponding palindrome of $2i+3$ which has a pair of symmetrically located occurrences of $2j$ and whose middle summand is increased by 1. Since the palindrome of $2i+3$ cannot have an even summand in the center, there is a one-to-one correspondence between the occurrences of the $(2j-1)$s in the palindromes of $2i$ and the $(2j)$s in the palindromes of $2i+3$.

c) Both $2i+2l$ and $2i-2l$ are even, and we are counting the number of occurrences of $2l+1$ and 1, respectively. Neither of these can occur in the center of the palindromes. To make the association between the palindromes of the two sizes, we think of the palindrome as a symmetric tiling. For a tiling of length $2i-2l$ which has at least one pair of 1 x 1 tiles, replace one pair of 1 x 1 tiles with a pair of 1 x $2l$ tiles. This increases the length of the tiling to $2i-2l+2(2l) = 2i+2l$, and each pair of 1s in the shorter tiling has an associated pair of $(2l+1)$s in the longer tiling. Thus, the number of 1s in the palindromes of $2i-2l$ equals the number of $(2l+1)$s in the palindromes of $2i+2l$. Figure 2 illustrates this process for $i=3$ and $l=1$ to show that $R_8(3) = R_4(1)$. There are two palindromes of 4 that contain 1s: 1+1+1+1 and 1+2+1, and 3 palindromes of 8 that contain 3s: 1+3+3+1, 3+1+1+3, and 3+2+3.

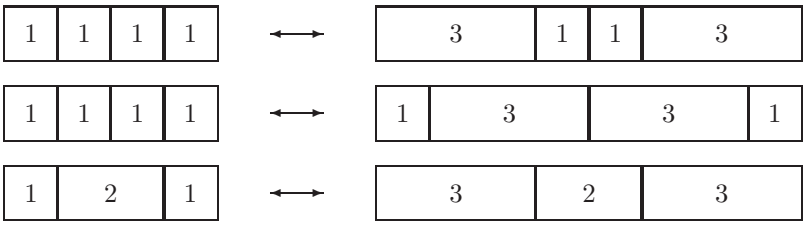

Figure 2: Replacing pairs of 1s by pairs of $(2l+1)$s

Note that a palindrome of $2i-2l$ with j pairs of 1s will have j palindromes of $2i+2l$ associated with it. However, the correspondence of the pairs is one-to-one. □

For diagonals that start in column 1 in a row for odd n, we only get equality of adjacent pairs, but not a repetition of the whole diagonal sequence.

Theorem 8 $R_{2i+1}(2j-1) = R_{2i+2}(2j)$ *for* $i \geq j \geq 1$.

Proof: A palindrome of an odd integer must have an odd middle summand. If this middle summand is $2j-1$, increase it by 1 to get a palindrome of $2i+2$ with middle summand $2j$. For $i \geq j$, we also get symmetric pairs of $(2j-1)$s. Increase each $2j-1$ by 1 to $2j$, and decrease the middle summand by 1. Thus, there is a one-to-one correspondence between the occurrences of $2j-1$ in the palindromes of $2i+1$ and the occurrences of $2j$ in the palindromes of $2i+2$. □

The next pattern is a bit more complex.

Theorem 9 *The sum of two adjacent entries for even n in an appropriate set of two columns is equal to the sum of the two adjacent entries below them:*

$$R_{2i}(2j) + R_{2i}(2j+1) = R_{2i+1}(2j) + R_{2i+1}(2j+1) \text{ for } i \geq j \geq 1.$$

Proof: Consider any even palindrome. Using the RPCM, the palindromes of the next odd integer are generated by increasing the middle summand by 1. Note, however, that in half of the palindromes of $2i$ this middle summand is a dummy 0 and the increase therefore does not change the number of occurrences of any integer greater than 1; in particular the number of occurrences of $2j$ and $2j+1$ remains unchanged. In the other half of the palindromes of $2i$, the middle summand is even and at least 2. Increasing a middle summand of size $2j$ leads to a loss in the count of $(2j)$s, which is, however, compensated for by an increase in the number of $(2j+1)$s. □

Before stating patterns that are specific to particular columns of Table 1, we will focus on the values of $R_n(1)$ for even and odd values of n, respectively. For $k=1$, the formulas given in Theorem 6 simplify to $R_{2i}(1) = (i+1)\cdot 2^{i-1}$ and $R_{2i-1}(1) = (i+1)\cdot 2^{i+1}$ for $i \geq 1$. For even n, the sequence of values $R_{2i}(1)$, given by {2, 6, 16, 40, 96, 224,

512, 1152, 2560, 5632, 12288,....}, matches the sequence $a(i)$ defined in A057711 of [7] (with $R_{2i}(1) = a(i-1)$), which arises as the number of states in a ferry problem [5]. For odd n, the sequence of values $R_{2i-1}(1)$, given by {1, 3, 8, 20, 48, 112, 256, 576, 1280, 2816, 6144,...}, matches the sequence $a(i)$ defined in A001792 of [7] (with $R_{2i+1}(1) = a(i)$). This sequence arises in several different contexts, for example in generalizations of the Stirling number triangles [6] and as a realization of oligomorphic permutation groups [2].

Now imagine that we "color" all the values that belong to a known sequence. Due to the repeated diagonals, the sequence for $R_{2i}(1)$ occurs in all columns. If k is odd, the sequence occurs in the even rows, and if k is even, it occurs in the odd rows. The first non-zero value, 2, occurs for $n = 2k+1$ when k is even, and for $n = 2k$ when k is odd. If the preceeding zeros are included, then these values fill all the diagonals that start in an even row in column 1, giving a checker-board coloring of the table.

We consider the remaining "uncolored" sequences in each column. In the even rows of column 2, we get the sequence for odd rows of column 1, due to the equality of diagonally adjacent entries, thus column 2 is now completely "colored". Likewise, the remaining "uncolored" sequences in adjacent odd and even columns are the same. We tested these "uncolored" sequences, {4, 10, 24, 56, 128, 288, 640, 1408, 3072,...} (for columns 3 and 4), {6, 14, 32, 72, 160, 352, 768, 1664, 3584,...} (for columns 5 and 6), {10, 22, 48, 104, 224, 480, 1024, 2176, 4608,...} (for columns 7 and 8), {18, 38, 80, 168, 352, 736, 1536, 3200, 6656,...} (for columns 9 and 10), and {34, 70, 144, 296, 608, 1248, 2560, 5248, 10752,...} (for columns 11 and 12), both with and without the entries for $n < 2k$, which are described by a different formula than those for $n \geq 2k$, against the On-Line Encyclopedia of Integer Sequences [7]. (The sequences above list only the values for $n \geq 2k$). The fact that none of these sequences occurs makes it unlikely that sequences for values of $k \geq 13$ are in the encyclopedia; we are therefore in the process of submitting this family of related sequences to the encyclopedia.

6 Specific Patterns in the Repetitions of k in all Palindromes of n

The remaining patterns are specific to particular columns of Table 1. We present only analytical proofs for these, rather than combinatorial ones. The fact that the patterns hold only for specific columns seems to indicate that no general method similar to those used in the proofs in Section 5 is applicable. For each of the following theorems, the range indicated for i ensures that for all values of n and k, $n \geq 2k$ holds.

Theorem 10
a) $R_{2i}(1) = 2 \cdot R_{2i+1}(2) + 2^{i-1}$ *for* $i \geq 2$.
b) $R_{2i}(1) = R_{2i+2}(3) + R_{2i+3}(3)$ *for* $i \geq 2$.

Proof: Using the appropriate formula in Theorem 6, we get:

$$\begin{aligned} R_{2i}(1) &= 2^{i-1}(2+i-1) = 2^{i-1}(i+1), \\ 2 \cdot R_{2i+1}(2) + 2^{i-1} &= 2 \cdot (2^{i-2}(2+i-2)) + 2^{i-1} = 2^{i-1}(i+1), \text{ and} \\ R_{2i+2}(3) + R_{2i+3}(3) &= 2^{(i+1)-3}(2+(i+1)-3) \\ &\quad +2^{(i+1)-3}(2+(i+1)-3+2^1) \\ &= 2^{i-2}(i+i+2) = 2^{i-1}(i+1), \end{aligned}$$

which completes the proof. □

Theorem 11 $R_{2i+1}(1) = R_{2i+4}(3) + R_{2i+3}(3) - R_{2i+2}(3)$ *for* $i \geq 1$.

Proof: From Theorem 6 we get:

$$R_{2i+1}(1) = 2^{i-1}(2+i-1+2^0) = 2^{i-1}(i+2)$$

and

$$\begin{aligned} &R_{2i+4}(3) + R_{2i+3}(3) - R_{2i+2}(3) \\ &\quad = 2^{(i+2)-3}(2+(i+2)-3) + 2^{(i+1)-3}(2+(i+1)-3+2^1) \\ &\qquad -2^{(i+1)-3}(2+(i+1)-3) \\ &\quad = 2^{i-2}\left(2(i+1)+(2+i)-i\right) = 2^{i-2}(2(i+2)+i-i) \\ &\quad = 2^{i-1}(i+2), \end{aligned}$$

which proves the statement. □

Theorem 12 $R_{2i}(2) = 2 \cdot R_{2i+1}(3)$ *for* $i \geq 3$.

Proof: Again, we use the formula for $R_n(k)$ given in Theorem 6.

$$\begin{aligned} R_{2i}(2) &= 2^{i-2}(2+i-2+2^0) = 2^{i-2}(i+1) \\ &= 2\left[2^{i-3}(2+i-3+2^1)\right] = 2 \cdot R_{2i+1}(3) \end{aligned}$$

which completes the proof. □

The next three theorems seem to have a similar structure, but there is no general underlying pattern. Furthermore, these types of pattern do

not seem to occur for larger values of k. The second pattern in Theorem 15 also differs somewhat from the ones of Theorems 13 and 14 in that the values are expressed as a difference rather than as a sum.

Theorem 13
a) $R_{2i+1}(2) = 4 \cdot R_{2i-1}(3)$ *for* $i \geq 4$.
b) $R_{2i+1}(2) = R_{2i+2}(4) + R_{2i+3}(4)$ *for* $i \geq 3$.

Proof: Using Theorem 6,

$$\begin{aligned} R_{2i+1}(2) &= 2^{i-2}(2+i-2) = 2^{i-2} \cdot i, \\ 4 \cdot R_{2i-1}(3) &= 4\left[2^{(i-1)-3}(2+(i-1)-3+2^1)\right] = 2^{i-2} \cdot i, \end{aligned}$$

and

$$\begin{aligned} R_{2i+2}(4) + R_{2i+3}(4) &= 2^{(i+1)-4}(2+(i+1)-4+2^1) \\ &\quad +2^{(i+1)-4}(2+(i+1)-4) \\ &= 2^{i-3}\left[(i+1)+(i-1)\right] = 2^{i-2} \cdot i, \end{aligned}$$

which proves the desired equalities. □

Theorem 14
a) $R_{2i}(3) = 4 \cdot R_{2i-2}(4)$ *for* $i \geq 5$.
b) $R_{2i}(3) = R_{2i}(4) + R_{2i+1}(4)$ *for* $i \geq 4$.

Proof: The formulas for $R_n(k)$ in Theorem 6 give

$$\begin{aligned} R_{2i}(3) &= 2^{i-3}(2+i-3) = 2^{i-3}(i-1), \\ 4 \cdot R_{2i-2}(4) &= 4 \cdot \left[2^{(i-1)-4}(2+(i-1)-4+2^1)\right] = 2^{i-3}(i-1), \end{aligned}$$

and

$$\begin{aligned} R_{2i}(4) + R_{2i+1}(4) &= 2^{i-4}(2+i-4+2^1) + 2^{i-4}(2+i-4) \\ &= 2^{i-4}(i+i-2) = 2^{i-3}(i-1). \end{aligned}$$

This completes the proof. □

Theorem 15
a) $R_{2i}(4) = 4 \cdot R_{2i-1}(5)$ *for* $i \geq 6$.
b) $R_{2i}(4) = R_{2i+3}(4) - R_{2i+2}(5)$ *for* $i \geq 4$.

Proof: Once more we use the formula for $R_n(k)$ given in Theorem 6.

$$\begin{aligned} R_{2i}(4) &= 2^{i-4}(2+i-4+2^1) = 2^{i-4}\cdot i \\ &= 4\cdot\left[2^{(i-1)-5}(2+(i-1)-5+2^2)\right] = 4\cdot R_{2i-1}(5) \end{aligned}$$

and

$$\begin{aligned} R_{2i+3}(4) - R_{2i+2}(5) &= 2^{(i+1)-4}(2+(i+1)-4) \\ &\quad -2^{(i+1)-5}(2+(i+1)-5) \\ &= 2^{i-4}\left[2(i-1)-(i-2)\right] = 2^{i-4}\cdot i, \end{aligned}$$

which completes the proof. □

Compositions of n with no occurrence of k

Phyllis Chinn, Humboldt State University
Silvia Heubach, California State University Los Angeles

Abstract

A *composition of n* is an ordered collection of one or more positive integers whose sum is n. The number of summands is called the number of *parts* of the composition. A *palindromic composition* or *palindrome* is a composition in which the summands are the same in the given or in reverse order. Compositions may be viewed as tilings of 1-by-n rectangles with 1-by-i rectangles, $1 \le i \le n$. We count the number of compositions and the number of palindromes of n that do not contain any occurrence of a particular positive integer k. We also count the total number of occurrences of each positive integer among all the compositions of n without occurrences of k. This counting problem corresponds to the number of rectangles of each allowable size among the tilings of length n without 1-by-k tiles. Finally we count the number of compositions without k having a fixed number of parts, and explore some patterns involving the number of parts in compositions without k.

Key words: Compositions, tilings, palindromes.

1. Introduction

A *composition of n* is an ordered collection of one or more positive integers whose sum is n. The number of summands is called the number of *parts* of the composition. A *palindromic composition* or *palindrome* is a composition in which the summands are the same in the given or in reverse order. Compositions may be viewed as tilings of 1-by-n rectangles with 1-by-i rectangles, $1 \le i \le n$. In this view, a palindromic composition is one corresponding to a symmetric tiling. Because of the relation of compositions to tilings, we sometimes refer to a composition of n as a *composition of length n.*

Grimaldi [5] explores the question of how many compositions of n exist when no 1's are allowed in the composition. In [4], the authors explore the question of how many compositions of n exist when no 2's are allowed in the composition. In this paper we explore the general question of how many compositions of n exist when no k's are allowed in the composition. Related to this question we will also explore how many of these compositions are palindromes.

We count the number of compositions and the number of palindromes without k, as well as the total number of occurrences of each positive integer among all the compositions of n with no k's. The preceding two counting problems correspond respectively to the number of 1-by-n tilings and the total number of tiles of a specific size used among all the tilings of length n without 1-by-k tiles. Finally, we explore particular patterns involving the number of

parts among all the compositions of n without occurrences of k. We will use the following notation.

$C(n)$	is the number of compositions of n
$C(n,\hat{k})$	is the number of compositions of n with no k's
$P(n,\hat{k})$	is the number of palindromes of n with no k's
$x(n,i)$	is the number of occurrences of i among all compositions of n
$x(n,i,\hat{k})$	is the number of occurrences of i among all compositions of n with no k's
$C_j(n)$	is the number of compositions of n with j parts
$C_j(n,\hat{k})$	is the number of compositions of n with j parts and no k's.

2. The number of compositions without *k*'s.

In the following theorem we will present three different ways to generate the compositions without k's, each of which gives rise to a different formula.

Theorem 1. The number of compositions of n without k's is given by

$$C(n,\hat{k}) = 2\cdot C(n-1,\hat{k}) + C(n-(k+1),\hat{k}) - C(n-k,\hat{k}) \quad \text{for } n \geq k+1 \tag{1}$$

or

$$C(n,\hat{k}) = \left(\sum_{i=0}^{n-1} C(i,\hat{k})\right) - C(n-k,\hat{k}) \quad \text{for } n \geq 1 \tag{2}$$

or

$$C(n,\hat{k}) = \left(\sum_{i=1}^{k} C(n-i,\hat{k})\right) + C(n-2k,\hat{k}) \quad \text{for } n \geq k+1, \tag{3}$$

with initial conditions $C(i,\hat{k}) = 0$ for $i < 0$, $C(i,\hat{k}) = 2^{i-1}$ for $0 < i < k$, $C(k,\hat{k}) = 2^{k-1} - 1$, and we define C(0, $\hat{k}$) = 1. The generating function for $C(n,\hat{k})$ is given by $\sum_{n=0}^{\infty} C(n,\hat{k})\cdot t^n = \dfrac{1-t}{1-2t+t^k-t^{k+1}}$.

Proof: The initial conditions follow from the fact that $C(n,\hat{k}) = C(n)$ for $n < k$, as no forbidden k's can occur in the compositions of n, and $C(n) = 2^{n-1}$ (see for example [6], p. 33). If $n = k$, then there is one composition of n consisting of just k, which has to be eliminated, hence $C(k,\hat{k}) = C(k) - 1 = 2^{k-1} - 1$. We now derive the individual formulas.

To show Eq. (1), we generate the compositions of n without k's recursively by the following process: to any such composition of $n-1$, one can add a 1 or increase the last summand by 1. However, this process needs two corrections. First, we must separately generate those compositions that end in $k+1$, since they will not be generated by this recursive method. They come from adding a $k+1$ to compositions of $n-(k+1)$. Secondly, we must subtract the compositions of $n-1$ that initially ended in k-1, since they would now end in k under this process. The number of such compositions corresponds to compositions of length $n-k$.

Eq. (2) follows readily from the following alternate creation method: append a 1 to all allowable compositions of $n-1$, append a 2 to those of $n-2$, and in general, appending j to all allowable compositions of $n-j$ except when $j=k$. This method gives rise to the second formula.

Note that in the summation of Eq. (2), the number of terms being added increases as n increases. A third way of generating the compositions of n without k's requires only a fixed number of summands. It is useful to express this method in terms of tilings. One can either add a tile of length i to any composition of length $n-i$ for $i=1,\ldots,k-1$ or extend the last tile in any composition of length $n-k$ by k units. Because none of the tilings used in this process end in k, we need to add in those that will not be created by the extension methods, namely the $C(n-2k,\hat{k})$ tilings that now end with a tile of length $2k$, which leads to Eq. (3).

Finally, to derive the generating function $G_C(t)=\sum_{n=0}^{\infty} C(n,\hat{k})\cdot t^n$, we multiply the Eq. (3) by t^n, then sum over $n\geq k+1$. Thus,

$$\sum_{n=k+1}^{\infty} C(n,\hat{k})\cdot t^n = \sum_{n=k+1}^{\infty}\left(\sum_{i=0}^{k} C(n-i,\hat{k})\right)\cdot t^n + \sum_{n=k+1}^{\infty} C(n-2k,\hat{k})\cdot t^n. \qquad (4)$$

Factoring out appropriate powers of t, then re-indexing the infinite series and expressing the resulting series in terms of $G_C(t)$ reduces Eq. (4) to

$$G_C(t)-\sum_{n=0}^{k} C(n,\hat{k})\cdot t^n = \sum_{i=1}^{k} t^i\left(G_C(t)-\sum_{n=0}^{k-i} C(n,\hat{k})\cdot t^n\right)+t^{2k}G_C(t).$$

Collecting the terms containing $G_C(t)$ and then combining terms according to powers of t yields

$$\begin{aligned} G_C(t)\left(1-\sum_{i=1}^{k} t^i - t^{2k}\right) &= \sum_{n=0}^{k} C(n,\hat{k})\cdot t^n - \sum_{i=1}^{k}\sum_{n=0}^{k-i} C(n,\hat{k})\cdot t^{n+i} \\ &= \sum_{j=0}^{k} t^j\left(C(j,\hat{k})-\sum_{i=1}^{j-1} C(i,\hat{k})\right). \end{aligned}$$

We now look at the summands on the right hand side. For $j = 0,$ we get $t^0 C(0,\hat{k}) = 1$. For $j = k,$ we get

$$t^k (C(k,\hat{k}) - \sum_{i=1}^{k-1} C(i,\hat{k})) = t^k (-C(0,\hat{k})) = -t^k$$

using Eq. (2). If $0 < j < k$ then $C(j,\hat{k}) = \sum_{i=1}^{j-1} C(i,\hat{k})$, thus all these powers of t have zero factors. Thus, $G_C(t)\left(1 - \sum_{i=1}^{k} t^i - t^{2k}\right) = 1 - t^k$, and

$$G_C(t) = \frac{1-t^k}{\left(1 - \sum_{i=1}^{k} t^i - t^{2k}\right)} = \frac{(1-t)(1+t+t^2+\cdots+t^{k-1})}{(1-2t+t^k-t^{k+1})(1+t+t^2+\cdots+t^{k-1})}$$

which gives the desired result. ■

Table 1 gives values for the number of compositions with no k's for $k \le 6$ and $n \le 17$, as well as the number of compositions without restrictions.

	No restrictions	No 1's	No 2's	No 3's	No 4's	No 5's	No 6's

Table 1: Values of $C(n,\hat{k})$ for $k \le 6$

Some patterns that occur in this table are a result of the initial conditions and were already mentioned in the proof of Theorem 1, for example that the column representing compositions without restrictions contains powers of 2, that each column agrees with the number of compositions with no restrictions through the entry $C(k-1,\hat{k})$ and that $C(k,\hat{k}) = C(k) - 1 = 2^{k-1} - 1$. Furthermore, it is easy to see that $C(k+1,\hat{k}) = C(k) - 2 = 2^k - 2$, since the only missing compositions of $k+1$ are the two involving an occurrence of k, namely $k+1$ and $1+k$.

The second column in Table 1 contains the Fibonacci numbers and was thoroughly investigated in the context of compositions with no 1's in [5]. Likewise, the column with no 2's appeared in [4]. The column representing the number of compositions with no 3's occurs in [7] as A049856 where it is given by the same recurrence relation as in Theorem 1 for $k = 3$ with no applications mentioned. The remaining columns do not appear in [7].

3. The number of occurrences of various summands among all the compositions of *n* with no occurrences of *k*

First let us look at the number of occurrences of various summands among all the compositions with no restrictions. Chinn et al. [1] showed that $x(n,1) = (n+2)2^{n-3}$ for $n > 1$, and $x(n+j,i+j) = x(n,i)$. The latter formula can easily be extended to the general case where no k's are allowed, as shown in the next theorem.

Theorem 2. The number of i's among all compositions of n with no k's is the same as the number of occurrences of $i+j$ among all the compositions of $n+j$ with no k's, i.e., $x(n+j,i+j,\hat{k}) = x(n,i,\hat{k})$ for all $i \neq k$, $i+j \neq k$.

Proof: Consider any occurrence of the summand i among the compositions of n without k's. There is a corresponding occurrence of $i+j$ in a composition of $n+j$ in which the summand i has been replaced by $i+j$ and all other summands are the same, as long as $i+j \neq k$. This process is reversible, thus the correspondence is one-to-one. ■

As a result of Theorem 2, we only need to generate the number of occurrences of 1 among all the compositions of n without k's, as long as $k \neq 1$, in order to know the number of occurrences of any summand. In the case that k=1, one needs to calculate $x(n,2,\hat{k})$, which by Theorem 2 gives the number of occurrences of $i > 2$. Note that Grimaldi calculated $x(n,2,\hat{k})$ in Table 1 in [5].

Theorem 3. The number of occurrences of 1 among all compositions of n

without k's for $k > 1$ is given by

$$x(n,1,\hat{k}) = 2 \cdot x(n-1,1,\hat{k}) - x(n-k,1,\hat{k}) + x(n-(k+1),1,\hat{k}) + C(n-1,\hat{k}) - C(n-2,\hat{k}) \tag{5}$$

or by

$$x(n,1,\hat{k}) = n \cdot C(n,\hat{k}) - \sum_{i=1}^{n-1} (n-i+1) \cdot x(i,1,\hat{k}) , \tag{6}$$

with initial conditions $x(n,1,\hat{k}) = x(n,1) = (n+2)2^{n-3}$ for $3 \le n \le k$, $x(1,1,\hat{k})$ = $x(1,1) = 1$ and $x(2,1,\hat{k}) = x(2,1) = 2$. Furthermore,

$$x(n,1,\hat{k}) = \sum_{i=0}^{n-1} C(i,\hat{k}) \cdot C(n-1-i,\hat{k}) , \tag{7}$$

which implies that the generating function $G_x(t)$ is given by

$$G_x(t) = t \cdot G_C(t)^2 = \frac{t(1-t)^2}{(1-2t+t^k-t^{k+1})^2} .$$

Proof: The initial conditions follow from the fact that for $n < k$, no k can occur. For $n = k$, the only composition that is excluded is the one consisting of k which does not contain any 1's.

Eq. (5) follows from the creation of the compositions of n from those of $n-1$ by either adding a 1 or by increasing the rightmost summand by 1. When adding a 1, we get all the "old" 1's, and for each composition an additional 1, altogether $x(n-1,1,\hat{k}) + C(n-1,\hat{k})$ 1's. When increasing the rightmost summand by 1, again we get all the "old" 1's (of which there are $x(n-1,1,\hat{k})$), except that we need to make the following adjustments: 1) subtract the 1's of those compositions of $n-1$ with terminal summand $k-1$, as they would result in a forbidden k; 2) subtract the terminal 1's in the compositions of $n-1$ that are lost when they turn into 2's; and 3) add the 1's for the compositions of n that end in $k+1$, which have to be created separately. The number of 1's in the compositions of $n-1$ ending in $k-1$ is identical to the number of 1's in the compositions of $(n-1)-(k-1) = n-k$, hence we subtract $x(n-k,1,\hat{k})$. We lose a 1 in every composition of $n-1$ with terminal 1, which equals the number of compositions of $n-2$, thus we subtract $C(n-2,\hat{k})$. Finally, the number of 1's in the compositions of n that end in $k+1$ is given by $x(n-(k+1),1,\hat{k})$, which we add to the total. Simplification gives the stated result.

The second formula for $x(n,1,\hat{k})$, Eq. (6), is based on a geometric argument involving all tilings of a 1-by-n board. The total area of all these

tilings, given by $n \cdot C(n,\hat{k})$, has to equal the sum of the areas covered by 1-by-1, 1-by-2,…, and 1-by-n tiles. The area covered by 1-by-i tiles is given by $i \cdot x(n,i,\hat{k})$, and thus, $n \cdot C(n,\hat{k}) = \sum_{i=1}^{n} i \cdot x(n,i,\hat{k})$. Solving for $x(n,1,\hat{k})$, using Theorem 2 to express the right-hand summands in terms of $x(i,1,\hat{k})$, and then re-indexing ($j = n-i+1$) gives that

$$\begin{aligned} x(n,1,\hat{k}) &= n \cdot C(n,\hat{k}) - \sum_{i=2}^{n} i \cdot x(n,i,\hat{k}) \\ &= n \cdot C(n,\hat{k}) - \sum_{i=2}^{n} i \cdot x(n-i+1,1,\hat{k}) \\ &= n \cdot C(n,\hat{k}) - \sum_{j=1}^{n-1} (n-j+1) \cdot x(j,1,\hat{k}). \end{aligned}$$

Eq. (7) also can be seen easily in the framework of tilings. The number of 1's in all compositions of n corresponds to the number of 1-by-1 tiles in all tilings of a 1-by-n board. If a tiling of length n has a 1-by-1 tile at position i, then this tile is preceded by any tiling of length $i-1$ and followed by a tiling of length $n-i$. The number of 1-by-1 tiles at position i is thus given by $C(i-1,\hat{k}) \cdot C(n-i,\hat{k})$. Since 1-by-1 tiles can occur at positions 1 through $n-1$, the formula follows after a simple re-indexing of the summation index. This formula for $x(n,1,\hat{k})$ implies (see for example [8], Rules 1 and 3, Section 2.2) that the generating function is of the form $G_x(t) = t \cdot G_C(t)^2$, from which the result follows by Theorem 1. ■

Table 2 gives the number of occurrences of 1's among all compositions of n with no k's for $1 \le k \le 6$. We also include the number of occurrences of 1's among the compositions of n without restrictions.

	No restrictions	No 2's	No 3's	No 4's	No 5's	No 6's
$n=1$	1	1	1	1	1	1
2	2	2	2	2	2	2

10	1536	350	832	1212	1404	1486
11	3328	661	1679	2538	2995	3196

Table 2. Values of $x(n,1,\hat{k})$

Clearly, the entries in the column for "no k's" agree with the entry in the column for the number of 1's without restrictions for $n \le k$, as indicated in the derivation of the initial conditions in the proof of Theorem 3. We now look at diagonals of slope –1, for the part of the table that refers to compositions without k. These sequences are given by $\{x(k,1,\widehat{k+i})\}_{k=\max\{1,2-i\}}^{\infty}$, where i is an integer. Values of $i \ge 0$ produce the part of the table that is shaded in dark gray, and the entries in those diagonals satisfy $x(k,1,\widehat{k+i}) = x(k,1)$, as explained above.

The next diagonal of slope –1 (entries in bold) is given by $\{x(k,1,\widehat{k-1})\}_{k=3}^{\infty}$, and we have $x(k,1,\widehat{k-1}) = x(k,1) - 2$ since the only compositions that are not allowed are $k+1$ and $1+k$, resulting in a difference of two 1's. Finally, the diagonal with entries $\{x(k,1,\widehat{k-2})\}_{k=4}^{\infty}$ (entries in light gray) satisfies $x(k,1,\widehat{k-2}) = x(k,1) - 6$, since the only compositions that are not allowed are those consisting of one k and two 1's, of which there are three, for a total of six 1's.

4. The number of palindromes with no *k*'s.

The number of palindromes of n with no occurrence of k depends on the relative parity of n and k as detailed in the following theorem. For simplicity in stating the results, let $n = 2m$ or $n = 2m+1$ and $k = 2j$ or $k = 2j+1$.

Theorem 4. The number of palindromes of n with no k's is given by the following formulas.

a) $$P(n,\hat{k}) = \begin{cases} \displaystyle\sum_{i=0,\ i\neq m-j}^{m} C(i,\hat{k}) & \text{if } n \text{ and } k \text{ have the same parity} \\ \displaystyle\sum_{i=0}^{m} C(i,\hat{k}) & \text{if } n \text{ and } k \text{ have opposite parity.} \end{cases}$$

b) $$P(n,\hat{k}) = \sum_{i=1}^{k} P(n-2i,\hat{k}) + P(n-4k,\hat{k}) + \delta_{n,3k} \text{ for } n \ge 2k,$$

where $\delta_{i,j} = 1$ if $i = j$ and $\delta_{i,j} = 0$ otherwise, with initial conditions $P(n,\hat{k}) = 0$ for $n < 0$, $P(0,\hat{k}) = 1$, $P(n,\hat{k}) = 2^{\lfloor n/2 \rfloor}$ for $0 < n < k$, $P(n,\hat{k}) = 2^{\lfloor n/2 \rfloor} - 1$ for $n = k$, $P(n,\hat{k}) = 2^{\lfloor n/2 \rfloor} - 2^{(n-k)/2-1}$ for $k < n < 2k$, n and k having the same parity, and $P(n,\hat{k}) = 2^{\lfloor n/2 \rfloor}$ for $k < n < 2k$, n and k having opposite parity.

Proof: a) An odd length palindrome has to have an odd middle summand, and an even length palindrome has to have an even middle summand or an even split, i.e., the parity of the middle summand is the same of that of *n*. Each palindrome can be created by attaching a composition of length $(n-l)/2$ on the left of a middle summand of size l and the reverse of the composition on the right. Thus, if *n* and *k* have opposite parity, *k* will never be a middle summand. If *n* and *k* have the same parity, then *k* has to be excluded as a possible middle summand. Now we count the palindromes according to the compositions used to form them.

b) The palindromes of *n* without *k*'s can also be created by adding the summand i on both sides of a palindrome of length $n-2i$ for $i=1,...,k-1$. To create end summands that are larger than *k*, we can increase both end summands of the palindromes of $n-2k$ by *k* if those palindromes consist of more than one summand. For the single palindrome of $n-2k$ consisting of just $n-2k$ we increase this summand by 2*k*, thus creating the single palindrome consisting of *n*. The only palindromes that will not be created in this manner are the palindromes with end summands $2k$, of which there are $P(n-4k,\hat{k})$, and the palindrome of $n=3k$ consisting of the single summand $3k$, which need to be added in separately. The initial conditions for $n<k$ follow from [3, Lemma 11], as $P(n,\hat{k})$ agrees with the number of palindromes of *n* without restrictions, given by $2^{\lfloor n/2 \rfloor}$. For $n=k$, we get one fewer palindrome, as we have to exclude the palindrome consisting of just *k*. For $k<n<2k$, we have to exclude those palindromes that contain a single *k*. This can only occur when *n* and *k* have the same parity, with *k* as the middle summand, combined with a composition of $(n-k)/2$ on either side. There are $C((n-k)/2)=2^{(n-k)/2-1}$ such palindromes, which need to be subtracted from the total. ■

Table 3 gives the number of palindromes of *n* with no occurrence of *k* for $1 \le k \le 6$. Note that none of the columns in the Table 3 appears in [7]. However, since there is a different formula for even and odd length palindromes, it makes sense to look at the subsequences consisting of every other entry in each column.

For $k=2$, we get interleaved Fibonacci sequences. If we look at the subsequences with $k \ge 3$ for which *n* and *k* have opposite parity, then the sequences initially agree with the *k*-generalized Fibonacci numbers [2] (sequence A000073 for $k=3$, A000078 for $k=4$, A001591 for $k=5$, and A001592 for $k=6$), which have a recursion of the form $F(n) = \sum_{i=1}^{k} F(n-i)$. This can be seen to agree with the formula given in

Theorem 3, part b), as long as $n \le 4k$, since $\delta_{n,3k} = 0$ whenever n and k have opposite parity. The first term that differs from the respective k-generalized Fibonacci sequence is displayed in bold in Table 3.

	$P(n,\hat{1})$	$P(n,\hat{2})$	$P(n,\hat{3})$	$P(n,\hat{4})$	$P(n,\hat{5})$	$P(n,\hat{6})$

Table 3. Values of $P(n,\hat{k})$ for $k \le 6$

However, two of the odd or even subsequences do agree with sequences in [7]. For $k = 2$, the subsequence for even n agrees with A005314, as was shown in [4]. For $k = 3$, the subsequence for even n agrees with all the terms given for A059633 in [7].

5. Some results on the number of parts in compositions with no *k*'s

When compositions are viewed as tilings, it is quite natural to sort tilings by the number of tiles used. This corresponds to the number of parts in compositions. In the current study of compositions with no occurrence of a particular summand, the number of tiles (parts in the composition) depends not only on n but also on k, the number omitted as a summand. Thus a single table cannot show the number of compositions with a given number of parts with

variable forbidden summands. We will state a general result for the number of compositions with no k's with a given number of parts, and then focus our attention on some special cases with $k \le 7$. The case $k = 2$ was thoroughly investigated in [4].

Theorem 5. The number of compositions of n with exactly j parts for $n \ge 1, j \ge 2, k \ge 2$ is given by either of these two formulas:

a) $C_j(n,\hat{k}) = \sum_{i=1}^{n-1} C_{j-1}(n-i,\hat{k}) - C_{j-1}(n-k,\hat{k})$,

b) $C_j(n,\hat{k}) = C_{j-1}(n-1,\hat{k}) + C_j(n-1,\hat{k}) - C_{j-1}(n-k,\hat{k}) + C_{j-1}(n-k-1,\hat{k})$,

with initial conditions $C_j(n,\hat{k}) = 0$ for $n \le 0$, $C_1(n,\hat{k}) = 1$ for $n \ne k$, and $C_1(k,\hat{k}) = 0$.

Proof: a) For any composition of $n-i$ having $j-1$ parts, we can form a composition of n having j parts by adding the summand i to the end of the shorter composition, except for $i = k$. This increases the number of parts by one as required. The initial conditions follow easily, as the only composition of n with one part is n itself.

b) A composition of n with j parts can either be created from a composition of $n-1$ with $j-1$ parts by adding a 1, or from a composition of $n-1$ having j parts by increasing the final summand by 1. The latter count needs to be modified to exclude those compositions that would end in a k if increased, and by adding in those compositions that end in $k+1$, which would not be created in the extension process. The compositions of n with j parts that end in k can be thought of as compositions of $n-k$ with $j-1$ parts, followed by a k, so there are $C_{j-1}(n-k,\hat{k})$ compositions that need to be subtracted. A similar argument shows that there are $C_{j-1}(n-(k+1),\hat{k})$ compositions of n with j parts that end in $k+1$, which need to be added to the total. ■

To understand some of the patterns for values of $C_j(n,\hat{k})$, let us first look at Table 4 which contains the number of compositions of n with j parts when there are no restrictions on the summands. For notational convenience, we will use $\text{bin}(n,k)$ to denote $\binom{n}{k}$.

Note that each row in Table 4 agrees with the corresponding row of Pascal's triangle. To understand why the binomial coefficients appear in this table it is once again convenient to think of a composition as a tiling. Note that any tiling

of a 1-by-n rectangle with j parts can be formed by selecting $j-1$ positions to separate the whole rectangle into shorter tiles. This can be accomplished in $\text{bin}(n-1, j-1)$ ways.

	$j=1$	2	3	4	5	6	7	8	9	10
$n=1$	1									
2	1	1								
3	1	2	1							
4	1	3	3	1						
5	1	4	6	4	1					
6	1	5	10	10	5	1				
7	1	6	15	20	15	6	1			
8	1	7	21	35	35	21	7	1		
9	1	8	28	56	70	56	28	8	1

12	1	11	55	165	330	462	462	330	165	55
13	1	12	66	220	495	792	924	792	495	220
14	1	13	78	286	715	1287	1716	1716	1287	715
15	1	14	91	364	1001	2002	3003	3432	3003	2002

Table 4. Values of $C_j(n)$

We now look at tables of values of $C_j(n,\hat{k})$ for $k = 3, \ldots, 7$ to illustrate the patterns that hold across the tables. We first look at the columns, then at diagonals of slope –1. For the entry in row n and column j of the m^{th} diagonal, we have $n - j = m - 1$, and thus the entries in m^{th} diagonal are given by $C_{n-m+1}(n,\hat{k})$. The column for $j = 1$ follows directly from the initial conditions. The next theorem states results for the second column and the first $k-1$ diagonals. No obvious uniform pattern exists for the other columns.

Theorem 6. a) The entries in the second column in Tables 5 to 9 are given by

$$C_2(n,\hat{k}) = \begin{cases} n-1 & n < k \\ n-2 & n = 2k \\ n-3 & \text{otherwise.} \end{cases}$$

b) For $k \geq 2$, the first $k-1$ diagonals in the respective table agree with the corresponding diagonals in Table 4, i.e., $C_j(n,\hat{k}) = C_j(n) = \text{bin}(n-1, j-1)$ for $n+1-k < j \leq n$.

Proof: a) The values in column 2 can be explained combinatorially by looking at tilings. If no k is allowed, then no cut can be made in the 1-by-n rectangle at position k or at position $n - k$. For $n < k$, this cannot happen, and thus the single cut can be made at any of the $n-1$ cutting positions. For $n = 2k$, the positions k and $n - k$ are identical, thus there is only one forbidden position, hence $C_2(2k, \hat{k}) = n-2$. In all other cases, two of the $n-1$ cutting positions are forbidden, thus $C_2(n, \hat{k}) = n-3$ (for $n > k, n \neq 2k$).

b) Note that for $m < k$, the number of parts $j = n - m + 1 > n - k + 1$, thus k cannot occur as a part. ■

Since the 1st through $(k-1)^{st}$ diagonals agree with the values in Table 4, they also appear as diagonals within Pascal's triangle. These entries are shown in bold in Tables 5 through 9. Note that any such diagonal that agrees with Pascal's triangle for a given value of k will also occur in the tables where the forbidden summand is bigger than the given value of k. We will give combinatorial interpretations for the diagonal sequences that also occur as diagonal sequences in Pascal's triangle, and also for the entries of the k^{th} diagonals, which do not reappear in the tables for larger values of k.

To explain the combinatorial interpretations, it is convenient to create the compositions of n having j parts as follows: we start with j 1's (as there are to be j parts), and then distribute the difference $n - j$ across these j parts, adding to the 1's that are already there. In order to count all possibilities, we will find the partitions of $n - j$, then count how many associated compositions without k exist. We illustrate the procedure for the compositions of $n = 4$ without 3's having $j = 2$ parts. First create two 1's, resulting in the composition 1+1. Next distribute the difference $n - j = 2$, i.e., consider all the partitions of 2, namely $\{2\}$ and $\{1,1\}$. Using the first partition leads to 3+1 (the first 1 is increased by 2) or 1+3 (the second 1 is increased by 2), and the second partition creates 2+2 (both 1's are increased by 1). The first two compositions are not allowed as they contain a 3, so we have to disregard all the partitions of $n - j$ that contain a 2, and in general, all the partitions of $n - j$ that contain $k-1$. We will refer to this procedure as the *distributive creation method.*

Table 5 through Table 9 contain the values of $C_j(n, \hat{k})$ for $3 \le k \le 7$. We begin by giving a derivation of the formula for the k^{th} diagonals in these tables (shown in gray), and in the case k = 3, also for the 4th diagonal, which is a known sequence.

The third (m = 3) diagonal of $n-2$ parts in Table 5 corresponds to a composition with two 2's and $n-4$ 1's for a total of $\text{bin}(n-2, 2)$ compositions, i.e., a triangle number of them. There is only one additional known sequence that occurs in Table 5, namely the diagonal of

$j = n - 3$ parts (m = 4, entries in italic). To count these compositions, we use the distributive creation method described above. The partitions of $n - j = 3$ without 2's are {1,1,1} and {3}, which result in the following partitions of n: either three 2's and $j - 3$ 1's or one 4 and $j - 1$ 1's for a total of $\text{bin}(j,3) + j = (j^3 - 3j^2 + 8j)/6$ compositions. This sequence occurs as A000125 in [7], the cake number, which gives the maximal number of pieces resulting from i planar cuts through a cube (or cake), and is given by $a(i) = (i^3 + 5i + 6)/6$. Basic algebra shows that $C_j(j+3, \hat{3}) = a(j-1)$.

Table 5. Values for $C_j(n, \hat{3})$

We now look at the case $k = 4$. Table 6 shows the number of compositions of n with no 4's having j parts. The diagonal of $j = n - 3$ parts (m = 4) occurs in [7] as A005581 and is given by the formula $a(i) = (i-1) \cdot i \cdot (i+4)/6$, which can be derived as follows. The partitions of $n - j = 3$ without 3's are {1,1,1} and {2,1}, which result in these partitions of n: three 2's and $j - 3$ 1's, or one 3, one 2, and $j - 2$ 1's, for a total of $\text{bin}(j,3) + 2 \cdot \text{bin}(j,2) = j(j-1)(j+4)/6$ compositions, thus $C_j(j+3, \hat{4}) = a(j)$.

Next we look at the case $k = 5$. Table 7 shows the number of compositions of n with no 5's having j parts.

14	1	11	57	192	465	882	1324	1492	1215

Table 7. Values for $C_j(n,\hat{5})$

The diagonal of $j=n-4$ parts (m = 5) occurs in [7] as A005718, the quadrinomial coefficients, and is given by $a(i)=\text{bin}(i,2)\cdot(i^2+7i+18)/12$, where $a(j)=C_j(j+4,\hat{5})$. We can show the equivalence of the two sequences as follows: The partitions of $n-j=4$ without 4's are {1,1,1,1}, {2,2}, {2,1,1},

and {3,1} which result in these partitions of n: four 2's and $j-4$ 1's, of which there are $\text{bin}(j,4)$; two 3's and $j-2$ 1's, of which there are $\text{bin}(j,2)$; one 3, two 2's and $j-3$ 1's, of which there are $j\cdot\text{bin}(j-1,2)$; one 4, one 2, and $j-2$ 1's, of which there are $j(j-1)$. Thus, $C_j(j+4,\hat{5}) = \text{bin}(j,4) + \text{bin}(j,2) + j\cdot\text{bin}(j-1,2) + j(j-1) = \text{bin}(j,2)\cdot(j^2+7j+18)/12$.

Next we look at the case $k = 6$. Table 8 shows the number of compositions of n with no 6's having j parts.

	$j=1$	2	3	4	5	6	7	8	9
$n=1$	**1**								
2	**1**	**1**							
3	**1**	**2**	**1**						
4	**1**	**3**	**3**	**1**					
5	**1**	**4**	**6**	**4**	**1**

10	1	7	27	72	121	**126**	**84**	**36**	**9**
11	1	8	33	96	190	246	**210**	**120**	**45**
12	1	10	40	125	280	432	455	**330**	**165**
13	1	10	51	160	395	702	882	784	**495**
14	1	11	60	208	540	1077	1569	1660	1278
15	1	12	70	264	731	1582	2611	3208	2931
16	1	13	81	329	975	2262	4123	5763	6111
17	1	14	93	404	1280	3168	6265	9760	11790

Table 8. Values for $C_j(n,\hat{6})$

The diagonal of $j = n-5$ parts (m = 6) occurs in [7] as A027659, the sixth column of the quintinomial coefficients, and is given by $a(i) = \text{bin}(i,2) + \text{bin}(i+1,3) + \text{bin}(i+2,4) + \text{bin}(i+3,5)$. We can show the equivalence of the two sequences as follows: The partitions of $n-j=5$ without 5's are {1,1,1,1,1}, {2,2,1}, {2,1,1,1}, {3,2}, {3,1,1}, and {4,1} which result in these partitions of n: five 2's and $j-5$ 1's, of which there are $\text{bin}(j,5)$; two 3's, one 2 and $j-3$ 1's, of which there are $j\cdot\text{bin}(j-1,2)$; one 3 , three 2's and $j-4$ 1's, of which there are $j\cdot\text{bin}(j-1,3)$; one 4, one 3 and $j-2$ 1's, of which there are $j(j-1)$; one 4, two 2's and $j-4$ 1's, of which there are

$j \cdot \text{bin}(j-1,2)$; and one 5, one 2 and $j-2$ 1's, of which there are $j(j-1)$. Thus there are a total of $\text{bin}(j,5) + j \cdot \text{bin}(j-1,3) + 2 \cdot j \cdot \text{bin}(j-1,2) + 2 \cdot j \cdot (j-1)$ compositions, which can be shown to agree with the formula given for sequence A027659, with $C_j(j+5,\hat{6}) = a(j-2)$.

Finally, we look at the case $k = 7$. Table 9 shows the number of compositions of n with no 7's having j parts.

	$j=1$	2	3	4	5	6	7	8	9
$n=1$	**1**								
2	**1**	**1**							
3	**1**	**2**	**1**

14	1	12	60	226	615	1197	1674	1708	**1287**
15	1	12	73	280	826	1792	2856	3376	2994
16	1	13	84	349	1085	2583	4613	6211	6363

Table 9. Values for $C_j(n,\hat{7})$

The diagonal of $j = n-6$ parts (m = 7) occurs in [7] as A062989, the 7th column of the generalized Catalan Array FS[5;i,6] and is given by $a(i) =$, $(i+1)(i+2)(i^4+24i^3+221i^2+954i+1800)/6!$,where $C_j(j+6,\hat{7}) = a(j-2)$. We can show the equivalence of the two sequences as follows: The partitions of $n-j=6$ without 6's are {1,1,1,1,1,1}, {2,2,2}, {2,2,1,1}, {2,1,1,1,1}, {3,3}, {3,2,1}, {3,1,1,1}, {4,2}, {4,1,1}, and {5,1} which result in these partitions of n: six 2's and $j-6$ 1's, of which there are $\text{bin}(j,6)$; three 3's and $j-3$ 1's, of which there are $\text{bin}(j,3)$, two 3's and two 2's and $j-6$ 1's, of which there are $\text{bin}(j,4) \cdot \text{bin}(4,2)$, one 3, four 2's and $j-5$ 1's, of which there are $j \cdot \text{bin}(j-1,4)$; two 4's and $j-2$ 1's, of which there are $\text{bin}(j,2)$; one 4, one 3, one 2 and $j-3$ 1's, of which there are $j(j-1)(j-2)$; one 4, three 2's and $j-4$ 1's, of which there are $j \cdot \text{bin}(j-1,3)$; one 5, one 3, and $j-2$ 1's,

of which there are $j(j-1)$; one 5, two 2's and $j-3$ 1's, of which there are $j \cdot \text{bin}(j-1,2)$; and one 6, one 2, and $j-2$ 1's, of which there are $j(j-1)$. Summing these terms and simplifying shows agreement of the number of compositions with the formula given for sequence A062989.

Similar derivations can be made for larger values of *k*; however, the number of partitions increases quite rapidly, and so far no pattern has emerged that would allow for easier counting of these quantities. Likewise, in each table, formulas for the diagonals for $m > k$ can be derived in the same manner. We have checked some of these diagonals, and none (except for $k = 3$, $m = 4$) appear in [7].

We now give derivations for the first six diagonals in Table 9 that occur as diagonals in Pascal's triangle. The first ($m = 1$) diagonal of *n* parts consists of all 1's, since there is only one composition of *n* with *n* parts. The diagonal of $n-1$ parts ($m = 2$) corresponds to a composition with one 2 and $n-2$ 1's for a total of $n-1$ compositions. The diagonal of $j = n-2$ parts ($m = 3$) consists of the triangle numbers, as the only compositions with $n-2$ parts are the $\text{bin}(j,2)$ compositions with two 2's and $j-2$ 1's. The diagonal of $j = n-3$ parts ($m = 4$) occurs as A000292 in [7], the tetrahedral or pyramidal numbers, and is given by $a(i) = (i+1)(i+2)(i+3)/6$, where $C_j(j+3,\hat{k}) = a(j-1)$. The partitions of $n-j=3$ are {1,1,1}, {2,1}, and {3}, which result in these partitions of *n*: three 2's and $j-3$ 1's; one 3, one 2, and $j-2$ 1's; or one 4 and $j-1$ 1's, for a total of $\text{bin}(j,3)+2\cdot\text{bin}(j,2)+j$ compositions. Algebraic simplification shows the equivalence of the 4th diagonal and sequence A000292. The diagonal of $j = n-4$ parts ($m = 5$) appears as A000332 in [7], with $a(i) = (i^4 - 6i^3 + 11i^2 - 6i)/24$, which has several interpretations, for example the number of intersection points of the diagonals of a convex *i*-gon. Arguments similar to the ones above show that $C_j(j+4,\hat{k}) = a(j+3)$. Finally, the 6th diagonal appears as A000389 in [7], with $a(i) = \text{bin}(i,5)$. Using the distributive creation method once more, it can be shown that $C_j(j+5,\hat{k}) = a(j+4)$.

For higher values of *k*, more diagonals from Pascal's triangle will occur, and in each case their formulas can be derived and shown to be equivalent to the known sequences using the distributive creation method.

Abstract

A $(1,k)$-composition of a positive integer n consists of an ordered sequence of the integers 1 and k whose sum is n. A palindromic $(1,k)$-composition is one for which the sequence is the same from left to right as from right to left. We give recursive equations and generating functions for the total number of such compositions and palindromes, and for the number of 1's, k's, "+"signs and summands in all $(1,k)$-compositions and $(1,k)$-palindromes. We look at patterns in the values for the total number of $(1,k)$-compositions and $(1,k)$-palindromes and derive recusive relations and generating functions for the number of levels, rises and drops in all $(1,k)$-compositions and $(1,k)$-palindromes.

Keywords: Compositions, palindromes.
A.M.S. Classification Number: 05A99

1. Introduction

A $(1,k)$-*composition* of a positive integer n consists of an ordered sequence of the integers 1 and k whose sum is n. A *palindromic* $(1,k)$-*composition* is one for which the sequence is the same from left to right as from right to left. For the remainder of this paper we will refer to palindromic $(1,k)$-compositions by the short-hand term $(1,k)$-*palindrome*.

Alladi and Hoggatt [1] have considered (1,2)-compositions and (1,2)-palindromes. They count the number of such compositions and palindromes, the number of summands, and the number of times either a 1 or a 2 occurs in all (1,2)-compositions and (1,2)-palindromes, respectively. Furthermore, they count the number of "+"-signs and the number of rises (a summand followed by a larger summand), levels (a summand followed by itself) and drops (a summand followed by a smaller summand) in all such compositions and palindromes, respectively. Hoggatt and Bicknell [3]

have looked at more general compositions and palindromes, namely those for which the summands are selected from a finite or countably infinite set S. For example, if only the summands 1 and 2 are allowed in the compositions, then $S = \{1, 2\}$. Hoggatt and Bicknell have derived generating functions for the number of compositions, palindromes, number of summands, "+"-signs, and the number of times a particular summand occurs in all such compositions or palindromes of n. However, since the possible values of the summands come from a very general set, they were not able to develop recurrence relations and generating functions for the number of rises, levels and drops in this setting.

We will focus on a generalization of the (1,2)-compositions, namely, we look at $(1, k)$-compositions and $(1, k)$-palindromes. In Section 2 we establish our notation and derive recurrence relations for the total number of $(1, k)$-compositions and $(1, k)$-palindromes, the number of times either a 1 or a k occurs in all $(1, k)$-compositions and $(1, k)$-palindromes, and the number of summands and "+"-signs in all $(1, k)$-compositions and $(1, k)$-palindromes of n. Furthermore, we state the generating functions for these quantities as a special case of the results in [3]. In Section 3, we investigate and give combinatorial proofs for patterns among the number of $(1, k)$-compositions and $(1, k)$-palindromes for different values of k. In Section 4 we derive recursive formulas and the generating functions for the number of levels, rises and drops in all $(1, k)$-compositions and $(1, k)$-palindromes of n.

2. Notation and basic results

We will use the following notation.

$C_{n,k}, P_{n,k}$	=	the number of $(1, k)$-compositions and $(1, k)$-palindromes of n, respectively, where $C_{0,k} = P_{0,k} = 1$ for all k
$C^{+}_{n,k}$, $P^{+}_{n,k}$	=	the number of "+" signs in all $(1, k)$-compositions and $(1, k)$-palindromes of n, respectively
$C^{\mathrm{s}}_{n,k}$, $P^{\mathrm{s}}_{n,k}$	=	the number of summands in all $(1, k)$-compositions and $(1, k)$-palindromes of n, respectively
$C^{l}_{n,k}$, $P^{l}_{n,k}$	=	the number of l's in all $(1, k)$-compositions and $(1, k)$-palindromes of n, respectively, where $l = 1$ or k
$r_{n,k}$, $l_{n,k}$, $d_{n,k}$	=	the number of rises, levels, and drops in all $(1, k)$-compositions of n, respectively
$\tilde{r}_{n,k}$, $\tilde{l}_{n,k}$, $\tilde{d}_{n,k}$	=	the number of rises, levels, and drops in all $(1, k)$-palindromes of n, respectively
$n \equiv k$, $n \not\equiv k$		denotes n and k having the same and opposite parity, respectively.

Before we derive recurrence relations for the quantities of interest, we will present different ways to create $(1,k)$-compositions and $(1,k)$-palindromes. The first method is a recursive one: for $n > k$, we create the $(1,k)$-compositions of n by either adding a 1 to the right end of the $(1,k)$-compositions of $n-1$, or by adding a k to the right end of the $(1,k)$-compositions of $n-k$. Likewise, for $(1,k)$-palindromes, we add a 1 to both sides of the $(1,k)$-palindromes of $n-2$ or a k to both sides of the $(1,k)$-palindromes of $n-2k$. We will refer to this method as the *recursive creation method*. In addition, we can also enumerate $(1,k)$-palindromes by focusing on the middle summand. Notice that the middle summand must have the same parity as n. Thus, if n is even, either there is no middle summand, and the $(1,k)$-palindrome is created by combining a $(1,k)$-composition of $n/2$ with its reverse, or the middle summand is (an even) k, combined with a $(1,k)$-composition of $(n-k)/2$ on the left and its reverse on the right. If n is odd, then either the middle summand is a 1, combined with a $(1,k)$-composition of $(n-1)/2$ on the left and its reverse on the right, or the middle summand is (an odd) k, combined with $(1,k)$-compositions of $(n-k)/2$. This observation provides for a connection between the number of $(1,k)$-compositions and $(1,k)$-palindromes.

Lemma 1 gives basic results for $(1,k)$-compositions, while Lemma 2 lists basic results for $(1,k)$-palindromes. Recall that the generating function $G_a(x)$ for a sequence $\{a_{n,k}\}_{n=0}^{\infty}$ is given by $G_a(x) = \sum_{n=0}^{\infty} a_{n,k} \cdot x^n$.

Lemma 1 *1.* $C_{n,k} = C_{n-1,k} + C_{n-k,k}$, *with* $C_{n,k} = 1$ *for* $0 \le n < k$. *Alternatively,* $C_{n,k} = \sum_{j=0}^{\lfloor n/k \rfloor} \binom{n-j(k-1)}{j}$ *and* $G_C(x) = \frac{1}{1-x-x^k}$.

2. $C^1_{n,k} = C^1_{n-1,k} + C^1_{n-k,k} + C_{n-1,k}$, *with* $C^1_{n,k} = n$ *for* $0 \le n < k$. *Alternatively,* $C^1_{n,k} = \sum_{j=0}^{\lfloor n/k \rfloor} (n - j \cdot k) \binom{n-j(k-1)}{j}$ *and* $G_{C^1}(x) = \frac{x}{(1-x-x^k)^2}$.

3. $C^k_{n,k} = C^k_{n-1,k} + C^k_{n-k,k} + C_{n-k,k}$, *with* $C^k_{n,k} = 0$ *for* $0 \le n < k$. *Alternatively,* $C^k_{n,k} = \sum_{j=0}^{\lfloor n/k \rfloor} j \binom{n-j(k-1)}{j}$ *and* $G_{C^k}(x) = \frac{x^k}{(1-x-x^k)^2}$.

4. $C^s_{n,k} = C^1_{n,k} + C^k_{n,k}$, *and* $G_{C^s}(x) = \frac{x+x^k}{(1-x-x^k)^2}$.

5. $C^+_{n,k} = C^s_{n,k} - C_{n,k}$ *for* $n \ge 1$ *with* $C^+_{0,k} = 0$, *and* $G_{C^+}(x) = \frac{(x+x^k)^2}{(1-x-x^k)^2}$.

Proof: The recurrence relation for $C_{n,k}$ follows directly from the recursive creation method. Likewise for the recurrence relations of $C^1_{n,k}$ and $C^k_{n,k}$, as we get all the 1's or k's from the $(1,k)$-compositions of $n-1$ and $n-k$, and then one additional 1 or k for each composition to which we add a 1 or k, respectively. The initial conditions for these three quantities follow easily

from the fact that the only $(1,k)$-composition of n for $n < k$ consist of n 1's. The alternative formulas for these quantities follow by counting the compositions first according to the number of k's in the $(1,k)$-compositions, and, for $C^1_{n,k}$ and $C^k_{n,k}$, by multiplying these counts by the number of 1's and k's, respectively, then summing according to the number of k's. The recurrence relation for $C^{\rm S}_{n,k}$ is obvious as each summand has to be either a 1 or a k, and the last recurrence relation follows because in each $(1,k)$-composition, the number of "+" signs is one less than the number of summands. The generating functions follow from Theorem 1.1, Theorem 1.3 and the remarks after Theorem 1.3 of [3], since the function $F(x) = \sum_{a_k \in S} x^{a_k}$ defined in [3] reduces to $F(x) = x + x^k$. □

We now derive the corresponding results for $(1,k)$-palindromes. In this case, the initial conditions depend on the parity of n and k. We will use $n = 2i$ or $n = 2i+1$ and $k = 2j$ or $k = 2j+1$, where i and j are non-negative integers.

Lemma 2 *1.* $P_{n,k} = P_{n-2,k} + P_{n-2k,k}$ *with* $P_{n,k} = 1$ *for* $0 \le n < k$, $P_{n,k} = 1$ *for* $k \le n < 2k$, $n \not\equiv k$, *and* $P_{n,k} = 2$ *for* $k \le n < 2k$, $n \equiv k$. *Alternatively,* $P_{n,k} = C_{i,k}$ *if* $n \not\equiv k$ *and* $P_{n,k} = C_{i-j,k} + C_{i,k}$ *if* $n \equiv k$, *and* $G_P(x) = \frac{1+x+x^k}{1-x^2-x^{2k}}$.

2. $P^1_{n,k} = P^1_{n-2,k} + P^1_{n-2k,k} + 2P_{n-2,k}$, *with* $P^1_{n,k} = n$ *for* $0 \le n < k$, $P^1_{n,k} = n$ *for* $k \le n \le 2k$, $n \not\equiv k$, *and* $P^1_{n,k} = 2n - k$ *for* $k \le n \le 2k$, $n \equiv k$ *with* $G_{P^1}(x) = \frac{x+2x^2+x^3+2x^{2+k}-x^{2k+1}}{(1-x^2-x^{2k})^2}$.

3. $P^k_{n,k} = P^k_{n-2,k} + P^k_{n-2k,k} + 2P_{n-2k,k}$, *with* $P^k_{n,k} = 0$ *for* $0 \le n < k$, $P^k_{n,k} = 0$ *for* $k \le n < 2k$, $n \not\equiv k$, $P^k_{n,k} = 1$ *for* $k \le n < 2k$, $n \equiv k$, $P^k_{2k,k} = 2$ *for* $n \not\equiv k$, *and* $P^k_{2k,k} = 3$ *for* $n \equiv k$ *with* $G_{P^k}(x) = \frac{x^k+2x^{2k}+x^{3k}+2x^{2k+1}-x^{2+k}}{(1-x^2-x^{2k})^2}$.

4. $P^s_{n,k} = P^1_{n,k} + P^k_{n,k}$, *with generating function* $G_{P^S}(x) = \frac{x+2x^2+x^3+x^{k+2}+x^{2k+1}+x^k+2x^{2k}+x^{3k}}{(1-x^2-x^{2k})^2}$.

5. $P^+_{n,k} = P^s_{n,k} - P_{n,k}$ *for* $n \ge 1$ *with* $P^+_{0,k} = 0$, *with* $G_{P^+}(x) = \frac{(x^2+x^{2k})(1+2x+x^2+2x^k+x^{2k})}{(1-x^2-x^{2k})^2}$.

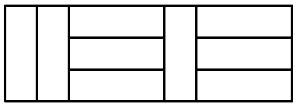
Proof: The first recurrence relation for $P_{n,k}$ follows from the recursive creation method. For the second recurrence relation, based on $(1,k)$-compositions, we need to look at the parity of n and k. If $n = 2i$, then there is either no middle summand, i.e., we get $C_{n/2,k} = C_{i,k}$ palindromes, or, if k

is also even, then we get additional $(1,k)$-palindromes with k as the middle summand, of which there are $C_{(n-k)/2,k} = C_{i-j,k}$. A similar argument can be made for $n = 2i+1$, where the middle summand is either 1 or an odd k, and there are $C_{(n-1)/2,k} = C_{i,k}$ and $C_{(n-k)/2,k} = C_{i-j,k}$ such palindromes, respectively. The recurrence relations for $P^1_{n,k}$ and $P^k_{n,k}$ follow again from the recursive creation method, except that we now get two additional 1's or k's for each palindrome of $n-2$ and $n-2k$, respectively. For all three cases, the initial conditions follow from the fact that for $n < k$, the only $(1,k)$-palindrome is the one consisting of n 1's. If $k \leq n < 2k$, then there is the $(1,k)$-palindrome of n 1's, and, if $n \equiv k$, the additional palindrome which has a k as the middle summand, together with $n-k$ 1's. For $n = 2k$, we get the $(1,k)$-palindrome consisting of two k's in addition to the two types of palindromes for $k \leq n < 2k$. The recurrence relations for $P^{\mathrm{S}}_{n,k}$ and $P^+_{n,k}$ follow exactly as in the case of $(1,k)$-compositions. Finally, the generating functions follow from Theorem 1.2, Theorem 1.4 and the remarks after Theorem 1.4 in [3]. □

3. Structures in values of $\{C_{n,k}\}_{n=0}^{\infty}$ for different k

We will now look at the sequences $\{C_{n,k}\}_{n=0}^{\infty}$ and $\{P_{n,k}\}_{n=0}^{\infty}$ for different values of k and will give combinatorial proofs of the structures exhibited in Table 1, which contains the values for $C_{n,k}$.

Note that the column for $k = 2$ in Table 1 contains the shifted Fibonacci numbers, and that the columns for $k = 3$ through $k = 9$ appear as sequences A000930, A03269, A003520, and A005708 - A005711 in [5]. There are several examples of objects that are counted by sequence A000930 ($k = 3$), and we show the equivalence of these counts to the number of (1,3)-compositions. The first example indicates that A000930 represents the number of tilings of a 3-by-n rectangle with straight trominoes, i.e., 1-by-3 tiles. It is easy to see how the two counts are related: the trominoes can only be placed vertically or as a block of three horizontal tiles. The first case corresponds to a 1 in the composition, the second to a 3, as indicated in the figure below.



$\longleftrightarrow\ 1+1+3+1+3$

Note that this process can be easily generalized to tilings of a k-by-n rectangle with 1-by-k tiles, thus showing equivalence to the number of (1,k)-compositions.

The second example indicates that A000930 represents the number of ordered partitions (= compositions) of $n-1$ consisting of 1's and 2's with no 2's adjacent. Here the correspondence between the counts is not immediately obvious, but can be easily demonstrated with an example. Since the 2's are not adjacent, each 2 is either followed by a 1, or appears as the last summand on the right. To each such composition of $n-1$, add a 1 on the right, making them compositions of n. Now replace every instance of 21 with a 3, which results in compositions of n with 1's and 3's only. This process can be reversed, thus the correspondence is one-to-one. Here is the correspondence for the example given in [5] for $n = 6$.

111111	$\longleftrightarrow$	11111	1131	$\longleftrightarrow$	1121
3111	$\longleftrightarrow$	2111	1113	$\longleftrightarrow$	1112
1311	$\longleftrightarrow$	1211	33	$\longleftrightarrow$	212

Note that this example also points to the obvious generalization: The number of $(1,k)$-compositions of n is equal to the number of compositions of $n-1$ with 1's and $(k-1)$'s, where no $(k-1)$'s are next to each other.

Sequence A000930 is also listed in [5, page 91] as an example of a third order linear recurrence, where $\bar{U}_{-n} = C_{n-1,3}$. The sequence $\bar{U}_n$ is defined by $\bar{U}_n = -\bar{U}_{n-2} + \bar{U}_{n-3}$ with initial conditions $\bar{U}_0 = \bar{U}_1 = 1$, and $\bar{U}_2 = 1$. This corresponds to initial conditions $C_{-3,3} = 1$ and $C_{-2,3} = C_{-1,3} = 0$.

Finally, there is one reference given in [5] which recognizes the sequences A000930, A03269, A003520, and A005708 - A005711 as members of a family with recurrence relation $a(n) = a(n-1) + a(n-k)$. Di Cera and Kong [2] count the number of ways to cover a linear lattice of n sites with molecules that are k sites wide, where there is no overlap of molecules, but gaps are allowed. It is easy to see how this relates to $(1,k)$-compositions — each summand k corresponds to a molecule of size k, and each summand 1 corresponds to an empty site on the lattice, as shown in the figure below:

$\longleftrightarrow \quad 1+1+3+1+3$

We will now look at patterns across columns. There are two particularly simple patterns: 1) the upper triangle of 1's; and 2) diagonals of slope -1 consisting of the same integer (from an appropriate starting point onwards). Both of these patterns are the result of the initial conditions, as they cover the cases $0 \le n < k$ and $k \le n < 2k$. For $n \ge 2k$, we notice three additional patterns: 1) pairs of repeated values (boxed); 2) diagonal sequences of slope -2 containing consecutive integers (from an appropriate starting point onwards), for example the sequence { 13, 14, 15, 16, 17,....} marked with a $\star$; and 3) sequences on diagonals of slope -3, whose terms have increasing

n \ k	2	3	4	5	6	7	8	9	10

Table 1: The number of $(1, k)$-compositions of n

differences, for example the sequence {21, 28, 36, 45, ...} (also in bold). The following theorem makes these patterns more precise.

Theorem 3 *1. For any k, $C_{3k+2,k+1} = C_{3k,k}$.*

2. For $2k \leq n < 3k$, $C_{n+2,k+1} = C_{n,k} + 1$.

3. For $3k \leq n < 4k$, $C_{n+3,k+1} = C_{n,k} + n - 2k + 4$.

Proof: 1. To show the first equality, we give a one-to-one correspondence between the respective compositions. Since $n = 3k$, the $(1, k)$-compositions of $3k$ can have either no k, one k, 2 k's or 3 k's, and the $(1,k+1)$-compositions of $3k+2$ can have either no $k+1$, one $k+1$ or two $(k+1)$'s. There is exactly one composition without any k or $k+1$, respectively, the composition of all 1's. The compositions of $3k$ with exactly two k's are in one-to-one correspondence with those of $3k+2$ containing exactly two $(k+1)$'s, as each k can be replaced by $k+1$. The compositions of $3k$ with

exactly one k have $2k+1$ summands, for a total of $2k+1$ such compositions, and there is only one composition of $3k$ that has exactly 3 k's. These are matched by the compositions of $3k+2$ with exactly one $k+1$, of which there are $(3k+2)-(k+1)+1 = 2k+2$. Below is an example illustrating these correspondences for $k=2$ and $n=6$:

$$\begin{array}{ccc} 111111 & \longleftrightarrow & 11111111 \\ 21111 & \longleftrightarrow & 311111 \\ 12111 & \longleftrightarrow & 131111 \\ 11211 & \longleftrightarrow & 113111 \\ 11121 & \longleftrightarrow & 111311 \\ 11112 & \longleftrightarrow & 111131 \\ 222 & \longleftrightarrow & 111113 \end{array} \qquad \begin{array}{c} 2211 \longleftrightarrow 3311 \\ 2121 \longleftrightarrow 3131 \\ 2112 \longleftrightarrow 3113 \\ 1221 \longleftrightarrow 1331 \\ 1212 \longleftrightarrow 1313 \\ 1122 \longleftrightarrow 1133 \end{array}$$

2. For the second equality, we match up the two types of compositions in the same way. Note however, that now there is no $(1,k)$-composition of n with three k's, thus there is no match for one of the $(1,\, k+1)$-compositions of $n+2$ with exactly one $k+1$.
3. We utilize the explicit formula for counting $(1,k)$-compositions, namely $C_{n,k} = \sum_{j=0}^{\lfloor n/k \rfloor} \binom{n-j(k-1)}{j}$. For $3k \le n < 4k$, $C_{n,k} = \sum_{j=0}^{3} \binom{n-j(k-1)}{j}$, since there can be at most three k's in the $(1,k)$-compositions of n. Likewise, for this range of values for n, there can be at most three $(k+1)$'s in the $(1,\, k+1)$-compositions of $n+3$, thus $C_{n+3,k+1} = \sum_{j=0}^{3} \binom{n+3-j\cdot k}{j}$. We now just compare the different counts:

$$C_{n,k} = 1 + (n-k+1) + \binom{n-2k+2}{2} + \binom{n-3k+3}{3}$$

and (after simplification)

$$C_{n+3,k+1} = 1 + (n+3-k) + \binom{n+3-2k}{2} + \binom{n+3-3k}{3}.$$

Comparing the respective summands, we see that the first and last ones are identical, the second ones differ by 2, and the third summands are of the form $\binom{m}{2}$ and $\binom{m+1}{2}$, for $m = n-2k+2$. Straightforward computation shows that the difference between these two terms is m, and thus, $C_{n+3,k+1} = C_{n,k} + 2 + n - 2k + 2$, which gives the desired result. □

When looking for patterns in the values for $P_{n,k}$, we need to distinguish between odd and even values of n, as they have different formulas. Thus, the sequence $\{P_{n,k}\}_{n=0}^{\infty}$ is the result of interleaving the two sequences $\{P_{2i+1,k}\}_{i=0}^{\infty}$ and $\{P_{2i,k}\}_{i=0}^{\infty}$. By Lemma 2, part 1, the subsequence for which $n \not\equiv k$ agrees with the sequence for the number of $(1,k)$-compositions.

Furthermore, Lemma 2, part 1 also provides for an easy means to compute the generating function for the subsequence for which $n \equiv k$, since $P_{n,k} = C_{i-j,k} + C_{i,k}$, where $n = 2i$ or $n = 2i+1$ and $k = 2j$ or $k = 2j+1$. Using standard methods for generating functions together with Lemma 1, we get that the generating function for $\hat{P}_{i,k} := P_{2i,k}$ or $\hat{P}_{i,k} := P_{2i+1,k}$ is given by $G_{\hat{P}}(x) = \frac{1+x^j}{(1-x-x^k)}$.

We have tested the sequences for $k = 2, \ldots, 10$ in the Online Encyclopedia of Integer Sequences [5], both using the full sequences and the subsequences for which $n \equiv k$. For $k = 2$, $\{P_{n,2}\}_{n=0}^{\infty}$ consists of two interleaved Fibonacci sequences, and the full sequence is also referenced in [5] as A053602, with a recurrence of the form $a(n) = a(n-1) - (-1)^n a(n-2)$, where $a(n+1) = P_{n,2}$. Thus we get the following two cases: $P_{n,2} = P_{n-1,2} + P_{n-2,2}$ for n even, and $P_{n,2} = P_{n-1,2} - P_{n-2,2}$ for n odd. These recurrences can be explained in terms of the (1,2)-palindromes by using an alternative construction, namely modifying the middle summands rather than the two ends of the palindromes. Note that for even n, the palindrome either has middle summand 2 or an even split; for odd n, the middle summand always is a 1. We can create the (1,2)-palindromes for even n by either increasing the middle summand of a (1,2)-palindrome of $n-1$ (which gives middle summand 2), or by modifying the center of a (1,2)-palindrome of $n-2$, inserting either $1+1$ into those with an even split, or replacing the middle summand of 2 by $2+2$. Thus, $P_{n,2} = P_{n-1,2} + P_{n-2,2}$ for n even. If n is odd, then we get the (1,2)-palindromes of n by inserting a 1 into the center of those (1,2)-palindromes of $n-1$ that have an even split. The number of (1,2)-palindromes of $n-1$ that have a 2 in the center (and thus need to be subtracted) were created by increasing the middle summand of the palindromes of $n-2$ by 1. Thus, $P_{n,2} = P_{n-1,2} - P_{n-2,2}$ for n odd.

For $k \geq 3$, none of the full sequences are listed in [5]. Of the subsequences with $n \equiv k$, only the sequence for $k = 3$ is listed in [5], as A058278, with $P_{2i+1,3} = a(i+2)$.

When looking for patterns across columns, there are several ways to arrange the tables of values. One can look at the complete table of values, which would not show patterns as easily due to the interleaving of the two subsequences that have different formulas. If one looks at the subsequences for odd and even n separately, then there are two choices: 1) making separate tables for sequences in which $n \equiv k$ and $n \not\equiv k$, or 2) making separate tables for the odd and even values of n. We have looked at both choices, and the patterns that arise are similar to the case for $(1,k)$-compositions.

4. Rises, levels and drops in $(1,k)$-compositions

Alladi and Hoggatt have counted the number of rises, levels and drops for (1,2)-compositions and (1,2)-palindromes [1]. We will now look at the

general case. Since for each non-palindromic $(1,k)$-composition a corresponding $(1,k)$-composition in reverse order exists, any rise will be matched by a drop and vice versa. In $(1,k)$-palindromes, symmetry provides for the match within the palindrome. Furthermore, each "+"-sign corresponds to either a rise, a level, or a drop, and therefore

$$r_{n,k} = d_{n,k} \text{ and } C^{+}_{n,k} = r_{n,k} + l_{n,k} + d_{n,k}. \tag{1}$$

Likewise, these formulas hold for $(1,k)$-palindromes. We first give the results for $(1,k)$-compositions.

Theorem 4 *1. For $n > k$, $r_{n,k} = r_{n-1,k}+r_{n-k,k}+C_{n-k-1,k}$, with $r_{n,k} = 0$ for $n \leq k$, and generating function $G_r(x) = \sum_{k=0}^{\infty} r_{n,k} \cdot x^n = \frac{x^{k+1}}{(1-x-x^k)^2}$.*
2. For $n > k$, $l_{n,k} = l_{n-1,k} + l_{n-k,k} + C_{n-2,k} + C_{n-2k,k}$, with $l_{n,k} = n-1$ for $n \leq k$, and generating function $G_l(x) = \sum_{k=0}^{\infty} l_{n,k} \cdot x^n = \frac{x^2+x^{2k}}{(1-x-x^k)^2}$.

Proof: For $n < k$, the only $(1,k)$-composition of n consists of all 1's, and if $n = k$, there is an additional composition consisting of only k. In either case, no rises occur. If $n > k$, then we look at the creation of the compositions of n from those of $n-1$ and $n-k$. If a 1 is added, no new rises occur. If a k is added, then additional rises are created if the $(1,k)$-composition of $n-k$ ends in 1. These are exactly the $(1,k)$-compositions of $n-k-1$, and one new rise is created for each of these, which gives the recursion. To get the generating function, we multiply each term in the recurrence relation by x^n, then sum over $n \geq 0$. (Note that the recurrence relation is also valid for $n \leq k$, since all terms are equal to zero.) Expressing the series in terms of $G_r(x)$ and $G_C(x)$ and using Theorem 1 leads to

$$G_r(x) = \frac{x^{k+1}G_C(x)}{(1-x-x^k)} = \frac{x^{k+1}}{(1-x-x^k)^2}.$$

The formula for the levels follows from a similar argument. For $n \leq k$, levels occur only in the $(1,k)$-compositions of all 1's, and there are $n-1$ of those. When creating $(1,k)$-compositions of n from those of $n-1$ and $n-k$, additional levels are created when adding either a 1 to a $(1,k)$-composition of $n-1$ ending in 1, or adding a k to a $(1,k)$-composition of $n-k$ ending in k. There are $C_{n-1-1,k} + C_{n-k-k,k}$ new levels, which gives the recurrence relation. Using Eq. 1, the generating functions is computed as $G_l(x) = G_{C^+}(x) - 2G_r(x) = \frac{x^2+x^{2k}}{(1-x-x^k)^2}$. □

We now derive the corresponding results for $(1,k)$-palindromes. As before, the initial conditions depend on the parity of n and k. Recall that $n \equiv k$ denotes n and k having the same parity.

Theorem 5 *1. For $n \geq 2(k+1)$, $\tilde{r}_{n,k} = \tilde{r}_{n-2,k} + \tilde{r}_{n-2k,k} + 2P_{n-2(k+1),k}$, with initial conditions*

$$\tilde{r}_{n,k} = \begin{cases} 0 & \text{for } n \leq k \\ 1 & \text{for } k < n \leq 2k, n \equiv k \\ 0 & \text{for } k < n \leq 2k, n \not\equiv k \\ 2 & \text{for } n = 2k+1, n \equiv k \\ 1 & \text{for } n = 2k+1, n \not\equiv k \end{cases},$$

with $G_{\tilde{r}}(x) = \sum_{k=0}^{\infty} \tilde{r}_{n,k} \cdot x^n = \frac{x^{k+1}(x-x^3+x^k-x^{3k}+2x^{k+1}+x^{k+2}+x^{2k+1})}{(1-x^2-x^{2k})^2}$.

Proof: As in the case of $(1,k)$-compositions, there are no rises for $n \leq k$. For $n < k < 2k$, the $(1,k)$-palindromes either consist of all 1's, or can have one occurrence of k, which must be in the center. For this to occur, n and k need to have the same parity, and then there is one rise. If $n = 2k$, we get the additional palindrome $k + k$, which does not have a rise. Finally, for $n = 2k+1$, we get either all 1's, or the palindrome $k+1+k$, and, if n and k have the same parity, the palindrome with a k at the center, combined with all 1's. The recurrence relation is derived similarly to the proof of Theorem 4. When adding a 1 to the $(1,k)$-palindromes of $n-2$, an additional rise occurs on the left side of those $(1,k)$-palindromes which end in k, of which there are $P_{n-2-2k,k}$. Likewise, one additional rise occurs on the right side when adding k on both sides of the $(1,k)$-palindromes of $n-2k$ which end in 1, of which there are $P_{n-2k-2,k}$.

To compute the generating function, we define $\hat{P}_{n,k}$ as $P_{n,k}$ for $n \geq 0$, and $\hat{P}_{-1,k} = \hat{P}_{-k,k} = 1/2$. Note that $G_{\hat{P}}(x) = G_P(x) + \frac{1}{2}x^{-1} + \frac{1}{2}x^{-k}$. We will show that $\tilde{r}_{n,k} = \tilde{r}_{n-2,k} + \tilde{r}_{n-2k,k} + 2\hat{P}_{n-2(k+1),k}$ for all n. It is clear that this recurrence relation holds for $n > 2k+1$, and we need to check that it also holds for $n \leq 2k+1$. The following table gives the values for the different cases:

case	n	parity	$\tilde{r}_{n,k}$	$\tilde{r}_{n-2,k}$	$\tilde{r}_{n-2k,k}$	$\hat{P}_{n-2(k+1),k}$
1	$\leq k$		0	0	0	0
2	$k+1$	(opp)	0	0	0	0
3	$k+2$	(same)	1	0	0	1/2
4	$k+2 < n \leq 2k$	same	1	1	0	0
5	$k+2 < n \leq 2k$	opp	0	0	0	0
6	$2k+1$	same	2	1	0	1/2
7	$2k+1$	opp	1	0	0	1/2

It now becomes clear why we made the definition $\hat{P}_{-1,k} = \hat{P}_{-k,k} = 1/2$. Note also that for cases 4 and 5, $-k < n-2(k+1) \leq -2$. Multiplying each

term in the recurrence relation by x^n, then summing over $n \geq -k$, we get

$$\begin{aligned}\sum_{n\geq -k} \tilde{r}_{n,k} \cdot x^n &= x^2 \sum_{n\geq -k} \tilde{r}_{n-2,k} \cdot x^{n-2} + x^{2k} \sum_{n\geq -k} \tilde{r}_{n-2k,k} \cdot x^{n-2k} \\ &\quad +2 \cdot x^{2(k+1)} \sum_{n\geq -k} \hat{P}_{n-2(k+1),k} \cdot x^{n-2(k+1)}.\end{aligned}$$

Since $\tilde{r}_{n,k} = 0$ for $n \leq 0$,

$$G_{\tilde{r}}(x)(1 - x^2 - x^{2k}) = 2 \cdot x^{2(k+1)} G_{\hat{P}}(x),$$

which after simplification gives the result. □

Acknowledgments

We would like to thank Ralph Grimaldi who suggested that we explore this generalization.

Cuisenaire rods ("c-rods") are a set of rectangular solids with cross-section of 1 cm by 1 cm squares, color-coded by length, and varying from 1 cm long white rods and 2 cm long red rods to 10 cm long orange rods. A variety of number-theoretic and combi natorial geometry problems can be modeled using the c-rods. In this paper we explore the number of ways of tiling 1 x n, 2 x n, and 3 x n rectangles with 1 x 1 and 1 x 3 c-rods. When the tiled rectangle is 1 by n, the tiling problem is equival ent to the number theory question of how many compositions, i.e. ordered partitions, of n use only 1's and 3's.

Key words: recurrence relations, tiling problems, Fibonacci numbers, Pascal's Triangle, using manipulatives to motivate mathematical discoveries

1. **Introduction**

Several papers in the last few years [1, 2. 5-8] have presented results on tilings of integer rectangles by rectangles of unit width. Most of this work was initially inspired by using a set of Cuisenaire rods ("c-rods") to explore discrete math questions at NSF-sponsored Project PROMPT (Professors Rethinking Options in Mathematics for Prospective Teachers) workshops. A Cuisenaire rod of length n is a 1xn rectangular solid. Such rods, in sets from n=1 to n=10, are employed in elementary grades to study properties of numbers. The rods in a set are color-coded by length, with white corresponding to n=1, red to n=2, green to n=3, etc. Chinn, et al, [2] explored a number of results when all lengths of rods are allowed. Brigham, et al, [1] restricted thei r attention to white and red rods and used them to derive a variety of relationship involving Fibonacci numbers. Here we will explore results derived from tilings with white and green rods.

One of the more fascinating aspects of studying tilings by Cuisenaire rods is the insight that working

with the rods gives to multiple approaches to the same problem. In this paper, we begin by presenting several methods to count the number of ways G(n) i n which white and green rods tile a 1xn rectangle. **(*)**

2. **Forming Trains**

In Cuisenaire rod terms, a tiling of a 1xn rectangle with Cuisenaire rods is often called a train of length n.

For n=1, 2, the only possible train uses just white rods. For n=3, there are two such trains. For n=4, there are 3 of them.

(*)In this paper, we consider this as a tiling problem. It could also be viewed as a number theory question, namly, how many compositions of n use only 1's and 3's?

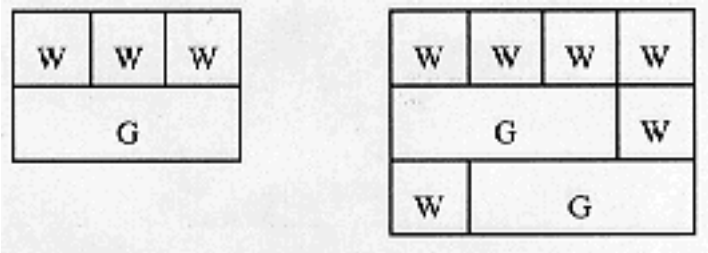

Figure 1. White/Green Trains of Length 3 and 4

A partial table of values follows.

n	0	1	2	3	4	5	6	7	8	9
G(n)	1	1	1	2	3	4	6	9	13	19

Table 1.

Remark 1. G(n) = G(n-1) + G(n-3) (1)

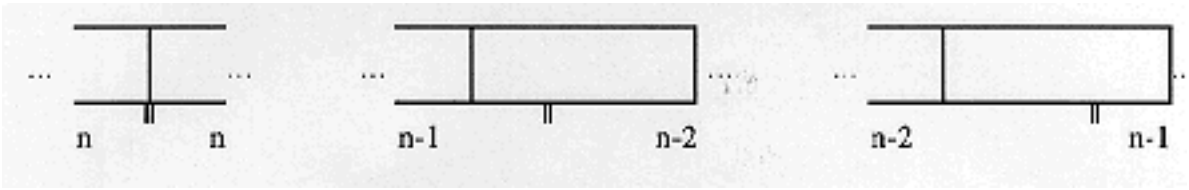
Proof. A train either ends in a white rod, added to any of trains of length , or ends in a green rod added to any of trains of length .

Corollary. Since G(n-1) = G(n-2) + G(n-4), we also have

$$G(n) = G(n-2) + G(n-3) + G(n-4)$$

3. **Some Relations Among the G(n)'s**

Consider a train of length 2n and the middle point: this can be a split between two rods, or can be spanned by a green rod in either of two positions:



Thus,

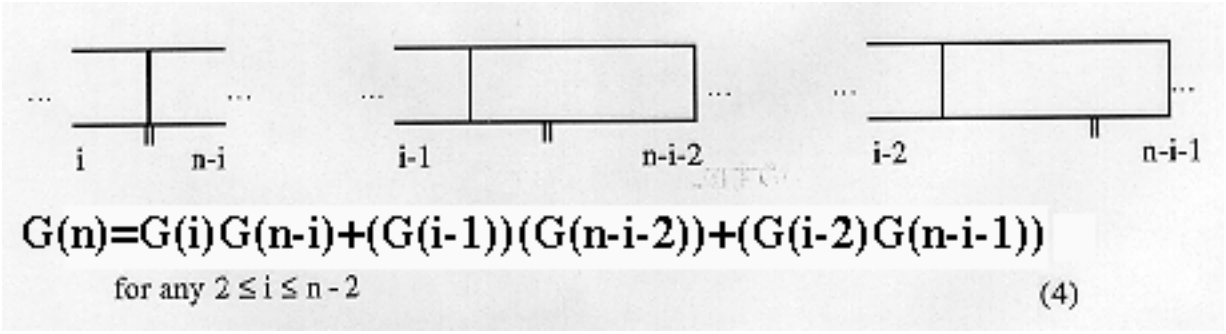
$$G(2n) = G(n)^2 + 2\big(G(n-1)G(n-2)\big) \quad n \geq 2 \quad (2).$$

.

Likewise from a train of length 2n + 1, again considering the nth position following the unit, we see that

$$G(2n+1) = G(n)G(n+1) + G(n)(G(n-2)) + G(n-1)^2 \quad n \geq 2$$

Similarly, a train of length n can be cut following the ith unit with a comparable three outcomes, thus:



4. **A Combinatorial point of view**

The sequence G(n) is known [3,4] and occurs as equation M0571 in [9]. In the references given in Sloane, the sequence G(n) is derived as a diagonal in Pascal's triangle. In particular, the "Fibonacci diagonals" in Pascal's triangle consist of the numbe rs along lines of slope as shown in Figure 2 below. The sum of the numbers along these diagonals are the Fibonacci numbers.

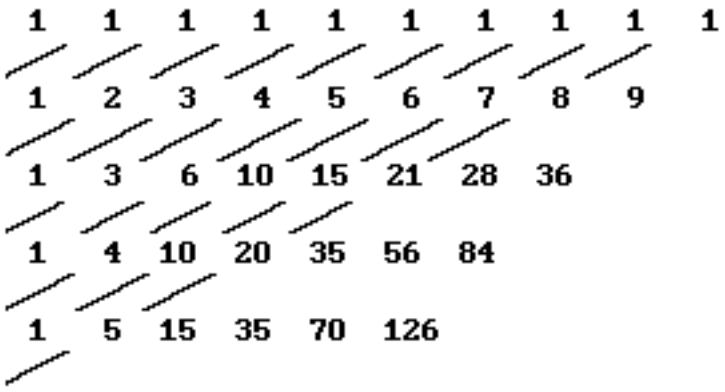


Figure 2. The Fibonacci diagonals

If, instead, you sum numbers along lines of slope 1/3, the white/green train numbers appear. These lines are shown in Figure 3.

The motivations for this connection to Fibonacci diagrams comes through working with Cuisenaire rods.

The rods chosen may have from I=0 to i=$\left\lceil \frac{n}{3} \right\rceil$ green rods with white rods. These rods may be arranged in $\binom{n-2i}{i}$ ways.

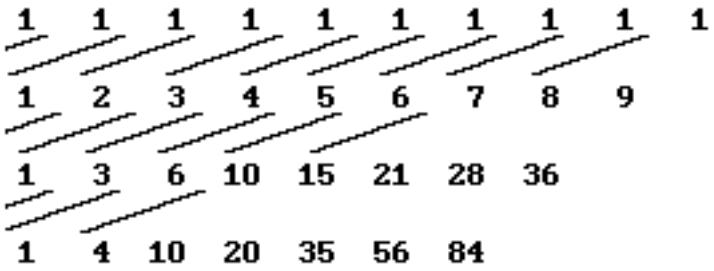

Figure 3. The diagonals of slope 1/3

Thus,

$$G(n) = \sum_{i=0}^{\lfloor \frac{n}{3} \rfloor} \binom{n-2i}{i} \quad (5)$$

Yet another equation can be derived by a focus on green rods. In particular, if there are any green rods in a train, the first one can occur starting after i white rods, . There is only one way to fill the portion with no green rods, and ways to fill t he end. There is also one train of all white rods. Thus,

$$G(n) = 1 + \sum_{i=0}^{n-3} G(n-i-3) = 1 + \sum_{i=0}^{n-3} G(i) \quad (6)$$

i.e., G(n) = 1 + G(n-3 + G(n-4) + ... + G(1) + G(0) (7)

This result can also be derived directly from the recurrence relation (1).

5. **Tilings of Rectangles**

Let us now consider a few results regarding tiling wider rectangles. We will use the notation to denote the number of ways to tile a rectangle that is n units long and i units wide using white and green rods. Clearly by rotational symmetry. This resu lt can be used to calculate for small values of i.

Remark 2. The number of tilings of a 3xn rectangle using only green rods = .

Proof: If one horizontal rod is used, three of them must be stacked on top of one another. Thus, the whole tiling is determined by the top row where a green rod in a train corresponds to 3 horizontal rods and a white rod in a train corresponds to a vert ical green rod.

The number of green/white tilings of a 2xn rectangle satisfies G(n,2) = G(n,1)*G(n,1) , since no rods can cross between the two rows. A partial table of these values is given below.

n	0	1	2	3	4	5	6	7	8	9
G(n,2)	1	1	1	4	9	16	36	81	169	289

Table 2

Let us next consider tilings of a nx3 rectangle with white/green rods. If no green rod is placed vertically, there are $[G(n,1)]^3$ possible tilings. If there are vertical green rods, and the first one occurs after i positions , then the ix3 r ectangle to the left can be filled ways and the by 3 rectangle to the right can be filled $[G(i,1)]^3$ ways. Thus,

$$G(n,3) = (G(n,1))^3 + \sum_{i=0}^{n-1} (G(i,1))^3 \bullet G(n-i-1,3) . \quad (8)$$

Note the slight similarity between this recurrence relation and the one that generates Catalan numbers. A partial table of values is given below.

n	0	1	2	3	4
G(n,3)	1	2	4	15	29

Table 3

Again, considering nx3 rectangles with white and green rods, there are a variety of things that can happen in one vertical position (as considered from either the right end or the left end of the rectangle) that could be used for some recursive ways of ex tending trains. In particular, there could be

1. A clear break.
2. Just one green extending one position out -- in any of 3 rows.
3. One green extending two units out -- in any of 3 ways.
4. Two greens extending one unit each (3 ways to arrange).
5. Two greens extending two units each (3 ways to arrange).
6. One green extending two units, one extending one unit (6 ways to arrange).
7. Two greens extending one unit each, one green extending two units (3 ways).
8. Two greens extending two units each, one green extending one unit (3 ways).

A recursive procedure could be established for generating all the trains, in a fashion similar to what Hare [6] did for 3 x n rectangles using white and red rods. The multiplication of possibilities created by having a longer second-color rod seems to ma ke this method too cumbersome to pursue here, although clearly a computer program could be established to generate the tilings or, at least, to count how many there are.

GENERALISED PATTERN AVOIDANCE

ANDERS CLAESSON

Abstract. Recently, Babson and Steingrímsson have introduced generalised permutation patterns that allow the requirement that two adjacent letters in a pattern must be adjacent in the permutation. We will consider pattern avoidance for such patterns, and give a complete solution for the number of permutations avoiding any single pattern of length three with exactly one adjacent pair of letters. For eight of these twelve patterns the answer is given by the Bell numbers. For the remaining four the answer is given by the Catalan numbers. We also give some results for the number of permutations avoiding two different patterns. These results relate the permutations in question to Motzkin paths, involutions and non-overlapping partitions. Furthermore, we define a new class of set partitions, called monotone partitions, and show that these partitions are in one-to-one correspondence with non-overlapping partitions.

1. Introduction

In the last decade a wealth of articles has been written on the subject of pattern avoidance, also known as the study of "restricted permutations" and "permutations with forbidden subsequences". Classically, a pattern is a permutation $\sigma \in \mathcal{S}_k$, and a permutation $\pi \in \mathcal{S}_n$ avoids σ if there is no subsequence in π whose letters are in the same relative order as the letters of σ. For example, $\pi \in \mathcal{S}_n$ avoids 132 if there is no $1 \leq i < j < k \leq n$ such that $\pi(i) < \pi(k) < \pi(j)$. In [4] Knuth established that for all $\sigma \in \mathcal{S}_3$, the number of permutations in $\mathcal{S}_n$ avoiding σ equals the nth Catalan number, $C_n = \frac{1}{1+n}\binom{2n}{n}$. One may also consider permutations that are required to avoid several patterns. In [5] Simion and Schmidt gave a complete solution for permutations avoiding any set of patterns of length three. Even patterns of length greater than three have been considered. For instance, West showed in [8] that permutations avoiding both 3142 and 2413 are enumerated by the Schröder numbers, $S_n = \sum_{i=0}^{n} \binom{2n-i}{i} C_{n-i}$.

In [1] Babson and Steingrímsson introduced generalised permutation patterns that allow the requirement that two adjacent letters in a pattern must be adjacent in the permutation. The motivation for Babson and Steingrímsson in introducing these patterns was the study of Mahonian statistics, and they showed that essentially all Mahonian permutation statistics in the literature can be written as linear combinations of such patterns. An example of a generalised pattern is $(a\text{-}cb)$. An $(a\text{-}cb)$-subword of a permutation $\pi = a_1 a_2 \cdots a_n$ is a subword $a_i a_j a_{j+1}$, $(i < j)$, such that $a_i < a_{j+1} < a_j$. More generally, a pattern p is a word over the alphabet $a < b < c < d \cdots$ where two adjacent letters may or may not be separated by a dash. The absence of a dash between two adjacent letters in a p indicates that the corresponding letters in a p-subword of a permutation must be adjacent. Also, the ordering of the letters in the p-subword must match the ordering of the letters in the pattern. This definition, as well as any other definition in the introduction, will be stated rigorously in Section 2. All classical patterns are generalised patterns where each pair of adjacent letters is separated by a dash. For example, the generalised pattern equivalent to 132 is $(a\text{-}c\text{-}b)$.

Date: July 29, 2002.

We extend the notion of pattern avoidance by defining that a permutation avoids a (generalised) pattern p if it does not contain any p-subwords. We show that this is a fruitful extension, by establishing connections to other well known combinatorial structures, not previously shown to be related to pattern avoidance. The main results are given below.

P	$\lvert\mathcal{S}_n(P)\rvert$	*Description*
a-bc	B_n	Partitions of $[n]$
a-cb	B_n	Partitions of $[n]$
b-ac	C_n	Dyck paths of length $2n$
a-bc, ab-c	B_n^*	Non-overlapping partitions of $[n]$
a-bc, a-cb	I_n	Involutions in $\mathcal{S}_n$
a-bc, ac-b	M_n	Motzkin paths of length n

Here $\mathcal{S}_n(P) = \{\pi \in \mathcal{S}_n : \pi \text{ avoids } p \text{ for all } p \in P\}$, and $[n] = \{1, 2, \dots, n\}$. When proving that $|\mathcal{S}_n(a\text{-}bc, ab\text{-}c)| = B_n^*$ (the nth Bessel number), we first prove that there is a one-to-one correspondence between $\{a\text{-}bc, ab\text{-}c\}$-avoiding permutations and *monotone partitions*. A partition is monotone if its non-singleton blocks can be written in increasing order of their least element and increasing order of their greatest element, simultaneously. This new class of partitions is then shown to be in one-to-one correspondence with non-overlapping partitions.

2. Preliminaries

By an *alphabet* X we mean a non-empty set. An element of X is called a *letter*. A *word* over X is a finite sequence of letters from X. We consider also the *empty word*, that is, the word with no letters; it is denoted by ϵ. Let $x = x_1x_2\cdots x_n$ be a word over X. We call $|x| := n$ the *length* of x. A *subword* of x is a word $v = x_{i_1}x_{i_2}\cdots x_{i_k}$, where $1 \le i_1 < i_2 < \cdots < i_k \le n$. A *segment* of x is a word $v = x_ix_{i+1}\cdots x_{i+k}$. If X and Y are two linearly ordered alphabets, then two words $x = x_1x_2\cdots x_n$ and $y = y_1y_2\cdots y_n$ over X and Y, respectively, are said to be *order equivalent* if $x_i < x_j$ precisely when $y_i < y_j$.

Let $X = A \cup \{\text{-}\}$ where A is a linearly ordered alphabet. For each word x let $\bar{x}$ be the word obtained from x by deleting all dashes in x. A word p over X is called a *pattern* if it contains no two consecutive dashes and $\bar{p}$ has no repeated letters. By slight abuse of terminology we refer to the *length of a pattern* p as the length of $\bar{p}$. If the ith letter in p is a dash precisely when the ith letter in q is a dash, and p and q are order equivalent, then p and q are *equivalent*. In what follows all patterns will be over the alphabet $\{a, b, c, d, \dots\} \cup \{\text{-}\}$ where $a < b < c < d < \cdots$.

Let $[n] := \{1, 2, \dots, n\}$ (so $[0] = \emptyset$). A *permutation* of $[n]$ is bijection from $[n]$ to $[n]$. Let $\mathcal{S}_n$ be the set of permutations of $[n]$. We shall usually think of a permutation π as the word $\pi(1)\pi(2)\cdots\pi(n)$ over the alphabet $[n]$. In particular, $\mathcal{S}_0 = \{\epsilon\}$, since there is only one bijection from $\emptyset$ to $\emptyset$, the empty map. We say that a subword σ of π is a *p-subword* if by replacing (possibly empty) segments of π with dashes we can obtain a pattern q equivalent to p such that $\bar{q} = \sigma$. However, all patterns that we will consider will have a dash at the beginning and one at the end. For convenience, we therefore leave them out. For example, $(a\text{-}bc)$ is a pattern, and the permutation 491273865 contains three $(a\text{-}bc)$-subwords, namely 127, 138, and 238. A permutation is said to be *p-avoiding* if it does not contain any p-subwords. Define $\mathcal{S}_n(p)$ to be the set of p-avoiding permutations in $\mathcal{S}_n$ and, more generally, $\mathcal{S}_n(A) = \bigcap_{p\in A} \mathcal{S}_n(p)$.

We may think of a pattern p as a permutation statistic, that is, define $p\,\pi$ as the number of p-subwords in π, thus regarding p as a function from $\mathcal{S}_n$ to $\mathbb{N}$. For example, $(a\text{-}bc)\,491273865 = 3$. In particular, π is p-avoiding if and only if $p\,\pi = 0$. We say that

two permutation statistics stat and stat$'$ are *equidistributed* over $A \subseteq \mathcal{S}_n$, if

$$\sum_{\pi \in A} x^{\operatorname{stat} \pi} = \sum_{\pi \in A} x^{\operatorname{stat}' \pi}.$$

In particular, this definition applies to patterns.

Let $\pi = a_1 a_2 \cdots a_n \in \mathcal{S}_n$. An i such that $a_i > a_{i+1}$ is called a *descent* in π. We denote by $\operatorname{des} \pi$ the number of descents in π. Observe that des can be defined as the pattern (ba), that is, $\operatorname{des} \pi = (ba)\pi$. A *left-to-right minimum* of π is an element a_i such that $a_i < a_j$ for every $j < i$. The number of left-to-right minima is a permutation statistic. Analogously we also define *left-to-right maximum*, *right-to-left minimum*, and *right-to-left maximum*.

In this paper we will relate permutations avoiding a given set of patterns to other better known combinatorial structures. Here follows a brief description of these structures. Two excellent references on combinatorial structures are [7] and [6].

Set partitions. A *partition* of a set S is a family, $\pi = \{A_1, A_2, \ldots, A_k\}$, of pairwise disjoint non-empty subsets of S such that $S = \cup_i A_i$. We call A_i a *block* of π. The total number of partitions of $[n]$ is called a *Bell number* and is denoted B_n. For reference, the first few Bell numbers are

$$1, 1, 2, 5, 15, 52, 203, 877, 4140, 21147, 115975, 678570, 4213597.$$

Let $S(n, k)$ be the number of partitions of $[n]$ into k blocks; these numbers are called the *Stirling numbers of the second kind*.

Non-overlapping partitions. Two blocks A and B of a partition π *overlap* if

$$\min A < \min B < \max A < \max B.$$

A partition is *non-overlapping* if no pairs of blocks overlap. Thus

$$\pi = \{\{1, 2, 5, 13\}, \{3, 8\}, \{4, 6, 7\}, \{9\}, \{10, 11, 12\}\}$$

is non-overlapping. A pictorial representation of π is

$\pi =$ 
Let B_n^* be the number of non-overlapping partitions of $[n]$; this number is called the nth *Bessel number* [3, p. 423]. The first few Bessel numbers are

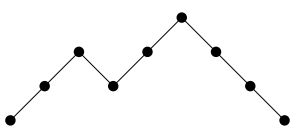
$$1, 1, 2, 5, 14, 43, 143, 509, 1922, 7651, 31965, 139685, 636712.$$

We denote by $S^*(n, k)$ the number of non-overlapping partitions of $[n]$ into k blocks.

Involutions. An *involution* is a permutation which is its own inverse. We denote by I_n the number of involutions in $\mathcal{S}_n$. The sequence $\{I_n\}_0^\infty$ starts with

$$1, 1, 2, 4, 10, 26, 76, 232, 764, 2620, 9496, 35696, 140152.$$

Dyck paths. A *Dyck path* of length $2n$ is a lattice path from $(0, 0)$ to $(2n, 0)$ with steps $(1, 1)$ and $(1, -1)$ that never goes below the x-axis. Letting u and d represent the steps $(1, 1)$ and $(1, -1)$ respectively, we code such a path with a word over $\{u, d\}$. For example, the path

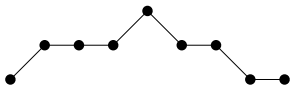


is coded by *uuduuddd*. A *return step* in a Dyck path δ is a d such that $\delta = \alpha u \beta d \gamma$, for some Dyck paths α, β, and γ. A useful observation is that every non-empty Dyck path δ can be uniquely decomposed as $\delta = u\alpha d\beta$, where α and β are Dyck paths. This is the so-called *first return decomposition* of δ.

The nth *Catalan number* $C_n = \frac{1}{n+1}\binom{2n}{n}$ counts the number of Dyck paths of length $2n$. The sequence of Catalan numbers starts with

$$1, 1, 2, 5, 14, 42, 132, 429, 1430, 4862, 16796, 58786, 208012.$$

Motzkin paths. A *Motzkin path* of length n is a lattice path from $(0, 0)$ to $(n, 0)$ with steps $(1, 0)$, $(1, 1)$, and $(1, -1)$ that never goes below the x-axis. Letting ℓ, u, and d represent the steps $(1, 0)$, $(1, 1)$, and $(1, -1)$ respectively, we code such a path with a word over $\{\ell, u, d\}$. For example, the path



is coded by $u\ell\ell ud\ell d\ell$. If δ is a non-empty Motzkin path, then δ can be decomposed as $\delta = \ell\gamma$ or $\delta = u\alpha d\beta$, where α, β and γ are Motzkin paths.

The nth *Motzkin number* M_n is the number of Motzkin paths of length n. The first few of the Motzkin numbers are

$$1, 1, 2, 4, 9, 21, 51, 127, 323, 835, 2188, 5798, 15511.$$

3. Three classes of patterns

Let $\pi = a_1 a_2 \cdots a_n \in \mathcal{S}_n$. Define the *reverse* of π as $\pi^r := a_n \cdots a_2 a_1$, and define the *complement* of π by $\pi^c(i) = n + 1 - \pi(i)$, where $i \in [n]$.

Proposition 1. *With respect to being equidistributed, the twelve pattern statistics of length three with one dash fall into the following three classes.*

(i) *a-bc, c-ba, ab-c, cb-a.*
(ii) *a-cb, c-ab, ba-c, bc-a.*
(iii) *b-ac, b-ca, ac-b, ca-b.*

Proof. The bijections $\pi \mapsto \pi^r$, $\pi \mapsto \pi^c$, and $\pi \mapsto (\pi^r)^c$ give the equidistribution part of the result. Calculations show that these three distributions differ pairwise on $\mathcal{S}_4$. □

4. Permutations avoiding a pattern of class one or two

Proposition 2. *Partitions of* $[n]$ *are in one-to-one correspondence with* $(a\text{-}bc)$*-avoiding permutations in* $\mathcal{S}_n$*. Hence* $|\mathcal{S}_n(a\text{-}bc)| = B_n$*.*

First proof. Recall that the Bell numbers satisfy $B_0 = 1$, and

$$B_{n+1} = \sum_{k=0}^{n} \binom{n}{k} B_k.$$

We show that $|\mathcal{S}_n(a\text{-}bc)|$ satisfy the same recursion. Clearly, $\mathcal{S}_0(a\text{-}bc) = \{\epsilon\}$. For $n > 0$, let $M = \{2, 3, \ldots, n + 1\}$, and let S be a k element subset of M. For each $(a\text{-}bc)$-avoiding permutation σ of S we construct a unique $(a\text{-}bc)$-avoiding permutation π of $[n+1]$. Let τ be the word obtained by writing the elements of $M \setminus S$ in decreasing order. Define $\pi := \sigma 1 \tau$.

Conversely, if $\pi = \sigma 1 \tau$ is a given $(a\text{-}bc)$-avoiding permutation of $[n + 1]$, where $|\sigma| = k$, then the letters of τ are in decreasing order, and σ is an $(a\text{-}bc)$-avoiding permutation of the k element set $\{2, 3, \ldots, n + 1\} \setminus \{i : i \text{ is a letter in } \tau\}$. □

Second proof. Given a partition π of $[n]$, we introduce a standard representation of π by requiring that:

(a) Each block is written with its least element first, and the rest of the elements of that block are written in decreasing order.
(b) The blocks are written in decreasing order of their least element, and with dashes separating the blocks.

Define $\widehat{\pi}$ to be the permutation we obtain from π by writing it in standard form and erasing the dashes. We now argue that $\widehat{\pi} := a_1 a_2 \cdots a_n$ avoids $(a\text{-}bc)$. If $a_i < a_{i+1}$, then a_i and a_{i+1} are the first and the second element of some block. By the construction of $\widehat{\pi}$, a_i is a left-to-right minimum, hence there is no $j \in [i-1]$ such that $a_j < a_i$.

Conversely, π can be recovered uniquely from $\widehat{\pi}$ by inserting a dash in $\widehat{\pi}$ preceding each left-to-right minimum, apart from the first letter in $\widehat{\pi}$. Indeed, it easy to see that the partition, π, in this way obtained is written in standard form. Thus $\pi \mapsto \widehat{\pi}$ gives the desired bijection. □

Example. As an illustration of the map defined in the above proof, let

$$\pi = \{\{1,3,5\},\{2,6,9\},\{4,7\},\{8\}\}.$$

Its standard form is 8-47-296-153. Thus $\widehat{\pi} = 847296153$.

Proposition 3. *Let $L(\pi)$ be the number of left-to-right minima of π. Then*

$$\sum_{\pi \in \mathcal{S}_n(a\text{-}bc)} x^{L(\pi)} = \sum_{k \geq 0} S(n,k) x^k.$$

Proof. This result follows readily from the second proof of Proposition 2. We here give a different proof, which is based on the fact that the Stirling numbers of the second kind satisfy

$$S(n,k) = S(n-1,k-1) + kS(n-1,k).$$

Let $T(n,k)$ be the number of permutations in $\mathcal{S}_n(a\text{-}bc)$ with k left-to-right minima. We show that the $T(n,k)$ satisfy the same recursion as the $S(n,k)$.

Let π be an $(a\text{-}bc)$-avoiding permutation of $[n-1]$. To insert n in π, preserving $(a\text{-}bc)$-avoidance, we can put n in front of π or we can insert n immediately after each left-to-right minimum. Putting n in front of π creates a new left-to-right minimum, while inserting n immediately after a left-to-right minimum does not. □

Proposition 4. *Partitions of $[n]$ are in one-to-one correspondence with $(a\text{-}cb)$-avoiding permutations in $\mathcal{S}_n$. Hence $|\mathcal{S}_n(a\text{-}cb)| = B_n$.*

Proof. Let π be a partition of $[n]$. We introduce a standard representation of π by requiring that:

(a) The elements of a block are written in increasing order.
(b) The blocks are written in decreasing order of their least element, and with dashes separating the blocks.

(Note that this standard representation is different from the one given in the second proof of Proposition 2.) Define $\widehat{\pi}$ to be the permutation we obtain from π by writing it in standard form and erasing the dashes. It easy to see that $\widehat{\pi}$ avoids $(a\text{-}cb)$. Conversely, π can be recovered uniquely from $\widehat{\pi}$ by inserting a dash in between each descent in $\widehat{\pi}$. □

Example. As an illustration of the map defined in the above proof, let

$$\pi = \{\{1,3,5\},\{2,6,9\},\{4,7\},\{8\}\}.$$

Its standard form is 8-47-269-135. Thus $\widehat{\pi} = 847269135$.

Proposition 5.

$$\sum_{\pi\in\mathcal{S}_n(a\text{-}cb)} x^{1+\operatorname{des}\pi} = \sum_{k\geq 0} S(n,k)x^k.$$

Proof. From the proof of Proposition 4 we see that π has $k+1$ blocks precisely when $\widehat{\pi}$ has k descents. □

Proposition 6. *Involutions in $\mathcal{S}_n$ are in one-to-one correspondence with permutations in $\mathcal{S}_n$ that avoid $(a\text{-}bc)$ and $(a\text{-}cb)$. Hence*

$$|\mathcal{S}_n(a\text{-}bc, a\text{-}cb)| = I_n.$$

Proof. We give a combinatorial proof using a bijection that is essentially identical to the one given in the second proof of Proposition 2.

Let $\pi \in \mathcal{S}_n$ be an involution. Recall that π is an involution if and only if each cycle of π is of length one or two. We now introduce a standard form for writing π in cycle notation by requiring that:

(a) Each cycle is written with its least element first.
(b) The cycles are written in decreasing order of their least element.

Define $\widehat{\pi}$ to be the permutation obtained from π by writing it in standard form and erasing the parentheses separating the cycles.

Observe that $\widehat{\pi}$ avoids $(a\text{-}bc)$: Assume that $a_i < a_{i+1}$, that is $(a_i\, a_{i+1})$ is a cycle in π, then a_i is a left-to-right minimum in π. This is guaranteed by the construction of $\widehat{\pi}$. Thus there is no $j < i$ such that $a_j < a_i$.

The permutation $\widehat{\pi}$ also avoids $(a\text{-}cb)$: Assume that $a_i > a_{i+1}$, then a_{i+1} must be the smallest element of some cycle. Whence a_{i+1} is a left-to-right minimum in $\widehat{\pi}$.

Conversely, if $\widehat{\pi} := a_1 \dots a_n$ is an $\{a\text{-}bc, a\text{-}cb\}$-avoiding permutation then the involution π is given by: $(a_i\, a_{i+1})$ is a cycle in π if and only if $a_i < a_{i+1}$. □

Example. The involution $\pi = 826543719$ written in standard form is

$$(9)(7)(4\,5)(3\,6)(2)(1\,8),$$

and hence $\widehat{\pi} = 974536218$.

Proposition 7. *The number of permutations in $\mathcal{S}_n(a\text{-}bc, a\text{-}cb)$ with $n-k-1$ descents equals the number of involutions in $\mathcal{S}_n$ with $n-2k$ fixed points.*

Proof. Under the bijection $\pi \mapsto \widehat{\pi}$ in the proof of Proposition 6, a cycle of length two in π corresponds to an occurrence of (ab) in $\widehat{\pi}$. Hence, if π has $n-2k$ fixed points, then $\widehat{\pi}$ has $n-k-1$ descents. □

Corollary 8.

$$\sum_{\pi\in\mathcal{S}_n(a\text{-}bc,a\text{-}cb)} x^{1+\operatorname{des}\pi} = \sum_{k=0}^{n} \binom{n}{k}\binom{n-k}{k}\frac{k!}{2^k}x^{n-k}.$$

Proof. Let I_n^k denote the number of involutions in $\mathcal{S}_n$ with k fixed points. Then Proposition 7 is equivalently stated as

$$\sum_{\pi\in\mathcal{S}_n(a\text{-}bc,a\text{-}cb)} x^{1+\operatorname{des}\pi} = \sum_{k\geq 0} I_n^{n-2k}x^{n-k}. \tag{1}$$

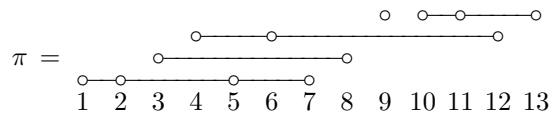
The result now follows from the well-known and easily to derived formula

$$I_n^k = \binom{n}{k}\binom{n-k}{r}\frac{r!}{2^r}, \text{ where } r = \frac{n-k}{2},$$

for $n-k$ even, with $I_n^k = 0$ for $n-k$ odd. □

Definition 9. Let π be an arbitrary partition whose non-singleton blocks $\{A_1, \ldots, A_k\}$ are ordered so that for all $i \in [k-1]$, $\min A_i > \min A_{i+1}$. If $\max A_i > \max A_{i+1}$ for all $i \in [k-1]$, then we call π a *monotone partition*. The set of monotone partitions of $[n]$ is denoted by $\mathcal{M}_n$.

Example. The partition



is monotone.

Proposition 10. *Monotone partitions of $[n]$ are in one-to-one correspondence with permutations in $\mathcal{S}_n$ that avoid $(a\text{-}bc)$ and $(ab\text{-}c)$. Hence*

$$|\mathcal{S}_n(a\text{-}bc, ab\text{-}c)| = |\mathcal{M}_n|.$$

Proof. Given π in $\mathcal{M}_n$, let $A_1\text{-}A_2\text{-}\cdots\text{-}A_k$ be the result of writing π in the standard form given in the second proof of Proposition 2, and let $\widehat{\pi} = A_1A_2\cdots A_k$. By the construction of $\widehat{\pi}$ the first letter in each A_i is a left-to-right minimum. Furthermore, since π is monotone the second letter in each non-singleton A_i is a right-to-left maximum. Therefore, if xy is an (ab)-subword of $\widehat{\pi}$, then x is left-to-right minimum and y is a right-to-left maximum. Thus $\widehat{\pi}$ avoids both $(a\text{-}bc)$ and $(ab\text{-}c)$.

Conversely, given $\widehat{\pi}$ in $\mathcal{S}_n(a\text{-}bc, ab\text{-}c)$, let $A_1\text{-}A_2\text{-}\cdots\text{-}A_k$ be the result of inserting a dash in $\widehat{\pi}$ preceding each left-to-right minimum, apart from the first letter in $\widehat{\pi}$. Since $\widehat{\pi}$ is $(ab\text{-}c)$-avoiding, the second letter in each non-singleton A_i is a right-to-left maximum. The second letter in A_i is the maximal element of A_i when A_i is viewed as a set. Thus $\pi = \{A_1, A_2, \ldots, A_k\}$ is monotone. □

We now show that there is a one-to-one correspondence between monotone partitions and non-overlapping partitions. The proof we give is strongly influenced by the paper [3], in which Flajolet and Schot showed that the ordinary generating function of the Bessel numbers admits a nice continued fraction expansion

$$\sum_{n\geq 0} B_n^* x^n = \cfrac{1}{1 - 1\cdot x - \cfrac{x^2}{1 - 2\cdot x - \cfrac{x^2}{1 - 3\cdot x - \cfrac{x^2}{\ddots}}}},$$

and using that as a starting point they derived the asymptotic formula

$$B_n^* \sim \sum_{k\geq 0} \frac{k^{n+2}}{(k!)^2}.$$

Proposition 11. *Monotone partitions of $[n]$ are in one-to-one correspondence with non-overlapping partitions of $[n]$. Hence $|\mathcal{M}_n| = B_n^*$.*

Proof. Let π be a non-overlapping partition of $[n]$. From π we will create a new partition by successively inserting $1, 2, \ldots, n$, in this order, into this new partition. During this process a block is labelled as either *open* or *closed*. More formally, in each step $k = 1, 2, \ldots, n$ in this process we will have a partition σ of $[k]$ together with a function from σ to the set of labels $\{\text{open}, \text{closed}\}$. Before we start we also need a labelling of the blocks of π. Actually we need n such labellings, one for each $k \in [n]$: At step k a block B of π is labelled open if $\max B > k$ and closed otherwise. For ease

of language, we say that a block is open if it is labelled open, and closed if it is labelled closed.

(a) If k is the minimal element of a non-singleton block of π, then create a new block $\{k\}$ and label it open.
(b) If k is the maximal element of a non-singleton block of π, then insert k into the open block with the smallest minimal element, and label it closed.
(c) If k belongs to a non-singleton block B of π and is not the minimal or the maximal element of B, and B has the ith largest minimal element of the open blocks of π, then insert k into the open block with the ith largest minimal element.
(d) If $\{k\}$ is a block of π then create a new block $\{k\}$ and label it closed.

Define $\Phi(\pi)$ as the partition obtained from π by applying the above process. Observe that $\Phi(\pi)$ is monotone. Indeed, the two crucial observations are (i) in (b) we label the open block with the smallest minimum closed, and (ii) a block labelled closed has received all its elements.

Conversely, we give a map Ψ that to each monotone partition π of $[n]$ gives a unique non-overlapping partition $\Psi(\pi)$ of $[n]$. Define Ψ the same way as Φ is defined, except for case (c), where we instead of inserting k into the block labelled open with the *smallest* minimal element, insert k into the block labelled open with the *largest* minimal element. It is easy to see that Φ and Ψ are each others inverses and hence they are bijections. □

Corollary 12. *The non-overlapping partitions of* $[n]$ *are in one-to-one correspondence with permutations in* $\mathcal{S}_n$ *that avoid* $(a\text{-}bc)$ *and* $(ab\text{-}c)$*. Hence*

$$|\mathcal{S}_n(a\text{-}bc, ab\text{-}c)| = B_n^*.$$

Proof. Follows immediately from Proposition 10 together with Proposition 11. □

Example. By the proof of Proposition 11, the non-overlapping partition

$\pi =$ 
corresponds to the monotone partition

$\Phi(\pi) =$ 
that according to the proof of Proposition 10 corresponds to the $\{a\text{-}bc, ab\text{-}c\}$-avoiding permutation

$$\widehat{\Phi(\pi)} = 10\ 13\ 11\ 9\ 4\ 12\ 6\ 3\ 8\ 1\ 7\ 5\ 2.$$

Proposition 13. *Let* $L(\pi)$ *be the number of left-to-right minima of* π*. Then*

$$\sum_{\pi \in \mathcal{S}_n(a\text{-}bc, ab\text{-}c)} x^{L(\pi)} = \sum_{k \geq 0} S^*(n,k) x^k.$$

Proof. Under the bijection $\pi \mapsto \widehat{\pi}$ in the proof of Proposition 10, the number of blocks in π determines the number of left-to-right minima of $\widehat{\pi}$, and vice versa. The number of blocks is not changed by the bijection Ψ in the proof of Proposition 11. □

5. Permutations avoiding a pattern of class three

In [4] Knuth observed that there is a one-to-one correspondence between $(b\text{-}a\text{-}c)$-avoiding permutations and Dyck paths. For completeness and future reference we give this result as a lemma, and prove it using a bijection which rests on the first return decomposition of Dyck paths. First we need a definition. For each word $x = x_1x_2\cdots x_n$ without repeated letters, we define the *projection* of x onto $\mathcal{S}_n$, which we denote $\mathrm{proj}(x)$, by

$$\mathrm{proj}(x) = a_1a_2\cdots a_n\,, \quad \text{where } \; a_i = |\{j \in [n] : x_j \le x_i\}|.$$

Equivalently, $\mathrm{proj}(x)$ is the permutation in $\mathcal{S}_n$ which is order equivalent to x. For example, $\mathrm{proj}(265) = 132$.

Lemma 1. $|\mathcal{S}_n(b\text{-}a\text{-}c)| = C_n$.

Proof. Let $\pi = a_1a_2\cdots a_n$ be a permutation of $[n]$ such that $a_k = 1$. Then π is $(b\text{-}a\text{-}c)$-avoiding if and only if $\pi = \sigma 1\tau$, where $\sigma := a_1\cdots a_{k-1}$ is a $(b\text{-}a\text{-}c)$-avoiding permutation of $\{n, n-1, \ldots, n-k+1\}$, and $\tau := a_{k+1}\cdots a_n$ is a $(b\text{-}a\text{-}c)$-avoiding permutation of $\{2, 3, \ldots, k\}$.

We define recursively a mapping Φ from $\mathcal{S}_n(b\text{-}a\text{-}c)$ onto the set of Dyck paths of length $2n$. If π is the empty word, then so is the Dyck path determined by π, that is, $\Phi(\epsilon) = \epsilon$. If $\pi \neq \epsilon$, then we can use the factorisation $\pi = \sigma 1\tau$ from above, and define $\Phi(\pi) = u\,(\Phi \circ \mathrm{proj})(\sigma)\,d\,(\Phi \circ \mathrm{proj})(\tau)$. It is easy to see that Φ may be inverted, and hence is a bijection. □

Lemma 2. *A permutation avoids $(b\text{-}ac)$ if and only if it avoids $(b\text{-}a\text{-}c)$.*

Proof. The sufficiency part of the proposition is trivial. The necessity part is not difficult either. Assume that π contains a $(b\text{-}a\text{-}c)$-subword. Then there is a segment $Bm_1\cdots m_r$ of π, where, for some $j < r$, $m_j < B$ and $m_r > B$. Now choose the largest i such that $m_i < B$, then $m_{i+1} > B$. □

Proposition 14. *Dyck paths of length $2n$ are in one-to-one correspondence with $(b\text{-}ac)$-avoiding permutations in $\mathcal{S}_n$. Hence*

$$|\mathcal{S}_n(b\text{-}ac)| = \frac{1}{n+1}\binom{2n}{n}.$$

Proof. Follows immediately from Lemmas 1 and 2. □

Proposition 15. *Let $L(\pi)$ be the number of left-to-right minima of π. Then*

$$\sum_{\pi \in \mathcal{S}_n(b-ac)} x^{L(\pi)} = \sum_{k \ge 0} \frac{k}{2n-k}\binom{2n-k}{n}x^k.$$

Proof. Let $R(\delta)$ denote the number of return steps in the Dyck path δ. It is well known (see [2]) that the distribution of R over all Dyck paths of length $2n$ is the distribution we claim that L has over $\mathcal{S}_n(b\text{-}ac)$. .

Let γ be a Dyck path of length $2n$, and let $\gamma = u\alpha d\beta$ be its first return decomposition. Then $R(\gamma) = 1 + R(\beta)$. Let $\pi \in \mathcal{S}_n(b\text{-}ac)$, and let $\pi = \sigma 1\tau$ be the decomposition given in the proof of Lemma 1. Then $L(\pi) = 1 + L(\sigma)$. The result now follows by induction. □

In addition, it is easy to deduce that left-to-right minima, left-to-right maxima, right-to-left minima, and right-to-left maxima all share the same distribution over $\mathcal{S}_n(b\text{-}ac)$.

Proposition 16. *Motzkin paths of length n are in one-to-one correspondence with permutations in $\mathcal{S}_n$ that avoid $(a\text{-}bc)$ and $(ac\text{-}b)$. Hence*

$$|\mathcal{S}_n(a\text{-}bc, ac\text{-}b)| = M_n.$$

Proof. We mimic the proof of Lemma 1. Let $\pi \in \mathcal{S}_n(a\text{-}bc, ac\text{-}b)$. Since π avoids $(ac\text{-}b)$ it also avoids $(a\text{-}c\text{-}b)$ by Lemma 2 via $\pi \mapsto (\pi^c)^r$. Thus we may write $\pi = \sigma n \tau$, where $\pi(k) = n$, σ is an $\{a\text{-}bc, ac\text{-}b\}$-avoiding permutation of $\{n-1, n-2, \ldots, n-k+1\}$, and τ is an $\{a\text{-}bc, ac\text{-}b\}$-avoiding permutation of $[n-k]$. If $\sigma \neq \epsilon$ then $\sigma = \sigma' r$ where $r = n-k+1$, or else an $(a\text{-}bc)$-subword would be formed with n as the 'c' in $(a\text{-}bc)$. Define a map Φ from $\mathcal{S}_n(a\text{-}bc, ac\text{-}b)$ to the set of Motzkin paths by $\Phi(\epsilon) = \epsilon$ and

$$\Phi(\pi) = \begin{cases} \ell\,(\Phi \circ \mathrm{proj})(\sigma) & \text{if } \pi = n\sigma, \\ u\,(\Phi \circ \mathrm{proj})(\sigma)\,d\,\Phi(\tau) & \text{if } \pi = \sigma r n \tau \text{ and } r = n-k+1. \end{cases}$$

It is routine to find the inverse of Φ. □

Example. Let us find the Motzkin path associated with the $\{a\text{-}bc, ac\text{-}b\}$-avoiding permutation 76453281.

$$\begin{aligned} \Phi(76453281) &= u\Phi(54231)d\Phi(1) \\ &= u\ell\Phi(4231)d\ell \\ &= u\ell\ell\Phi(231)d\ell \\ &= u\ell\ell ud\Phi(1)d\ell \\ &= u\ell\ell ud\ell d\ell \end{aligned}$$

Acknowledgement

I am greatly indebted to my advisor Einar Steingrímsson, who put his trust in me and gave me the opportunity to study mathematics on a postgraduate level. This work has benefited from his knowledge, enthusiasm and generosity.

COUNTING OCCURRENCES OF A PATTERN OF TYPE $(1,2)$ OR $(2,1)$ IN PERMUTATIONS

ANDERS CLAESSON AND TOUFIK MANSOUR

Abstract. Babson and Steingrímsson introduced generalized permutation patterns that allow the requirement that two adjacent letters in a pattern must be adjacent in the permutation. Claesson presented a complete solution for the number of permutations avoiding any single pattern of type $(1,2)$ or $(2,1)$. For eight of these twelve patterns the answer is given by the Bell numbers. For the remaining four the answer is given by the Catalan numbers.

With respect to being equidistributed there are three different classes of patterns of type $(1,2)$ or $(2,1)$. We present a recursion for the number of permutations containing exactly one occurrence of a pattern of the first or the second of the aforementioned classes, and we also find an ordinary generating function for these numbers. We prove these results both combinatorially and analytically. Finally, we give the distribution of any pattern of the third class in the form of a continued fraction, and we also give explicit formulas for the number of permutations containing exactly r occurrences of a pattern of the third class when $r \in \{1,2,3\}$.

1. Introduction and preliminaries

Let $[n] = \{1, 2, \ldots, n\}$ and denote by $\mathcal{S}_n$ the set of permutations of $[n]$. We shall view permutations in $\mathcal{S}_n$ as words with n distinct letters in $[n]$.

Classically, a pattern is a permutation $\sigma \in \mathcal{S}_k$, and an occurrence of σ in a permutation $\pi = a_1 a_2 \cdots a_n \in \mathcal{S}_n$ is a subword of π that is order equivalent to σ. For example, an occurrence of 132 is a subword $a_i a_j a_k$ $(1 \le i < j < k \le n)$ of π such that $a_i < a_k < a_j$. We denote by $s^r_\sigma(n)$ the number of permutations in $\mathcal{S}_n$ that contain exactly r occurrences of the pattern σ.

In the last decade much attention has been paid to the problem of finding the numbers $s^r_\sigma(n)$ for a fixed $r \ge 0$ and a given pattern σ (see [1, 2, 4, 6, 7, 8, 11, 13, 14, 16, 17, 18, 19, 20, 21]). Most of the authors consider only the case $r = 0$, thus studying permutations *avoiding* a given pattern. Only a few papers consider the case $r > 0$, usually restricting themselves to patterns of length 3. Using two simple involutions (*reverse* and *complement*) on $\mathcal{S}_n$ it is immediate that with respect to being equidistributed, the six patterns of length three fall into the two classes $\{123, 321\}$ and $\{132, 213, 231, 312\}$. Noonan [15] proved that $s^1_{123}(n) = \frac{3}{n}\binom{2n}{n-3}$. A general approach to the problem was suggested by Noonan and Zeilberger [16]; they gave another proof of Noonan's result, and conjectured that

$$s^2_{123}(n) = \frac{59n^2 + 117n + 100}{2n(2n-1)(n+5)} \binom{2n}{n-4}$$

and $s^1_{132}(n) = \binom{2n-3}{n-3}$. The latter conjecture was proved by Bóna in [7]. A conjecture of Noonan and Zeilberger states that $s^r_\sigma(n)$ is P-recursive in n for any r and σ. It was proved by Bóna [5] for $\sigma = 132$.

Mansour and Vainshtein [14] suggested a new approach to this problem in the case $\sigma = 132$, which allows one to get an explicit expression for $s^r_{132}(n)$ for any given r.

Date: October 8, 2002.

More precisely, they presented an algorithm that computes the generating function $\sum_{n\geq 0} s^r_{132}(n)x^n$ for any $r \geq 0$. To get the result for a given r, the algorithm performs certain routine checks for each element of the symmetric group S_{2r}. The algorithm has been implemented in C, and yields explicit results for $1 \leq r \leq 6$.

In [3] Babson and Steingrímsson introduced generalized permutation patterns that allow the requirement that two adjacent letters in a pattern must be adjacent in the permutation. The motivation for Babson and Steingrímsson in introducing these patterns was the study of Mahonian permutation statistics. Two examples of (generalized) patterns are 1-32 and 13-2. An occurrence of 1-32 in a permutation $\pi = a_1a_2\cdots a_n$ is a subword $a_ia_ja_{j+1}$ of π such that $a_i < a_{j+1} < a_j$. Similarly, an occurrence of 13-2 is a subword $a_ia_{i+1}a_j$ of π such that $a_i < a_j < a_{i+1}$. More generally, if $xyz \in \mathcal{S}_3$ and $\pi = a_1a_2\cdots a_n \in \mathcal{S}_n$, then we define

$$(x\text{-}yz)\,\pi \;=\; |\{a_ia_ja_{j+1} : \mathrm{proj}(a_ia_ja_{j+1}) = xyz, 1 \leq i < j < n\}|,$$

where $\mathrm{proj}(x_1x_2x_3)(i) = |\{j \in \{1,2,3\} : x_j \leq x_i\}|$ for $i \in \{1,2,3\}$ and $x_1, x_2, x_3 \in [n]$. For instance, $\mathrm{proj}(127) = \mathrm{proj}(138) = \mathrm{proj}(238) = 123$, and

$$(1\text{-}23)\,491273865 = |\{127, 138, 238\}| = 3.$$

Similarly, we also define $(xy\text{-}z)\,\pi = (z\text{-}yx)\,\pi^r$, where π^r denotes the reverse of π, that is, π read backwards.

For any word (finite sequence of letters), w, we denote by $|w|$ the length of w, that is, the number of letters in w. A pattern $\sigma = \sigma_1\text{-}\sigma_2\text{-}\cdots\text{-}\sigma_k$ containing exactly $k-1$ dashes is said to be of type $(|\sigma_1|, |\sigma_2|, \ldots, |\sigma_k|)$. For example, the pattern 142-5-367 is of type $(3,1,3)$, and any classical pattern of length k is of type $(\underbrace{1,1,\ldots,1}_{k})$.

In [11] Elizalde and Noy presented the following theorem regarding the distribution of the number of occurrences of any pattern of type (3).

Theorem 1 (Elizalde and Noy [11])**.** *Let $h(x) = \sqrt{(x-1)(x+3)}$. Then*

$$\sum_{\pi\in\mathcal{S}} x^{(123)\pi}\frac{t^{|\pi|}}{|\pi|!} = \frac{2h(x)e^{\frac{1}{2}(h(x)-x+1)t}}{h(x)+x+1+(h(x)-x-1)e^{h(x)t}},$$

$$\sum_{\pi\in\mathcal{S}} x^{(213)\pi}\frac{t^{|\pi|}}{|\pi|!} = \frac{1}{1-\int_0^t e^{(x-1)z^2/2}dz}.$$

The easy proof of the following proposition can be found in [9].

Proposition 2 (Claesson [9])**.** *With respect to being equidistributed, the twelve patterns of type $(1,2)$ or $(2,1)$ fall into the three classes*

$$\{\ 1\text{-}23,\ 3\text{-}21,\ 12\text{-}3,\ 32\text{-}1\ \},$$
$$\{\ 1\text{-}32,\ 3\text{-}12,\ 21\text{-}3,\ 23\text{-}1\ \},$$
$$\{\ 2\text{-}13,\ 2\text{-}31,\ 13\text{-}2,\ 31\text{-}2\ \}.$$

In the subsequent discussion we refer to the classes of the proposition above (in the order that they appear) as Class 1, 2 and 3 respectively.

Claesson [9] also gave a solution for the number of permutations avoiding any pattern of the type $(1,2)$ or $(2,1)$ as follows.

Proposition 3 (Claesson [9])**.** *Let $n \in \mathbb{N}$. We have*

$$|\mathcal{S}_n(\sigma)| = \begin{cases} B_n & \text{if } \sigma \in \{1\text{-}23, 3\text{-}21, 12\text{-}3, 32\text{-}1, 1\text{-}32, 3\text{-}12, 21\text{-}3, 23\text{-}1\}, \\ C_n & \text{if } \sigma \in \{2\text{-}13, 2\text{-}31, 13\text{-}2, 31\text{-}2\}, \end{cases}$$

where B_n and C_n are the nth Bell and Catalan numbers, respectively.

In particular, since B_n is not P-recursive in n, this result implies that for generalized patterns the conjecture that $s^r_\sigma(n)$ is P-recursive in n is false for $r = 0$ and, for example, $\sigma = 1\text{-}23$.

This paper is organized as follows. In Section 2 we find a recursion for the number of permutations containing exactly one occurrence of a pattern of Class 1, and we also find an ordinary generating function for these numbers. We prove these results both combinatorially and analytically. Similar results are also obtained for patterns of Class 2. In Section 3 we give the distribution of any pattern of Class 3 in the form of a continued fraction, and we also give explicit formulas for the number of permutations containing exactly r occurrences of a pattern of Class 3 when $r \in \{1, 2, 3\}$.

2. Counting occurrences of a pattern of Class 1 or 2

Theorem 4. *Let $u_1(n)$ be the number of permutations of length n containing exactly one occurrence of the pattern 1-23 and let B_n be the nth Bell number. The numbers $u_1(n)$ satisfy the recurrence*

$$u_1(n+2) = 2u_1(n+1) + \sum_{k=0}^{n-1} \binom{n}{k} \big[u_1(k+1) + B_{k+1}\big],$$

whenever $n \geq -1$, with the initial condition $u_1(0) = 0$.

Proof. Each permutation $\pi \in \mathcal{S}^1_{n+2}(1\text{-}23)$ contains a unique subword abc such that $a < b < c$ and bc is a segment of π. Let x be the last letter of π and define the sets $\mathcal{T}$, $\mathcal{T}'$, and $\mathcal{T}''$ by

$$\pi \in \begin{cases} \mathcal{T} & \text{if } x = 2, \\ \mathcal{T}' & \text{if } x \neq 2 \text{ and } a = 1, \\ \mathcal{T}'' & \text{if } x \neq 2 \text{ and } a \neq 1. \end{cases}$$

Then $\mathcal{S}^1_{n+2}(1\text{-}23)$ is the disjoint union of $\mathcal{T}$, $\mathcal{T}'$, and $\mathcal{T}''$, so

$$u_1(n+2) = |\mathcal{T}| + |\mathcal{T}'| + |\mathcal{T}''|.$$

Since removing/adding a trailing 2 from/to a permutation does not affect the number of hits of 1-23, we immediately get

$$|\mathcal{T}| = u_1(n+1).$$

For the cardinality of $\mathcal{T}'$ we observe that if $x \neq 2$ and $a = 1$ then $b = 2$: If the letter 2 precedes the letter 1 then every hit of 1-23 with $a = 1$ would cause an additional hit of 1-23 with $a = 2$ contradicting the uniqueness of the hit of 1-23; if 1 precedes 2 then $a = 1$ and $b = 2$. Thus we can factor any permutation $\pi \in \mathcal{T}'$ uniquely in the form $\pi = \sigma 2 \tau$, where σ is (1-23)-avoiding, the letter 1 is included in σ, and τ is nonempty and (12)-avoiding. Owing to Proposition 3 we have showed

$$|\mathcal{T}'| = \sum_{k=0}^{n-1} \binom{n}{k} B_{k+1}.$$

Suppose $\pi \in \mathcal{T}''$. Since $x \neq 2$ and $a \neq 1$ we can factor π uniquely in the form $\pi = \sigma 1 \tau$, where σ contains exactly one occurrence of 1-23, the letter 2 is included in σ, and τ is nonempty and (12)-avoiding. Consequently,

$$|\mathcal{T}''| = \sum_{k=0}^{n} \binom{n}{k} u_1(k+1),$$

which completes the proof. □

Example 5. Let us consider all permutations of length 5 that contain exactly one occurrence of 1-23, and give a small illustration of the proof of Theorem 12. If $\mathcal{T}$, $\mathcal{T}'$ and $\mathcal{T}''$ are defined as above then

$$\begin{aligned}
\mathcal{T} &= \underline{1354}|2\ \ \underline{1435}|2\ \ \underline{1453}|2\ \ \underline{1534}|2\ \ 4\underline{135}|2\ \ 5\underline{134}|2\ \ \underline{3451}|2\\
\mathcal{T}' &= \begin{array}{l}\underline{1}|\underline{2543}\ \ \underline{13}|\underline{254}\ \ \underline{14}|\underline{253}\ \ \underline{143}|\underline{25}\ \ \underline{15}|\underline{243}\ \ \underline{153}|\underline{24}\\ \underline{154}|\underline{23}\ \ \underline{31}|\underline{254}\ \ 3\underline{14}|\underline{25}\ \ 3\underline{15}|\underline{24}\ \ 3\underline{41}|\underline{25}\ \ 3\underline{51}|\underline{24}\\ 4\underline{1}|\underline{253}\ \ 4\underline{13}|\underline{25}\ \ 4\underline{15}|\underline{23}\ \ 4\underline{31}|\underline{25}\ \ 4\underline{51}|\underline{23}\ \ 5\underline{1}|\underline{243}\\ 5\underline{13}|\underline{24}\ \ 5\underline{14}|\underline{23}\ \ 5\underline{31}|\underline{24}\ \ 5\underline{41}|\underline{23}\end{array}\\
\mathcal{T}'' &= \begin{array}{l}\underline{234}|15\ \ \underline{235}|14\ \ \underline{2354}|1\ \ \underline{2435}|1\ \ \underline{245}|13\\ \underline{2453}|1\ \ \underline{2534}|1\ \ \underline{3452}|1\ \ 4\underline{235}|1\ \ 5\underline{234}|1\end{array}
\end{aligned}$$

where the underlined subword is the unique hit of 1-23, and the bar indicates how the permutation is factored in the proof of Theorem 12.

Theorem 6. *Let $v_1(n)$ be the number of permutations of length n containing exactly one occurrence of the pattern* 1-32 *and let B_n be the nth Bell number. The numbers $v_1(n)$ satisfy the recurrence*

$$v_1(n+1) = v_1(n) + \sum_{k=1}^{n-1}\left[\binom{n}{k}v_1(k) + \binom{n-1}{k-1}B_k\right],$$

whenever $n \geq 0$, with the initial condition $v_1(0) = 0$.

Proof. Each permutation $\pi \in \mathcal{S}^1_{n+2}$(1-32) contains a unique subword acb such that $a < b < c$ and cb is a segment of π. Define the sets $\mathcal{T}$ and $\mathcal{T}'$ by

$$\pi \in \begin{cases}\mathcal{T} & \text{if } a = 1,\\ \mathcal{T}' & \text{if } a \neq 1.\end{cases}$$

Then $\mathcal{S}^1_{n+2}$(1-32) is the disjoint union of $\mathcal{T}$ and $\mathcal{T}'$, so

$$v_1(n+2) = |\mathcal{T}| + |\mathcal{T}'|.$$

For the cardinality of $\mathcal{T}$ we observe that if $a = 1$ then $b = 2$: If the letter 2 precedes the letter 1 or 12 is a segment of π then every hit of 1-23 with $a = 1$ would cause an additional hit of 1-32 with $a = 2$ contradicting the uniqueness of the hit of 1-23; if 1 precedes 2 then $a = 1$ and $b = 2$. Thus we can factor π uniquely in the form $\pi = \sigma x 2 \tau$, where σx is (1-32)-avoiding, the letter 1 is included in σ, and τ is nonempty and (12)-avoiding. Let $\mathcal{R}_n$ be the set of (1-32)-avoiding permutations of $[n]$ that do not end with the letter 1. Since the letter 1 cannot be the last letter of a hit of 1-32, we have, by Proposition 3, that $|\mathcal{S}^0_n(1\text{-}32) \setminus \mathcal{R}_n| = B_{n-1}$. Consequently, $|\mathcal{R}_n| = B_n - B_{n-1}$ and

$$\begin{aligned}
|\mathcal{T}| &= \sum_{k=1}^{n}\binom{n-1}{k-1}|\mathcal{R}_k|\\
&= \sum_{k=1}^{n}\binom{n-1}{k-1}(B_k - B_{k-1})\\
&= \sum_{k=1}^{n-1}\binom{n-1}{k-1}B_k.
\end{aligned}$$

For the last identity we have used the familiar recurrence relation $B_{n+1} = \sum_{k=0}^{n}\binom{n}{k}B_k$.

Suppose $\pi \in \mathcal{T}'$. Since $a \neq 1$ we can factor π uniquely in the form $\pi = \sigma 1 \tau$, where σ contains exactly one occurrence of 1-32, and τ is nonempty and (12)-avoiding. Accordingly,

$$|\mathcal{T}''| = \sum_{k=0}^{n} \binom{n}{k} v_1(k),$$

which completes the proof. □

Let σ be a pattern of Class 1 or 2. Using combinatorial reasoning we have found a recursion for the number of permutations containing exactly one occurrence of the pattern σ (Theorem 4 and 6). More generally, given $r \geq 0$, we would like to find a recursion for the number of permutations containing exactly r occurrence of the pattern σ. Using a more general and analytic approach we will now demonstrate how this (at least in principle) can be achieved.

Let $S_\sigma^r(x)$ be the generating function $S_\sigma^r(x) = \sum_n s_\sigma^r(n) x^n$. To find functional relations for $S_\sigma^r(x)$ the following lemma will turn out to be useful.

Lemma 7. *If $\{a_n\}$ is a sequence of numbers and $A(x) = \sum_{n\geq 0} a_n x^n$ is its ordinary generating function, then, for any $d \geq 0$,*

$$\sum_{n\geq 0} \left[\sum_{j=0}^{n} \binom{n}{j} a_{j+d} \right] x^n = \frac{(1-x)^{d-1}}{x^d} \left[A\Big(\frac{x}{1-x}\Big) - \sum_{j=0}^{d-1} a_j \Big(\frac{x}{1-x}\Big)^j \right].$$

Proof. It is plain that

$$\sum_{n\geq 0} \Big[\sum_{j=0}^{n} \binom{n}{j} a_j \Big] x^n = \frac{1}{1-x} A\Big(\frac{x}{1-x}\Big).$$

See for example [12, p 192]. On the other hand,

$$\sum_{n\geq 0} a_{n+d} x^n = \frac{1}{x^d} \Big[A(x) - \sum_{j=0}^{d-1} a_j x^j \Big].$$

Combining these two identities we get the desired result. □

Define $\mathcal{S}_n^r(\sigma)$ to be the set of permutations $\pi \in S_n$ such that $(\sigma)\pi = r$. Let $s_\sigma^r(n) = |\mathcal{S}_n^r(\sigma)|$ for $r \geq 0$ and $s_\sigma^r(n) = 0$ for $r < 0$. Given $b_1, b_2, \ldots, b_k \in \mathbb{N}$, we also define

$$s_\sigma^r(n; b_1, b_2, \ldots, b_k) = \#\{a_1 a_2 \cdots a_n \in \mathcal{S}_n^r(\sigma) \mid a_1 a_2 \cdots a_k = b_1 b_2 \cdots b_k\}.$$

As a direct consequence of the above definitions, we have

$$s_\sigma^r(n) = \sum_{j=1}^{n} s_\sigma^r(n; j). \tag{1}$$

We start by considering patterns that belong to Class 1 and we use 12-3 as a representative of this class. Let us define

$$\begin{aligned} u_r(n; b_1, \ldots, b_k) &= s_{12\text{-}3}^r(n; b_1, \ldots, b_k), \\ u_r(n) &= s_{12\text{-}3}^r(n), \\ U_r(x) &= S_{12\text{-}3}^r(x). \end{aligned}$$

Lemma 8. *Let $n \geq 1$. We have $u_r(n; n-1) = u_r(n; n) = u_r(n-1)$ and*

$$u_r(n; i) = \sum_{j=1}^{i-1} u_r(n-1; j) + \sum_{j=0}^{n-i-1} u_{r-j}(n-1; n-1-j),$$

whenever $1 \leq i \leq n-2$.

Proof. If $a_1a_2\cdots a_n$ is any permutation of $[n]$ then

$$(12\text{-}3)a_1a_2\cdots a_n = (12\text{-}3)a_2a_3\cdots a_n + \begin{cases} n-a_2 & \text{if } a_1 < a_2, \\ 0 & \text{if } a_1 > a_2. \end{cases}$$

Hence,

$$\begin{aligned} u_r(n;i) &= \sum_{j=1}^{i-1} u_r(n;i,j) + \sum_{j=i+1}^{n} u_r(n;i,j) \\ &= \sum_{j=1}^{i-1} u_r(n-1;j) + \sum_{j=i+1}^{n} u_{r-n+j}(n-1;j-1) \\ &= \sum_{j=1}^{i-1} u_r(n-1;j) + \sum_{j=0}^{n-i-1} u_{r-j}(n-1;n-1-j). \end{aligned}$$

For $i = n-1$ or $i = n$ it is easy to see that $u_r(n;i) = u_r(n-1)$. □

Using Lemma 8 we quickly generate the numbers $u_r(n)$; the first few of these numbers are given in Table 1. Given $r \in \mathbb{N}$ we can also use Lemma 8 to find a

$n\backslash r$	0	1	2	3	4	5	6
0	1						
1	1						
2	2						
3	5	1					
4	15	7	1	1			
5	52	39	13	12	2	1	1
6	203	211	112	103	41	24	17
7	877	1168	843	811	492	337	238
8	4140	6728	6089	6273	4851	3798	2956
9	21147	40561	43887	48806	44291	38795	33343
10	115975	256297	321357	386041	394154	379611	355182

TABLE 1. The number of permutations of length n containing exactly r occurrences of the pattern 12-3.

functional relation determining $U_r(x)$. Here we present such functional relations for $r = 0, 1, 2$ and also explicit formulas for $r = 0, 1$.

Equation 1 tells us how to compute $u_r(n)$ if we are given the numbers $u_r(n;i)$. For the case $r = 0$ Lemma 9, below, tells us how to do the converse.

Lemma 9. *If* $1 \leq i \leq n-2$ *then*

$$u_0(n;i) = \sum_{j=0}^{i-1} \binom{i-1}{j} u_0(n-2-j).$$

Proof. For $n = 1$ the identity is trivially true. Assume the identity is true for $n = m$. We have

$$\begin{aligned} u_0(m+1;i) &= \sum_{j=1}^{i-1} u_0(m;j) + u_0(m-1) && \text{by Lemma 8} \\ &= \sum_{j=1}^{i-1}\sum_{k=0}^{j-1} \binom{j-1}{k} u_0(m-2-k) + u_0(m-1) && \text{by the induction hypothesis} \\ &= \sum_{j=1}^{i-1}\sum_{k=j-1}^{i-2} \binom{k}{j-1} u_0(m-1-j). \end{aligned}$$

Using the familiar equality $\binom{1}{k} + \binom{2}{k} + \cdots + \binom{n}{k} = \binom{n+1}{k+1}$ we then get

$$u_0(m+1;i) = \sum_{j=1}^{i-1} \binom{i-1}{j} u_0(m-1-j).$$

Thus the identity is true for $n = m+1$ and by the principle of induction the desired identity is true for all $n \geq 1$. □

The following proposition is a direct consequence of Proposition 3. However, we give a different proof. The proof is intended to illustrate the general approach. It is advisable to read this proof before reading the proof of Theorem 4′ below.

Proposition 10. *The ordinary generating function for the number of* (12-3)*-avoiding permutations of length* n *is*

$$U_0(x) = \sum_{k\geq 0} \frac{x^k}{(1-x)(1-2x)\cdots(1-kx)}.$$

Proof. We have

$$\begin{aligned} u_0(n) &= \sum_{k=1}^{n} u_0(n;k) && \text{by Equation 1} \\ &= 2u_0(n-1) + \sum_{i=1}^{n-2}\sum_{j=0}^{i-1} \binom{i-1}{j} u_0(n-2-j) && \text{by Lemma 8 and 9} \\ &= u_0(n-1) + \sum_{i=0}^{n-2} \binom{n-2}{i} u_0(n-1-i) && \text{by } \sum_{i=k}^{n} \binom{i}{k} = \binom{n+1}{k+1} \\ &= u_0(n-1) + \sum_{i=0}^{n-2} \binom{n-2}{i} u_0(i+1). \end{aligned}$$

Therefore, by Lemma 7, we have

$$U_0(x) = xU_0(x) + 1 - x + xU_0\left(\frac{x}{1-x}\right),$$

which is equivalent to

$$U_0(x) = 1 + \frac{x}{1-x} U_0\left(\frac{x}{1-x}\right).$$

An infinite number of applications of this identity concludes the proof. □

We now derive a formula for $U_1(x)$ that is somewhat similar to the one for $U_0(x)$. The following lemma is a first step in this direction.

Lemma 11. *If $1 \le i \le n-2$ then*

$$u_1(n;i) = \sum_{j=0}^{i-1} \binom{i-1}{j} u_1(n-2-j) + u_0(n;i).$$

Proof. For $n = 1$ the identity is trivially true. Assume the identity is true for $n = m$. Lemma 8 and the induction hypothesis imply

$$\begin{aligned} u_1(m+1;i) &= \sum_{j=1}^{i-1} u_1(m;j) + u_1(m-1) + u_0(m-1) \\ &= \sum_{j=0}^{i-1} \binom{j-1}{k} u_1(m-1-j) + \sum_{j=1}^{i-1} u_0(m;j) + u_0(m-1). \end{aligned}$$

In addition, Lemma 9 implies

$$\begin{aligned} u_0(m+1;i) &= \sum_{j=1}^{i-1}\sum_{k=0}^{j-1} \binom{j-1}{k} u_0(n-2-k) + u_0(n-1) \\ &= \sum_{j=0}^{i-1} \binom{i-1}{j} u_0(n-1-j) \\ &= \sum_{j=1}^{i-1} u_0(m;j) + u_0(m-1). \end{aligned}$$

Thus the identity is true for $n = m+1$ and by the principle of induction the desired identity is true for all $n \ge 1$. □

Next, we rediscover Theorem 4.

Theorem 4′. *Let $u_1(n)$ be the number of permutations of length n containing exactly one occurrence of the pattern 12-3 and let B_n be the nth Bell number. The numbers $u_1(n)$ satisfy the recurrence*

$$u_1(n+2) = 2u_1(n+1) + \sum_{k=0}^{n-1} \binom{n}{k} \big[u_1(k+1) + B_{k+1}\big],$$

whenever $n \ge -1$, with the initial condition $u_1(0) = 0$.

Proof. Similarly to the proof of Proposition 10, we use Equation 1, Lemma 8, 9, and 11 to get

$$\begin{aligned} u_1(n) &= 2u_1(n-1) + \sum_{i=1}^{n-2} \left[\sum_{j=0}^{i-1} \binom{i-1}{j} u_1(n-2-j) + u_0(n;i) \right] \\ &= 2u_1(n-1) + \sum_{i=1}^{n-2}\sum_{j=0}^{i-1} \binom{i-1}{j} \big(u_1(n-2-j) + u_0(n-2-j)\big) \\ &= u_1(n-1) - u_0(n-1) + \sum_{i=0}^{n-2} \binom{n-2}{i} \big(u_1(i+1) + u_0(i+1)\big) \\ &= 2u_1(n-1) + \sum_{i=0}^{n-3} \binom{n-2}{i} \big(u_1(i+1) + u_0(i+1)\big). \end{aligned}$$

□

Corollary 12. *The ordinary generating function, $U_1(x)$, for the number of permutations of length n containing exactly one occurrence of the pattern* 12-3 *satisfies the functional equation*

$$U_1(x) = \frac{x}{1-x}\Big(U_1\Big(\frac{x}{1-x}\Big) + U_0\Big(\frac{x}{1-x}\Big) - U_0(x)\Big).$$

Proof. The result follows from Theorem 4 together with Lemma 7. □

Corollary 13. *The ordinary generating function for the number of permutations of length n containing exactly one occurrence of the pattern* 12-3 *is*

$$U_1(x) = \sum_{n\geq 1} \frac{x}{1-nx} \sum_{k\geq 0} \frac{kx^{k+n}}{(1-x)(1-2x)\cdots(1-(k+n)x)}.$$

Proof. We simply apply Corollary 12 an infinite number of times and in each step we perform some rather tedious algebraic manipulations. □

Theorem 14. *The ordinary generating function, $U_2(x)$, for the number of permutations of length n containing exactly two occurrences of the pattern* 12-3 *satisfies the functional equation*

$$\begin{aligned} U_2(x) = \frac{x}{(1-x)^2(1-2x)}\Big(& U_2\Big(\frac{x}{1-x}\Big) - (1-x)U_2(x) + \\ & U_1\Big(\frac{x}{1-x}\Big) - (1-x)^2U_1(x) + \\ & U_0\Big(\frac{x}{1-x}\Big) - (1-x)^2U_0(x) \Big). \end{aligned}$$

Proof. The proof is similar to the proofs of Lemma 11, Theorem 4' and Corollary 12, and we only sketch it here.

Lemma 8 yields

$$\begin{aligned} u_2(n;n) &= u_2(n-1) \\ u_2(n;n-1) &= u_2(n-1) \\ u_2(n;n-2) &= u_2(n-1) - u_2(n-2) + u_1(n-2) \end{aligned}$$

and, by means of induction,

$$u_2(n;i) = u_1(n;i) + u_0(n;i) - u_0(n-1;i) + \sum_{j=0}^{i-1} \binom{i-1}{j} u_2(n-2-j),$$

whenever $1 \leq i \leq n-3$. Therefore, $u_2(0) = u_2(1) = u_2(2) = 0$ and

$$\begin{aligned} u_2(n) = {} & 3u_2(n-1) - u_2(n-2) + u_1(n-2) + \\ & \sum_{i=1}^{n-3} \binom{n-3}{i} (u_2(n-1-i) + u_1(n-1-i) + u_0(n-1-i) - u_0(n-2-i)). \end{aligned}$$

whenever $n \geq 3$. Thus, the result follows from Lemma 7. □

We now turn our attention to patterns that belong to Class 2 and we use 23-1 as a representative of this class. The results found below regarding the 23-1 pattern are very similar to the ones previously found for the 12-3 pattern, and so are the proofs; therefore we choose to omit most of the proofs. However, we give the necessary lemmas from which the reader may construct her/his own proofs.

Define

$$\begin{aligned} v_r(n;b_1,\dots,b_k) &= s^r_{23\text{-}1}(n;b_1,\dots,b_k),\\ v_r(n) &= s^r_{23\text{-}1}(n),\\ V_r(x) &= S^r_{23\text{-}1}(x). \end{aligned}$$

If $a_1a_2\cdots a_n$ is any permutation of $[n]$ then

$$(23\text{-}1)a_1a_2\cdots a_n = (23\text{-}1)a_2a_3\cdots a_n + \begin{cases} a_1-1 & \text{if } a_1 < a_2,\\ 0 & \text{if } a_1 > a_2. \end{cases}$$

Lemma 15. *Let $n \geq 1$. We have $v_r(n;1) = v_r(n;n) = v_r(n-1)$ and*

$$v_r(n;i) = \sum_{j=1}^{i-1} v_r(n-1;j) + \sum_{j=i}^{n-1} v_{r-i+1}(n-1;j),$$

whenever $2 \leq i \leq n-1$.

Using Lemma 15 we quickly generate the numbers $v_r(n)$; the first few of these numbers are given in Table 2.

$n\backslash r$	0	1	2	3	4	5	6
0	1						
1	1						
2	2						
3	5	1					
4	15	6	3				
5	52	32	23	10	3

9	21147	32919	43626	46508	46880	41979	36774
10	115975	208816	304939	360376	396545	393476	377610

TABLE 2. The number of permutations of length n containing exactly r occurrences of the pattern 23-1.

Lemma 16. *If $2 \leq i \leq n-1$ then*

$$v_0(n;i) = \sum_{j=0}^{i-2} \binom{i-2}{j} v_0(n-2-j).$$

Proposition 17. *The ordinary generating function for the number of $(23\text{-}1)$-avoiding permutations of length n is*

$$V_0(x) = \sum_{k\geq 0} \frac{x^k}{(1-x)(1-2x)\cdots(1-kx)}.$$

Lemma 18. *If $2 \leq i \leq n-1$ then*

$$v_1(n;i) = \sum_{j=0}^{i-2} \binom{i-2}{j} v_1(n-2-j) + v_0(n;i-1) - v_0(n-1,i-1).$$

Theorem 6′. *Let $v_1(n)$ be the number of permutations of length n containing exactly one occurrence of the pattern* 23-1 *and let B_n be the nth Bell number. The numbers $v_1(n)$ satisfy the recurrence*

$$v_1(n+1) = v_1(n) + \sum_{k=1}^{n-1} \left[\binom{n}{k} v_1(k) + \binom{n-1}{k-1} B_k \right],$$

whenever $n \geq 0$, with the initial condition $v_1(0) = 0$.

Corollary 19. *The ordinary generating function for the number of permutations of length n containing exactly one occurrence of the pattern* 23-1 *satisfies the functional equation*

$$V_1(x) = \frac{x}{1-x} V_1\Big(\frac{x}{1-x}\Big) + x\bigg(V_0\Big(\frac{x}{1-x}\Big) - V_0(x)\bigg).$$

Corollary 20. *The ordinary generating function for the number of permutations of length n containing exactly one occurrence of the pattern* 23-1 *is*

$$V_1(x) = \sum_{n\geq 1} \frac{x}{1-(n-1)x} \sum_{k\geq 0} \frac{kx^{k+n}}{(1-x)(1-2x)\cdots(1-(k+n)x)}.$$

Theorem 21. *The ordinary generating function, $V_2(x)$, for the number of permutations of length n containing exactly two occurrences of the pattern* 23-1 *satisfies the functional equation*

$$V_2(x) = \frac{x}{1-x}\bigg(V_2\Big(\frac{x}{1-x}\Big) + (1-2x)V_1\Big(\frac{x}{1-x}\Big) + (1-3x+x^2)V_0\Big(\frac{x}{1-x}\Big)\bigg) - x + x^2$$

Proof. By Lemma 5

$$\begin{aligned}
v_2(n;n) &= v_2(n-1)\\
v_2(n;1) &= v_2(n-1)\\
v_2(n;2) &= v_2(n-2) + v_1(n-1) - v_1(n-2)\\
v_2(n;3) &= v_2(n-2) + v_2(n-3) + v_1(n-2) - v_1(n-3) +\\
&\qquad + v_0(n-1) - v_0(n-2) - v_0(n-3)
\end{aligned}$$

and, by means of induction,

$$v_2(n;i) = \sum_{j=0}^{i-2} \binom{i-2}{j} v_2(n-2-j) + v_1(n;i-1) + v_1(n-1;i-1) - v_0(n-1;i-2)$$

for $n-1 \geq i \geq 4$. Thus $v_2(0) = v_2(1) = v_2(2) = 0$ and for all $n \geq 3$

$$\begin{aligned}
v_2(n) = v_2(n-1) &+ \sum_{j=0}^{n-2} \binom{n-2}{j} v_2(n-1-j) +\\
&+ \sum_{j=0}^{n-3} \binom{n-3}{j} \big(v_1(n-1-j) - v_1(n-2-j)\big) +\\
&+ \sum_{j=0}^{n-4} \binom{n-4}{j} \big(v_0(n-1-j) - v_0(n-2-j) - v_0(n-3-j)\big).
\end{aligned}$$

The result now follows from Lemma 7. □

3. Counting occurrences of a pattern of Class 3

We choose 2-13 as our representative for Class 3 and we define $w_r(n)$ as the number of permutations of length n containing exactly r occurrences of the pattern 2-13. We could apply the analytic approach from the previous section to the problem of determining $w_r(n)$. However, a result by Clarke, Steingrímsson and Zeng [10, Corollary 11] provides us with a better option.

Theorem 22. *The following Stieltjes continued fraction expansion holds*

$$\sum_{\pi\in\mathcal{S}} x^{1+(12)\pi} y^{(21)\pi} p^{(2\text{-}31)\pi} q^{(31\text{-}2)\pi} t^{|\pi|} = \cfrac{1}{1-\cfrac{x[\,1\,]_{p,q}t}{1-\cfrac{y[\,1\,]_{p,q}t}{1-\cfrac{x[\,2\,]_{p,q}t}{1-\cfrac{y[\,2\,]_{p,q}t}{\ddots}}}}}$$

where $[\,n\,]_{p,q} = q^{n-1} + pq^{n-2} + \cdots + p^{n-2}q + p^{n-1}$.

Proof. In [10, Corollary 11] Clarke, Steingrímsson and Zeng derived the following continued fraction expansion

$$\sum_{\pi\in\mathcal{S}} y^{\operatorname{des}\pi} p^{\operatorname{Res}\pi} q^{\operatorname{Ddif}\pi} t^{|\pi|} = \cfrac{1}{1-\cfrac{[\,1\,]_p t}{1-\cfrac{yq[\,1\,]_p t}{1-\cfrac{q[\,2\,]_p t}{1-\cfrac{yq^2[\,2\,]_p t}{\ddots}}}}}$$

where $[\,n\,]_p = 1 + p + \cdots + p^{n-1}$. We refer the reader to [10] for the definitions of Ddif and Res. However, given these definitions, it is easy to see that Res $=$ (2-31) and Ddif $=$ (21) $+$ (2-31) $+$ (31-2). Moreover, des $=$ (21) and $|\pi| = 1 + (12)\pi + (21)\pi$. Thus, substituting $y(xq)^{-1}$ for y, pq^{-1} for p, and xt for t, we get the desired result. □

The following corollary is an immediate consequence of Theorem 22.

Corollary 23. *The bivariate ordinary generating function for the distribution of occurrences of the pattern* 2-13 *admits the Stieltjes continued fraction expansion*

$$\sum_{\pi\in\mathcal{S}} p^{(2\text{-}13)\pi} t^{|\pi|} = \cfrac{1}{1-\cfrac{[\,1\,]_p t}{1-\cfrac{[\,1\,]_p t}{1-\cfrac{[\,2\,]_p t}{1-\cfrac{[\,2\,]_p t}{\ddots}}}}}$$

where $[\,n\,]_p = 1 + p + \cdots + p^{n-1}$

Using Corollary 23 we quickly generate the numbers $w_r(n)$; the first few of these numbers are given in Table 3.

Corollary 24. *The number of* (2-13)*-avoiding permutations of length* n *is*

$$w_0(n) = \frac{1}{n+1}\binom{2n}{n}.$$

$n\backslash r$	0	1	2	3	4	5	6
0	1						
1	1						
2	2						
3	5	1					
4	14	8	2				
5	42	45	25	7	1		
6	132	220	198	112	44	12	2
7	429	1001	1274	1092	700	352	140
8	1430	4368	7280	8400	7460	5392	3262
9	4862	18564	38556	56100	63648	59670	47802
10	16796	77520	193800	341088	470934	541044	535990

TABLE 3. The number of permutations of length n containing exactly r occurrences of the pattern 2-13.

Proof. This result is explicitly stated in Proposition 3, but it also follows from Corollary 23 by putting $p = 0$. □

Corollary 25. *The number of permutations of length n containing exactly one occurrence of the pattern* 2-13 *is*

$$w_1(n) = \binom{2n}{n-3}.$$

Proof. For $m > 0$ let

$$W(p,t;m) = \cfrac{1}{1-\cfrac{[\,m\,]_p t}{1-\cfrac{[\,m\,]_p t}{1-\cfrac{[\,m+1\,]_p t}{1-\cfrac{[\,m+1\,]_p t}{\ddots}}}}}$$

Note that

$$W(p,t;m) = \cfrac{1}{1-\cfrac{[\,m\,]_p t}{1-[\,m\,]_p t W(p,t;m+1).}}$$

Assume $m > 1$. Differentiating $W(p,t;m)$ with respect to p and evaluating the result at $p = 0$ we get

$$D_p W(p,t;m)\big|_{p=0} = tC(t)^3 + t^2C(t)^5 + t^2C(t)^4 D_p W(p,t;m+1)\big|_{p=0}$$

where $C(t) = W(0,t,1)$ is the generating function for the Catalan numbers. Applying this identity an infinite number of times we get

$$D_p W(p,t,m)\big|_{p=0} = tC(t)^3 + t^2C(t)^5 + t^3C(t)^7 + \cdots = \frac{tC(t)^3}{1-tC(t)^2}.$$

On the other hand, $D_p W(p,t;1)\big|_{p=0} = t^2C(t)^4 D_p W(p,t;2)\big|_{p=0}$. Combining these two identities we get

$$D_p W(p,t;1)\big|_{p=0} = \frac{t^3C(t)^7}{1-tC(t)^2}.$$

Since $\sum_{n\geq 0} w_1(n)t^n = D_pW(p,t;1)\big|_{p=0}$ the proof is completed on extracting coefficients in the last identity. □

The proofs of the following two corollaries are similar to the proof of Corollary 25 and are omitted.

Corollary 26. *The number of permutations of length n containing exactly two occurrences of the pattern* 2-13 *is*

$$w_2(n) = \frac{n(n-3)}{2(n+4)}\binom{2n}{n-3}.$$

Corollary 27. *The number of permutations of length n containing exactly three occurrences of the pattern* 2-13 *is*

$$w_3(n) = \frac{1}{3}\binom{n+2}{2}\binom{2n}{n-5}.$$

As a concluding remark we note that there are many questions left to answer. What is, for example, the formula for $w_k(n)$ in general? What are the combinatorial explanations of $ns^1_{1\text{-}2\text{-}3}(n) = 3s^1_{2\text{-}13}(n)$ and

$$(n+3)(n+2)(n+1)s^1_{2\text{-}13}(n) = 2n(2n-1)(2n-2)s^1_{2\text{-}1\text{-}3}(n)?$$

In addition, Corollary 25 obviously is in need of a combinatorial proof.

ENUMERATING PERMUTATIONS AVOIDING A PAIR OF BABSON-STEINGRÍMSSON PATTERNS

ANDERS CLAESSON AND TOUFIK MANSOUR

Abstract. Babson and Steingrímsson introduced generalized permutation patterns that allow the requirement that two adjacent letters in a pattern must be adjacent in the permutation. Subsequently, Claesson presented a complete solution for the number of permutations avoiding any single pattern of type $(1,2)$ or $(2,1)$. For eight of these twelve patterns the answer is given by the Bell numbers. For the remaining four the answer is given by the Catalan numbers.

In the present paper we give a complete solution for the number of permutations avoiding a pair of patterns of type $(1,2)$ or $(2,1)$. We also conjecture the number of permutations avoiding the patterns in any set of three or more such patterns.

1. Introduction

Classically, a pattern is a permutation $\sigma \in \mathcal{S}_k$, and a permutation $\pi \in \mathcal{S}_n$ avoids σ if there is no subword of π that is order equivalent to σ. For example, $\pi \in \mathcal{S}_n$ avoids 132 if there is no $1 \le i < j < k \le n$ such that $\pi(i) < \pi(k) < \pi(j)$. We denote by $\mathcal{S}_n(\sigma)$ the set permutations in $\mathcal{S}_n$ that avoids σ.

The first case to be examined was the case of permutations avoiding one pattern of length 3. Knuth [6] found that, for any $\tau \in \mathcal{S}_3$, $|\mathcal{S}_n(\tau)| = C_n$, where $C_n = \frac{1}{n+1}\binom{2n}{n}$ is the nth Catalan number. Later Simion and Schmidt [7] found the cardinality of $\mathcal{S}_n(P)$ for all $P \subseteq \mathcal{S}_3$.

In [1] Babson and Steingrímsson introduced generalized permutation patterns that allow the requirement that two adjacent letters in a pattern must be adjacent in the permutation. The motivation for Babson and Steingrímsson in introducing these patterns was the study of Mahonian statistics. Two examples of such patterns are 1-32 and 13-2 (1-32 and 13-2 are of type $(1,2)$ and $(2,1)$ respectively). A permutation $\pi = a_1 a_2 \cdots a_n$ avoids 1-32 if there are no subwords $a_i a_j a_{j+1}$ of π such that $a_i < a_{j+1} < a_j$. Similarly π avoids 13-2 if there are no subwords $a_i a_{i+1} a_j$ of π such that $a_i < a_j < a_{i+1}$.

Claesson [2] presented a complete solution for the number of permutations avoiding any single pattern of type $(1,2)$ or $(2,1)$ as follows.

Proposition 1 (Claesson [2])**.** *Let $n \in \mathbb{N}$. We have*

$$|\mathcal{S}_n(p)| = \begin{cases} B_n & \text{if } p \in \{1\text{-}23, 3\text{-}21, 12\text{-}3, 32\text{-}1, 1\text{-}32, 3\text{-}12, 21\text{-}3, 23\text{-}1\}, \\ C_n & \text{if } p \in \{2\text{-}13, 2\text{-}31, 13\text{-}2, 31\text{-}2\}, \end{cases}$$

where B_n and C_n are the nth Bell and Catalan numbers, respectively.

In addition, Claesson gave some results for the number of permutations avoiding a pair of patterns.

Proposition 2 (Claesson [2])**.** *Let $n \in \mathbb{N}$. We have*

$$\mathcal{S}_n(1\text{-}23,\ 12\text{-}3) = B_n^*, \quad \mathcal{S}_n(1\text{-}23,\ 1\text{-}32) = I_n, \quad \text{and} \quad \mathcal{S}_n(1\text{-}23,\ 13\text{-}2) = M_n,$$

Date: July 29, 2002.

Key words and phrases. permutation, pattern avoidance.

where B_n^* is the nth Bessel number (# non-overlapping partitions of $[n]$ (see [4])), I_n is the number of involutions in $\mathcal{S}_n$, and M_n is the nth Motzkin number.

This paper is organized as follows. In Section 2 we define the notion of a pattern and some other useful concepts. For a proof of Proposition 1 we could refer the reader to [2]. We will however prove Proposition 1 in Section 3 in the context of binary trees. The idea being that this will be a useful aid to understanding of the proofs of Section 4. In Section 4 we give a solution for the number of permutations avoiding any given pair of patterns of type $(1,2)$ or $(2,1)$. These results are summarized in the following table.

# pairs	$\lvert\mathcal{S}_n(p,q)\rvert$
2	$0, n>5$
2	$2(n-1)$
4	$\binom{n}{2}+1$
34	2^{n-1}
8	M_n
2	a_n
4	b_n
4	I_n
4	C_n
2	B_n^*

Here

$$\sum_{n\geq 0} a_n x^n = \frac{1}{1-x-x^2\sum_{n\geq 0} B_n^* x^n}$$

and

$$b_{n+2} = b_{n+1} + \sum_{k=0}^{n} \binom{n}{k} b_k.$$

Finally, in Section 5 we conjecture the sequences $\lvert\mathcal{S}_n(P)\rvert$ for sets P of three or more patterns of type $(1,2)$ or $(2,1)$.

2. Preliminaries

By an *alphabet* X we mean a non-empty set. An element of X is called a *letter*. A *word* over X is a finite sequence of letters from X. We consider also the *empty word*, that is, the word with no letters; it is denoted by ϵ. Let $w = x_1x_2\cdots x_n$ be a word over X. We call $|w| := n$ the *length* of w. A *subword* of w is a word $v = x_{i_1}x_{i_2}\cdots x_{i_k}$, where $1 \leq i_1 < i_2 < \cdots < i_k \leq n$.

Let $[n] := \{1, 2, \ldots, n\}$ (so $[0] = \emptyset$). A *permutation* of $[n]$ is bijection from $[n]$ to $[n]$. Let $\mathcal{S}_n$ be the set of permutations of $[n]$, and $\mathcal{S} = \cup_{n\geq 0}\mathcal{S}_n$. We shall usually think of a permutation π as the word $\pi(1)\pi(2)\cdots\pi(n)$ over the alphabet $[n]$.

Define the *reverse* of π by $\pi^r(i) = \pi(n+1-i)$, and define the *complement* of π by $\pi^c(i) = n+1-\pi(i)$, where $i \in [n]$.

For each word $w = x_1x_2\cdots x_n$ over the alphabet $\{1,2,3,4,\ldots\}$ without repeated letters, we define the *projection* of w onto $\mathcal{S}_n$, which we denote $\mathrm{proj}(w)$, by

$$\mathrm{proj}(w) = a_1a_2\cdots a_n\,, \quad \text{where } \; a_i = |\{j \in [n] : x_j \leq x_i\}|.$$

Equivalently, $\mathrm{proj}(w)$ is the permutation in $\mathcal{S}_n$ which is order equivalent to w. For example, $\mathrm{proj}(2659) = 1324$.

We may regard a *pattern* as a function from $\mathcal{S}_n$ to the set $\mathbb{N}$ of natural numbers. The patterns of main interest to us are defined as follows. Let $xyz \in \mathcal{S}_3$ and $\pi = a_1a_2\cdots a_n \in \mathcal{S}_n$, then

$$(x\text{-}yz)\,\pi \;=\; |\{a_ia_ja_{j+1} : \mathrm{proj}(a_ia_ja_{j+1}) = xyz, 1 \leq i < j < n\}|$$

and similarly $(xy\text{-}z)\,\pi = (z\text{-}yx)\,\pi^r$. For instance

$$(1\text{-}23)\,491273865 = |\{127, 138, 238\}| = 3.$$

A pattern $p = p_1\text{-}p_2\text{-}\cdots\text{-}p_k$ containing exactly $k-1$ dashes is said to be of type $(|p_1|, |p_2|, \ldots, |p_k|)$. For example, the pattern 142-5-367 is of type $(3,1,3)$, and any classical pattern of length k is of type $(\underbrace{1,1,\ldots,1}_{k})$.

We say that a permutation π *avoids* a pattern p if $p\,\pi = 0$. The set of all permutations in $\mathcal{S}_n$ that avoids p is denoted $\mathcal{S}_n(p)$ and, more generally, $\mathcal{S}_n(P) = \bigcap_{p\in P} \mathcal{S}_n(p)$ and $\mathcal{S}(P) = \bigcup_{n\geq 0} \mathcal{S}_n(P)$.

We extend the definition of reverse and complement to patterns the following way. Let us call π the *underlying permutation* of the pattern p if π is obtained from p by deleting all the dashes in p. If p is a pattern with underlying permutation π, then p^c is the pattern with underlying permutation π^c and with dashes at precisely the same positions as there are dashes in p. We define p^r as the pattern we get from regarding p as a word and reading it backwards. For example, $(1\text{-}23)^c = 3\text{-}21$ and $(1\text{-}23)^r = 32\text{-}1$. Observe that

$$\sigma \in \mathcal{S}_n(p) \iff \sigma^r \in \mathcal{S}_n(p^r)$$
$$\sigma \in \mathcal{S}_n(p) \iff \sigma^c \in \mathcal{S}_n(p^c).$$

These observations of course generalize to $\mathcal{S}_n(P)$ for any set of patterns P.

The operations reverse and complement generates the dihedral group D_2 (the symmetry group of a rectangle). The orbits of D_2 in the set of patterns of type $(1,2)$ or $(2,1)$ will be called *symmetry classes*. For instance, the symmetry class of $1\text{-}23$ is

$$\{1\text{-}23, 3\text{-}21, 12\text{-}3, 32\text{-}1\}.$$

We also talk about symmetry classes of sets of patterns (defined in the obvious way). For example, the symmetry class of $\{1\text{-}23, 3\text{-}21\}$ is $\{\{1\text{-}23, 3\text{-}21\}, \{32\text{-}1, 12\text{-}3\}\}$.

A set of patterns P such that if $p, p' \in P$ then, for each n, $|\mathcal{S}_n(p)| = |\mathcal{S}_n(p')|$ is called a *Wilf-class*. For instance, by Proposition 1, the Wilf-class of $1\text{-}23$ is

$$\{1\text{-}23, 3\text{-}21, 12\text{-}3, 32\text{-}1, 1\text{-}32, 3\text{-}12, 21\text{-}3, 23\text{-}1\}.$$

We also talk about Wilf-classes of sets of patterns (defined in the obvious way). It is clear that symmetry classes are Wilf-classes, but as we have seen the converse does not hold in general.

In what follows we will frequently use the following well known bijection between increasing binary trees and permutations (e.g. see [8, p. 24]). Let π be any word on the alphabet $\{1, 2, 3, 4, \ldots\}$ with no repeated letters. If $\pi \neq \epsilon$ then we can factor π as $\pi = \sigma\,\hat{0}\,\tau$, where $\hat{0}$ is the minimal element of π. Define $T(\epsilon) = \bullet$ (a leaf) and

$$T(\pi) \;=\; \begin{array}{ccc} & \hat{0} & \\ T(\sigma) & & T(\tau) \end{array}$$

In addition, we define $U(t)$ as the unlabelled counterpart of the labelled tree t. For instance

$$T(316452) \;=\; \begin{array}{ccccc} & & 1 & & \\ & 3 & & 2 & \\ & & & 4 & \\ & 6 & & 5 & \end{array} \qquad U \circ T(316452) \;=\; \begin{array}{ccccc} & & \circ & & \\ & \circ & & \circ & \\ & & & \circ & \\ & \circ & & \circ & \end{array}$$

Note that we, for ease of presentation, do not display the leafs ($\bullet$).

3. Single patterns

There are 3 symmetry classes and 2 Wilf-classes of single patterns. The details are as follows.

Proposition 3 (Claesson [2])**.** *Let $n \in \mathbb{N}$. We have*

$$|\mathcal{S}(p)| = \begin{cases} B_n & \text{if } p \in \{1\text{-}23, 3\text{-}21, 12\text{-}3, 32\text{-}1\}, \\ B_n & \text{if } p \in \{1\text{-}32, 3\text{-}12, 21\text{-}3, 23\text{-}1\}, \\ C_n & \text{if } p \in \{2\text{-}13, 2\text{-}31, 13\text{-}2, 31\text{-}2\}, \end{cases}$$

where B_n and C_n are the nth Bell and Catalan numbers, respectively.

Proof of the first case. Note that

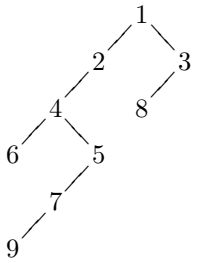
$$\sigma 1 \tau \in \mathcal{S}(1\text{-}23) \iff \begin{cases} \mathrm{proj}(\sigma) \in \mathcal{S}(1\text{-}23) \\ \mathrm{proj}(\tau) \in \mathcal{S}(12) \\ \sigma 1 \tau \in \mathcal{S} \end{cases}$$

where of course $\mathcal{S}(12) = \{\epsilon, 1, 21, 321, 4321, \ldots\}$. This enable us to give a bijection Φ between $\mathcal{S}_n(1\text{-}23)$ and the set of partitions of $[n]$, by induction. Let the elements of 1τ form the first block of $\Phi(\sigma 1 \tau)$ and let the rest of the blocks be as in $\Phi(\sigma)$. □

The most transparent way to see the above correspondence is perhaps to view the permutation as an increasing binary tree.

Example 4. The tree

$T(649752183) =$



corresponds to the partition $\{\{1, 3, 8\}, \{2\}, \{4, 5, 7, 9\}, \{6\}\}$.

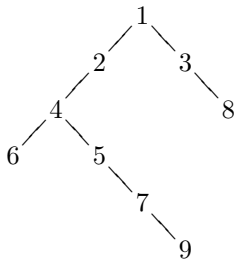
Proof of the second case. This case is analogous to the previous one. We have

$$\sigma 1 \tau \in \mathcal{S}(1\text{-}32) \iff \begin{cases} \mathrm{proj}(\sigma) \in \mathcal{S}(1\text{-}32) \\ \mathrm{proj}(\tau) \in \mathcal{S}(21) \\ \sigma 1 \tau \in \mathcal{S} \end{cases}$$

We give a bijection Φ between $\mathcal{S}_n(1\text{-}23)$ and the set of partitions of $[n]$, by induction. Let the elements of 1τ form the first block of $\Phi(\sigma 1 \tau)$ and let the rest of the blocks be as in $\Phi(\sigma)$. □

Example 5. The tree

$T(645792138) =$



corresponds to the partition $\{\{1, 3, 8\}, \{2\}, \{4, 5, 7, 9\}, \{6\}\}$.

Now that we have seen the structure of $\mathcal{S}(1\text{-}23)$ and $\mathcal{S}(1\text{-}32)$, it is trivial to give a bijection between the two sets. Indeed, if $\Theta : \mathcal{S}(1\text{-}23) \to \mathcal{S}(1\text{-}32)$ is given by $\Theta(\epsilon) = \epsilon$ and $\Theta(\sigma 1 \tau) = \Theta(\sigma)\, 1\, \tau^r$ then Θ is such a bijection. Actually Θ is its own inverse.

Proof of the third case. It is plain that a permutation avoids 2-13 if and only if it avoids 2-1-3 (see [2]). Note that

$$\sigma 1\tau \in \mathcal{S}(2\text{-}1\text{-}3) \iff \begin{cases} \mathrm{proj}(\sigma), \mathrm{proj}(\tau) \in \mathcal{S}(2\text{-}1\text{-}3) \\ \tau > \sigma \\ \sigma 1\tau \in \mathcal{S} \end{cases}$$

where $\tau > \sigma$ means that any letter of τ is greater than any letter of σ. Hence we get a unique labelling of the binary tree corresponding to $\sigma 1\tau$, that is, if $\pi_1, \pi_2 \in \mathcal{S}(2\text{-}1\text{-}3)$ and $U \circ T(\pi_1) = U \circ T(\pi_2)$ then $\pi_1 = \pi_2$. It is well known that there are exactly C_n (unlabelled) binary trees with n (internal) nodes. The validity of the last statement is for example seen from the following simple bijection between Dyck words and binary trees. Fixing notation, we let the set of Dyck words be the smallest set of words over $\{u, d\}$ that contains the empty word and is closed under $(\alpha, \beta) \mapsto u\alpha d\beta$. Now the promised bijection is given by $\Psi(\bullet) = \epsilon$ and

$$\Psi\left(\begin{array}{ccc} & \circ & \\ L & & R \end{array} \right) = u\Psi(L)d\Psi(R).$$

□

4. Pairs of patterns

There are $\binom{12}{2} = 66$ pairs of patterns altogether. It turns out that there are 21 symmetry classes and 10 Wilf-classes. The details are as follows.

4.1. The Wilf-class corresponding to $\{0\}_n$.

Proposition 6. *Let $n \in \mathbb{N}$ with $n > 5$. For any pair $\{p, q\}$ in the set*

$$\left\{ \{1\text{-}23, 32\text{-}1\}, \{3\text{-}21, 12\text{-}3\} \right\}$$

we have $|\mathcal{S}_n(p, q)| = 0$.

Proof. We have

$$\sigma 1\tau \in \mathcal{S}(1\text{-}23, 32\text{-}1) \iff \begin{cases} \mathrm{proj}(\sigma) \in \mathcal{S}(21, 1\text{-}23) \\ \mathrm{proj}(\tau) \in \mathcal{S}(12, 32\text{-}1) \\ \sigma 1\tau \in \mathcal{S} \end{cases}$$

The result now follows from $\mathcal{S}(21, 1\text{-}23) = \{\epsilon, 1, 12\}$ and $\mathcal{S}(12, 32\text{-}1) = \{\epsilon, 1, 21\}$. □

4.2. The Wilf-class corresponding to $\{2(n-1)\}_n$.

Proposition 7. *Let $n \in \mathbb{N}$ with $n > 1$. For any pair $\{p, q\}$ in the set*

$$\left\{ \{1\text{-}23, 3\text{-}21\}, \{32\text{-}1, 12\text{-}3\} \right\}$$

we have $|\mathcal{S}_n(p, q)| = 2(n-1)$.

Proof. Since 3-21 is the complement of 1-23, the cardinality of $\mathcal{S}_n(1\text{-}23, 3\text{-}21)$ is twice the number of permutations in $\mathcal{S}_n(1\text{-}23, 3\text{-}21)$ in which 1 precedes n. In addition, 1 and n must be adjacent letters in a permutation avoiding 1-23 and 3-21. Let $\sigma 1n\tau$ be such a permutation. Note that τ must be both increasing and decreasing, that is, $\tau \in \{\epsilon, 2, 3, 4, \ldots, n-1\}$, so there are $n-1$ choices for τ. Furthermore, there is exactly one permutation in $\mathcal{S}_n(1\text{-}23, 3\text{-}21)$ of the form $\sigma 1n$, namely $(\lceil \frac{n+1}{2} \rceil, \ldots, n-2, 3, n-1, 2, n, 1)$, and similarly there is exactly one of the form $\sigma 1nk$ for each $k \in \{2, 3, \ldots, n-1\}$. This completes our argument. □

4.3. **The Wilf-class corresponding to $\{\binom{n}{2}+1\}_n$.**

Proposition 8. *Let $n \in \mathbb{N}$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}23, 2\text{-}31\}, \{3\text{-}21, 2\text{-}13\}, \{12\text{-}3, 31\text{-}2\}, \{32\text{-}1, 13\text{-}2\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = \binom{n}{2} + 1$.

Proof. Note that

$$\sigma 1 \tau \in \mathcal{S}(1\text{-}23, 2\text{-}31) \iff \begin{cases} \mathrm{proj}(\sigma), \mathrm{proj}(\tau) \in \mathcal{S}(12) \\ \sigma 1 \tau \in \mathcal{S}(2\text{-}31) \end{cases}$$

It is now rather easy to see that $\pi \in \mathcal{S}_n(1\text{-}23, 2\text{-}31)$ if and only if $\pi = n \cdots 21$ or π is constructed the following way. Choose i and j such that $1 \le j < i \le n$. Let $\pi(i-1) = 1$, $\pi(i) = n + 1 - j$ and arrange the rest of the elements so that $\pi(1) > \pi(2) > \cdots > \pi(i-1)$ and $\pi(i) > \pi(i+1) > \cdots > \pi(n)$ (this arrangement is unique). Since there are $\binom{n}{2}$ ways of choosing i and j we get the desired result. □

4.4. **The Wilf-class corresponding to $\{2^{n-1}\}_n$.**

Proposition 9. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}23, 2\text{-}13\}, \{3\text{-}21, 2\text{-}31\}, \{12\text{-}3, 13\text{-}2\}, \{32\text{-}1, 31\text{-}2\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

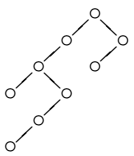
Proof. We have

$$\sigma 1 \tau \in \mathcal{S}(1\text{-}23, 2\text{-}13) \iff \begin{cases} \mathrm{proj}(\sigma) \in \mathcal{S}(1\text{-}23, 2\text{-}13) \\ \mathrm{proj}(\tau) \in \mathcal{S}(12) \\ \sigma > \tau \\ \sigma 1 \tau \in \mathcal{S}, \end{cases}$$

where $\sigma > \tau$ means that any letter of τ is greater than any letter of σ. This enable us to give a bijection between $\mathcal{S}_n(1\text{-}23, 2\text{-}13)$ and the set of compositions (ordered formal sums) of n. Indeed, such a bijection Ψ is given by $\Psi(\epsilon) = \epsilon$ and $\Psi(\sigma 1 \tau) = \Psi(\sigma) + |1\tau|$. □

Example 10. The tree

$$U \circ T(958764132) \;=$$



corresponds to the composition $1 + 3 + 1 + 4$ of 9.

Proposition 11. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}23, 23\text{-}1\}, \{3\text{-}21, 21\text{-}3\}, \{12\text{-}3, 3\text{-}12\}, \{32\text{-}1, 1\text{-}32\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. We have

$$\sigma 1 \tau \in \mathcal{S}(1\text{-}23, 23\text{-}1) \iff \begin{cases} \mathrm{proj}(\sigma), \mathrm{proj}(\tau) \in \mathcal{S}(12) \\ \sigma 1 \tau \in \mathcal{S} \end{cases}$$

Hence a permutation in $\mathcal{S}(1\text{-}23, 23\text{-}1)$ is given by the following procedure. Choose a subset $S \subseteq \{2, 3, 4, \ldots, n\}$, let σ be the word obtained by writing the elements of S in decreasing order, and let τ be the word obtained by writing the elements of $\{2, 3, 4, \ldots, n\} \setminus S$ in decreasing order. □

Example 12. The tree

$T(421653) \;=$ 
corresponds to the subset $\{2, 4\}$ of $\{2, 3, 4, 5, 6\}$.

Proposition 13. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}23, 31\text{-}2\}, \{3\text{-}21, 13\text{-}2\}, \{12\text{-}3, 2\text{-}31\}, \{32\text{-}1, 2\text{-}13\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. This case is essentially identical to the case dealt with in Proposition 9. □

Proposition 14. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}32, 2\text{-}13\}, \{3\text{-}12, 2\text{-}31\}, \{13\text{-}2, 21\text{-}3\}, \{23\text{-}1, 31\text{-}2\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. The bijection Θ between $\mathcal{S}(1\text{-}23)$ and $\mathcal{S}(1\text{-}32)$ (see page 3) provides a one-to-one correspondence between $\mathcal{S}_n(1\text{-}32, 2\text{-}13)$ and $\mathcal{S}_n(1\text{-}23, 2\text{-}13)$. Consequently the result follows from Proposition 9. □

Proposition 15. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}32, 2\text{-}31\}, \{3\text{-}12, 2\text{-}13\}, \{31\text{-}2, 21\text{-}3\}, \{23\text{-}1, 13\text{-}2\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. We have

$$\sigma 1 \tau \in \mathcal{S}(3\text{-}12, 2\text{-}13) \iff \begin{cases} \mathrm{proj}(\sigma), \mathrm{proj}(\tau) \in \mathcal{S}(3\text{-}12, 2\text{-}13) \\ \sigma = \epsilon \;\text{ or }\; \tau = \epsilon \\ \sigma 1 \tau \in \mathcal{S} \end{cases}$$

Thus a bijection between $\mathcal{S}_n(3\text{-}12, 2\text{-}13)$ and $\{0, 1\}^{n-1}$ is given by $\Psi(\epsilon) = \epsilon$ and

$$\Psi(\sigma 1 \tau) = x\Psi(\sigma\tau) \text{ where } x = \begin{cases} 1 & \text{if } \sigma \neq \epsilon, \\ 0 & \text{if } \tau \neq \epsilon, \\ \epsilon & \text{otherwise.} \end{cases}$$

□

Example 16. The tree

$U \circ T(136542) \;=$ 
corresponds to $01011 \in \{0, 1\}^5$.

Proposition 17. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}32, 3\text{-}12\}, \{23\text{-}1, 21\text{-}3\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. Since 3-12 is the complement of 1-32, the cardinality of $\mathcal{S}_n(1\text{-}32, 3\text{-}12)$ is twice the number of permutations in $\mathcal{S}_n(1\text{-}32, 3\text{-}12)$ in which 1 precedes n. In addition, n must be the last letter in such a permutation or else a hit of 1-32 would be formed. We have

$$\sigma 1 \tau n \in \mathcal{S}(1\text{-}32, 3\text{-}12) \iff \begin{cases} \operatorname{proj}(\sigma 1 \tau) \in \mathcal{S}(1\text{-}32, 3\text{-}12) \\ \operatorname{proj}(\tau) \in \mathcal{S}(21) \\ \sigma 1 \tau \in \mathcal{S} \end{cases}$$

$$\iff \begin{cases} \operatorname{proj}(\sigma) \in \mathcal{S}(1\text{-}32, 3\text{-}12) \\ \operatorname{proj}(\tau) \in \mathcal{S}(21) \\ \sigma < \tau \\ \sigma 1 \tau \in \mathcal{S} \end{cases}$$

The rest of the proof follows the same lines as the proof of Proposition 9. □

Proposition 18. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\{\, \{1\text{-}32, 23\text{-}1\}, \{3\text{-}12, 21\text{-}3\} \,\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. We can copy almost verbatim the proof of Proposition 15, indeed, it is easy to see that $\mathcal{S}_n(1\text{-}32, 23\text{-}1) = \mathcal{S}_n(1\text{-}32, 2\text{-}31)$. □

Proposition 19. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\{\, \{1\text{-}32, 31\text{-}2\}, \{3\text{-}12, 13\text{-}2\}, \{21\text{-}3, 2\text{-}31\}, \{23\text{-}1, 2\text{-}13\} \,\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. We can copy almost verbatim the proof of Proposition 17, indeed, it is easy to see that $\mathcal{S}_n(1\text{-}32, 31\text{-}2) = \mathcal{S}_n(1\text{-}32, 3\text{-}12)$. □

Proposition 20. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\{\, \{2\text{-}13, 2\text{-}31\}, \{31\text{-}2, 13\text{-}2\} \,\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. $|\mathcal{S}_n(2\text{-}13, 2\text{-}31)| = |\mathcal{S}_n(2\text{-}1\text{-}3, 2\text{-}3\text{-}1)| = 2^{n-1}$ by [7, Lemma 5(d)]. □

Proposition 21. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\{\, \{2\text{-}13, 13\text{-}2\}, \{2\text{-}31, 31\text{-}2\} \,\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. $|\mathcal{S}_n(2\text{-}13, 13\text{-}2)| = |\mathcal{S}_n(1\text{-}3\text{-}2, 2\text{-}1\text{-}3)| = 2^{n-1}$ by [7, Lemma 5(b)]. □

Proposition 22. *Let $n \in \mathbb{N}$ with $n > 0$. For any pair $\{p, q\}$ in the set*

$$\{\, \{2\text{-}13, 31\text{-}2\}, \{2\text{-}31, 13\text{-}2\} \,\}$$

we have $|\mathcal{S}_n(p, q)| = 2^{n-1}$.

Proof. $|\mathcal{S}_n(2\text{-}13, 31\text{-}2)| = |\mathcal{S}_n(2\text{-}1\text{-}3, 3\text{-}1\text{-}2)| = 2^{n-1}$ by [7, Lemma 5(c)]. □

4.5. **The Wilf-class corresponding to $\{M_n\}_n$.**

Proposition 23. *Let $n \in \mathbb{N}$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}23, 13\text{-}2\}, \{3\text{-}21, 31\text{-}2\}, \{12\text{-}3, 2\text{-}13\}, \{32\text{-}1, 2\text{-}31\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = M_n$, where M_n is the nth Motzkin number.

Proof. See Proposition 2. □

Proposition 24. *Let $n \in \mathbb{N}$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}23, 21\text{-}3\}, \{3\text{-}21, 23\text{-}1\}, \{12\text{-}3, 1\text{-}32\}, \{32\text{-}1, 3\text{-}12\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = M_n$, where M_n is the nth Motzkin number.

Proof. We give a bijection $\Lambda : \mathcal{S}_n(1\text{-}23, 21\text{-}3) \to \mathcal{S}_n(1\text{-}23, 13\text{-}2)$ by means of induction. Let $\pi \in \mathcal{S}_n(1\text{-}23, 21\text{-}3)$. Define $\Lambda(\pi) = \pi$ for $n \leq 1$. Assume $n \geq 2$ and $\pi = a_1 a_2 \cdots a_n$. It is plain that either $a_1 = n$ or $a_2 = n$, so we can define

$$\Lambda(\pi) = \begin{cases} (a'_1 + 1, \ldots, a'_{n-1} + 1, a'_{n-2} + 1, 1) & \text{if } \begin{cases} a_1 = n \quad \text{and} \\ a'_1 \cdots a'_{n-1} = \Lambda(a_2 a_3 a_4 \cdots a_n), \end{cases} \\ (a'_1 + 1, \ldots, a'_{n-1} + 1, 1, a'_{n-2} + 1) & \text{if } \begin{cases} a_2 = n \quad \text{and} \\ a'_1 \cdots a'_{n-1} = \Lambda(a_1 a_3 a_4 \cdots a_n). \end{cases} \end{cases}$$

Observing that if $\sigma \in \mathcal{S}_n(1\text{-}23, 13\text{-}2)$ then $\sigma(n-1) = 1$ or $\sigma(n) = 1$, it easy to find the inverse of Λ. □

4.6. **The Wilf-class corresponding to $\{1, 1, 2, 4, 9, 22, 58, 164, 496, 1601, \ldots\}$.** In [2] Claesson introduced the notion of a monotone partition. A partition is *monotone* if its non-singleton blocks can be written in increasing order of their least element and increasing order of their greatest element, simultaneously. He then proved that monotone partitions and non-overlapping partitions are in ono-to-one correspondence. Non-overlapping partitions where first studied by Flajolet and Schot in [4]. A partition π is *non-overlapping* if for no two blocks A and B of π we have $\min A < \min B < \max A < \max B$. Let B^*_n be the number of non-overlapping partitions of $[n]$; this number is called the nth *Bessel number*. Proposition 2 tells us that there is a bijection between non-overlapping partitions and permutations avoiding 1-23 and 12-3. Below we define a new class of partitions called strongly monotone partitions and then show that there is a bijection between strongly monotone partitions and permutations avoiding 1-32 and 21-3.

Definition 25. Let π be an arbitrary partition whose blocks $\{A_1, \ldots, A_k\}$ are ordered so that for all $i \in [k-1]$, $\min A_i > \min A_{i+1}$. If $\max A_i > \max A_{i+1}$ for all $i \in [k-1]$, then we call π a *strongly monotone partition*.

In other words a partition is strongly monotone if its blocks can be written in increasing order of their least element and increasing order of their greatest element, simultaneously. Let us denote by a_n the number of strongly monotone partitions of $[n]$. The sequence $\{a_n\}_0^\infty$ starts with

$$1, 1, 2, 4, 9, 22, 58, 164, 496, 1601, 5502, 20075, 77531, 315947, 1354279.$$

It is routine to derive the continued fraction expansion

$$\sum_{n\geq 0} a_n x^n = \cfrac{1}{1-1\cdot x-\cfrac{x^2}{1-1\cdot x-\cfrac{x^2}{1-2\cdot x-\cfrac{x^2}{1-3\cdot x-\cfrac{x^2}{1-4\cdot x-\cfrac{x^2}{\ddots}}}}}}$$

using the standard machinery of Flajolet [3] and Françon and Viennot [5]. One can also note that there is a one-to-one correspondence between strongly monotone partitions and non-overlapping partition, π, such that if $\{x\}$ and B are blocks of π then either $x < \min B$ or $\max B < x$. In addition, we observe that

$$\sum_{n\geq 0} a_n x^n = \frac{1}{1-x-x^2B^*(x)},$$

where $B^*(x) = \sum_{n\geq 0} B_n^* x^n$ is the ordinary generating function for the Bessel numbers.

Proposition 26. *Let $n \in \mathbb{N}$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}32, 21\text{-}3\}, \{3\text{-}12, 23\text{-}1\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = a_n$, where a_n is the number of strongly monotone partitions of $[n]$ (see Definition 25).

Proof. Suppose $\pi \in \mathcal{S}_n$ has $k+1$ left-to-right minima $1, 1', 1'', \ldots, 1^{(k)}$ such that

$$1 < 1' < 1'' < \cdots < 1^{(k)}, \text{ and } \pi = 1^{(k)}\tau^{(k)} \cdots 1'\tau' 1\tau.$$

Then π avoids 1-32 if and only if, for each i, $\tau^{(i)} \in \mathcal{S}(21)$. If π avoids 1-32 and $x_i = \max 1^{(i)}\tau^{(i)}$ then π avoids 21-3 precisely when $x_0 < x_1 < \cdots < x_k$. This follows from observing that the only potential (21-3)-subwords of π are $x_{i+1}1^{(k)}x_j$ with $j \leq i$.

Mapping π to the partition $\{1\sigma, 1'\sigma', \ldots, 1^{(k)}\tau^{(k)}\}$ we thus get a one-to-one correspondence between permutations in $\mathcal{S}_n(1\text{-}32, 21\text{-}3)$ and strongly monotone partitions of $[n]$. □

4.7. **The Wilf-class corresponding to $\{1, 1, 2, 4, 9, 23, 65, 199, 654, 2296, \ldots\}$.**

Proposition 27. *Let $n \in \mathbb{N}$. For any pair $\{p, q\}$ in the set*

$$\big\{\, \{1\text{-}23, 3\text{-}12\}, \{3\text{-}21, 1\text{-}32\}, \{23\text{-}1, 12\text{-}3\}, \{32\text{-}1, 21\text{-}3\} \,\big\}$$

we have $|\mathcal{S}_n(p, q)| = b_n$, where the sequence $\{b_n\}$ satisfies $b_0 = 1$ and, for $n \geq -2$,

$$b_{n+2} = b_{n+1} + \sum_{k=0}^{n} \binom{n}{k} b_k.$$

Proof. Suppose $\pi \in \mathcal{S}_n$ has $k+1$ left-to-right minima $1, 1', 1'', \ldots, 1^{(k)}$ such that

$$1 < 1' < 1'' < \cdots < 1^{(k)}, \text{ and } \pi = 1^{(k)}\tau^{(k)} \cdots 1'\tau' 1\tau.$$

Then π avoids 1-23 if and only if, for each i, $\tau^{(i)} \in \mathcal{S}(12)$. If π avoids 1-23 and $x_i = \max 1^{(i)}\tau^{(i)}$ then π avoids 3-12 precisely when

$$j > i \text{ and } x_i \neq 1^{(i)} \implies x_j < x_i.$$

This follows from observing that the only potential (3-12)-subwords of π are $x_j 1^{(k)} x_i$ with $j \leq i$. Thus we have established

$$\sigma 1 \tau \in \mathcal{S}_n(1\text{-}23, 3\text{-}12) \iff \begin{cases} \mathrm{proj}(\sigma) \in \mathcal{S}(1\text{-}23, 3\text{-}12) \\ \tau \neq \epsilon \ \Rightarrow \ \tau = \tau' n \text{ and } \mathrm{proj}(\tau') \in \mathcal{S}(12) \\ \sigma 1 \tau \in \mathcal{S}_n \end{cases}$$

If we know that $\sigma 1 \tau' n \in \mathcal{S}_n(1\text{-}23, 3\text{-}12)$ and $\mathrm{proj}(\tau') \in \mathcal{S}_k(12)$ then there are $\binom{n-2}{k}$ candidates for τ'. In this way the recursion follows. □

4.8. **The Wilf-class corresponding to I_n.**

Proposition 28. *Let $n \in \mathbb{N}$. For any pair $\{p, q\}$ in the set*

$$\big\{ \{1\text{-}23, 1\text{-}32\}, \{3\text{-}21, 3\text{-}12\}, \{21\text{-}3, 12\text{-}3\}, \{32\text{-}1, 23\text{-}1\} \big\}$$

we have $|\mathcal{S}_n(p, q)| = I_n$, where I_n is the number of involutions in $\mathcal{S}_n$.

Proof. See Proposition 2. □

4.9. **The Wilf-class corresponding to C_n.**

Proposition 29. *Let $n \in \mathbb{N}$. For any pair $\{p, q\}$ in the set*

$$\big\{ \{1\text{-}32, 13\text{-}2\}, \{3\text{-}12, 31\text{-}2\}, \{21\text{-}3, 2\text{-}13\}, \{23\text{-}1, 2\text{-}31\} \big\}$$

we have $|\mathcal{S}_n(p, q)| = C_n$, where C_n is the nth Catalan number.

Proof. $\mathcal{S}_n(1\text{-}32, 13\text{-}2) = \mathcal{S}_n(1\text{-}3\text{-}2)$. □

4.10. **The Wilf-class corresponding to B_n^*.**

Proposition 30. *Let $n \in \mathbb{N}$. For any pair $\{p, q\}$ in the set*

$$\big\{ \{1\text{-}23, 12\text{-}3\}, \{3\text{-}21, 32\text{-}1\} \big\}$$

we have $|\mathcal{S}_n(p, q)| = B_n^*$, where B_n^* is the nth Bessel number.

Proof. See Proposition 2. □

5. More than two patterns

Let P be a set of patterns of type $(1, 2)$ or $(2, 1)$. With the aid of a computer we have calculated the cardinality of $\mathcal{S}_n(P)$ for sets P of three ore more patterns. From these results we arrived at the plausible conjectures of table 1 (some of which are trivially true). We use the notation $m \times n$ to express that there are m symmetric classes each of which contains n sets. Moreover, we denote by F_n the nth *Fibonacci number* ($F_0 = F_1 = 1, F_{n+1} = F_n + F_{n-1}$).

Acknowledgements

Abstract. This paper deals with our work on interactive mathematical documents. These documents accomodate various sources, users, and mathematical services. Communication of mathematics between these entities is based on the OpenMath standard and Java technology. But, for the management of the communication, more protocols and tools are needed. We describe an architecture that serves as a framework for our work on interactive documents, and we report on what we have implemented so far.

1 Introduction

An interactive mathematical document is to be regarded as a book, an article, or announcement on computer that can be read in the way their ordinary (paper) counterparts can, but which, in addition, enables a variety of activities. Among these interactions, we count storing and communicating mathematics, presenting mathematics (e.g., in browsers) and performing mathematical operations, possibly elsewhere on the Web.

Although the notion of an interactive mathematical document has been around for several years [14] its realization is nowhere near the final stage. Recent web technological progress, for instance, has enabled a smoother communication of mathematics than ever before. The use of an interactive mathematical document can provide a window to the world of mathematical services on the internet. Moreover, a mathematical service on the internet can be created by the construction of an interactive mathematical document. In §3 of this paper we paint the contours of such a mathematical document. In particular, we describe a *mathematical document server* which takes input from various sources (the document source, mathematical services, and users), creates a highly interactive mathematical set-up, and serves it to the user. In this vein, the paper can be viewed as a sequel to [11].

We would like to stress that the technology for achieving such goals already exists, mainly (for our purposes) in the form of Java software. In §4, we describe some of the main tools we have developed for realizing the interactive mathematical documents. We envision that it will require a few

more years before integrated authoring tools, as easy to use as LaTeX, will be widely available. With the work presented here, we intend to contribute to these developments.

Before going into details regarding interactive documents, in §2, we discuss the general picture of mathematics on the Web.

2 A Framework for Interactive Mathematics

In this section we describe our approach to interactive mathematics. In §2.1, we begin by overviewing OpenMath, a standard for communicating mathematics across the Web. Next, in §2.2, we discuss web services and, in particular, address two additional requirements for our purposes: query facilities and a notion of the state of the mathematics that is being communicated.

2.1 OpenMath

A starting point for semantically rich communication across the Web is the standard for mathematical expressions OpenMath, cf. [25], and, for our purposes, its XML encoding. The representation of mathematics in OpenMath relies on four 'expression tree' constructors (viz., application, binding, attribution, and error), on five basic objects (byte arrays, strings, integers, IEEE floats, variables), and on a special, sixth, basic object: symbols, defined in Content Dictionaries (CDs for short). The core CDs are publicly available collections of mathematical definitions. The standard documents and the collection of public CDs for OpenMath are available in XML format from [25]. An example of the XML encoding of an OpenMath object expressing that $\cos(\pi) = -1$ is given in Figure 1.

```
<OMOBJ>
 <OMA>
  <OMS cd="relation1" name="eq"/>
  <OMA> <OMS cd="transc1" name="cos"/> <OMS cd="nums" name="pi"/> </OMA>
  <OMI>-1</OMI>
 </OMA>
</OMOBJ>
```

Fig. 1. OpenMath fragment.

For a further introduction to OpenMath, see [11]. There it is also explained how OpenMath and MathML [21] complement each other in that OpenMath objects express mathematical content whereas MathML mainly focuses on presentation. The connection between the two rests upon

- the fact that MathML works with a relatively small number of commonplace mathematical constructs chosen within the high school realm of applications and

- the content symbol (`csymbol`) in MathML for introducing a new symbol whose semantics is not one of the core content elements of MathML. In particular, such an external definition may reside in an OpenMath Content Dictionary.

For purposes of alignment of MathML and OpenMath, the core CDs contain symbols matching the MathML constructs.

As it stands, the OpenMath mechanism works quite well for conveying mathematical objects: by declaring which CDs are relevant, two parties agree on a common understanding of the mathematics they communicate. The public CDs are (well-wrought) examples, but two parties may choose whichever CDs they like. They could even create CDs for the sole purpose of a brief communication. This feature ensures a great flexibility in the use of OpenMath.

In Figure 2, by way of example, we display an experimental CD for planar Euclidean geometry, which was recently constructed in joint work with Ulrich Kortenkamp for the purpose of interfacing with Cinderella, [29].

Phrasebooks provide the means to convert OpenMath objects to/from software applications. They parse OpenMath objects into an application-native language (e.g., *Mathematica*, Maple, GAP), sending the result to the application, catching the response from the application, and translating it back into OpenMath. The phrasebook communicates only OpenMath objects of which the symbols are defined in the CDs that the phrasebook recognizes. Thus, a phrasebook performs the translation back and forth as well as the communication. The actual task performed by the totality of the phrasebook actions depends on the interpretation. If the application is a computer algebra system, the interpretation is often 'evaluation' or 'simplification': when passed $2+3$, these applications will return 5. If the application is a proof assistant (e.g., Lego or Coq, cf. [9]), then 'verifying' or 'proving' is a more likely interpretation of what the application is supposed to do, and if the application is a browser or printing, the interpretation is to prepare the mathematical object for a presentation.

Phrasebooks providing interfaces to and from OpenMath have been built into Axiom and GAP [2,16].

We have developed a Java library, called ROML, for building full phrasebooks outside mathematical software packages. It is described in [4] and can be found at [28]. By use of ROML, such external phrasebooks have been implemented for the proof checkers Lego and Coq, for the computer algebra packages Maple, *Mathematica*, and GAP [5,6].

2.2 Mathematical Web Services

An important mode of communicating mathematics across the Web, is by means of queries. Generally a query in Web technology refers to a request for a service, see [37]. Naturally, we would like a standard way of expressing queries, a management system for parameters accompanying the question,

```
<CD>
<CDName> plangeo1 </CDName>

 (... further data like URL, creation date, CDs on which this one depends ...)

<Description>
This CD defines symbols for planar Euclidean geometry.
</Description>

<CDDefinition>
<Name> point </Name>
<Description>
The symbol is used to indicate a point of  planar Euclidean geometry
by a variable. The point may (but need not) be subject to constraints.
</Description>
</CDDefinition>

 (... a similar definition for ‘line’ ...)

<CDDefinition>
<Name> incident </Name>
<Description>
The symbol represents the logical incidence fucntion which is a
binary function taking arguments representing
gemetric objects like points and lines and returning a boolean value.
It is true if and only if the first argument is incident to the second.
</Description>

<Example> The line l through (points) A and B is given by:

<OMOBJ>
  <OMA>
    <OMS cd="plangeo1" name="line"/>
    <OMV name="l"/>
    <OMA>
      <OMS cd="plangeo1" name="incident"/>
      <OMV name="A"/>
      <OMV name="l"/>
    </OMA>
    <OMA>
      <OMS cd="plangeo1" name="incident"/>
      <OMV name="B"/>
      <OMV name="l"/>
    </OMA>
  </OMA>
</OMOBJ>
</Example>
</CDDefinition>
</CD>

 (... further definitions ...)
```

Fig. 2. CD fragment.

and a reference mechanism to couple a message to the query which it answers. Such systems are under construction (e.g., work of Caprotti), often based on more general standards, such as the Web Service Description Language, WSDL. We refer to [32] for a discussion of computational and other Web services. Confidentiality and privacy are important user requirements that will have to be present in user profiles. Clearly, there is a need for the development of service management frameworks with adequate provision for resilience, persistence, security, confidentiality and end user privacy. Here, however, our focus is on the mathematical aspects. We shall depart from the OpenMath set-up for the communication of mathematical objects. A mathematical query usually refers to mathematical objects, which can be phrased in OpenMath, but often the user wants to convey more than just the mathematical objects themselves. As we have seen above, a mathematical object can often be interpreted as a query by a phrasebook (e.g., interpret $\cos(\pi)$ as 'evaluate $\cos(\pi)$' or interpret an assertion GRH as 'verify GRH'), but this is a poor way of formulating a query. A more elaborate mechanism is needed.

Regarding mathematical services across the Web, we face three issues that need further exploration:

- mathematical reliability,
- expressing mathematical queries, and
- taking into account the state, or context, in which a mathematical query takes place.

Reliability. In [9], the reliability (quality guarantee) aspects are emphasized. Up till now, complexity, the (estimated) time a computation will take, has been one of the major concerns regarding mathematical computations. Although it will remain useful for clients to be aware of feasibility, they will be more concerned with the validity of the answer. Here an interesting shift in focus from complexity to convincibility may take place. To gain experience with this issue, we work out (within our MathBook technology, see §3) some concrete examples where besides the usual invocation of an algorithm, additional work is carried out to provide the users with witnesses as to the truth of the answer. In one of these examples, in response to a query for the stabilizer H of the vertex, 1 say, of a permutation group G specified by generating permutations $a_1, \ldots, a_t$, one usually expects just a set $b_1, \ldots, b_s$ of permutations fixing 1, which will generate H. Now it is a straightforward check that $b_1, \ldots, b_s$ fix 1, but it requires some work to see that these permutations actually belong to G, whence to H. Expressions of the b_j as products of $a_1, \ldots, a_t$ will solve this. Finally, a proof that each element of H lies in the subgroup of G generated by $b_1, \ldots, b_s$ requires further information, corresponding to Schreier's lemma [13]. By means of a little programming at the back engine, the additional information can be supplied, and embedded in a proof in words that supplies a substantiated answer to the query.

Queries. We have argued that, so far, the OpenMath set-up seems rather primitive in that only mathematical expressions are passed, with no indica-

tion of the required action on the object. Currently, the phrasebook makes this interpretation, and so the matter is resolved by a declaration from the phrasebook of what its action (interpretation) is, see [11]. For instance, an OpenMath object like

```
Factors(Polynomial(X,X^2-1,Rationals))
```

will result in a response of the form

```
List(Polynomial(X,X-1,Rationals),Polynomial(X,X+1,Rationals)))
```

when sent to GAP, because its phrasebook tends to interpret the OpenMath object as an evaluation command, whereas the same expression would just be printed as something like "Factors of $X^2 - 1$" when sent to a typesetting program.

In [31], a mode of interaction is implemented where the behavior of a computer algebra system can be controlled from within a JSP page (see §4.2 below) by using a set of primitives such as assigning and retrieving OpenMath objects to CAS variables, manipulating variables using the language of the CAS. Indeed, this seems to come closer to the intended user control.

But, as hinted at in [9], there are probably better solutions from automated proof checking. A slight extension of the language in which we formulate mathematical assertions will enable us to formulate mathematical queries. Typed λ calculus expressions like $\Gamma \vdash ? : P$, where Γ represents the context (see below) and $? : P$ stands for the request for a proof of assertion P, are expected to embed into a full type checking mechanism without problems. In other words, we expect that it is possible to set up a language of well-formed query expressions, recognizable by means of a proper type inference algorithm. So, importing this language within the OpenMath framework, we expect to obtain a sound method of expressing queries by means of a CD defining the primitive symbols (corresponding to question marks used such as in $? : P$) for the most fundamental types of question asked. This approach to queries is as yet unexplored, and we intend to explore it in the near future.

Context. The problem of how to handle the state in which a mathematical query takes place has not been addressed in some of the more successful mathematical services on the internet, such as Sloane [30], Faugère's Gröbner basis service [15], Wilson's Atlas of representations of finite simple groups [36], Brouwer's coding theory data base [3], and Web*Mathematica* [35].

For example, Web*Mathematica* is a way of accessing *Mathematica* via the Web. Via browser pages users can formulate either full *Mathematica* commands or input for pre-programmed *Mathematica* commands (so that no specific knowledge of *Mathematica* is required) which will then be carried out by a *Mathematica* program run by a server accessible to the user. However, after the command is carried out, the *Mathematica* session is 'cleaned' in that the user can no longer refer to the previous command. So, it is possible to, say, compute the determinant of a matrix but the user cannot assign the

matrix to a variable, say A, and change an entry of A, and/or ask for A^{-1} without re-entering the entries of A.

Clearly, as is the case for a *Mathematica* session per se, it is desirable to be able to refer to the variables at hand in a work session, to be able to ask for a second computation regarding an object passed on earlier, and so on. From a computer algebra point of view, the *context* is a list of definitions, that is, assignments to variables, of objects introduced (and computed) before (think of the assignment statements and of the In[n] and Out[n] variables for $n = 1, 2, \ldots$ in *Mathematica*). In the Javamath API, discussed in [31], there is a notion of session, in which it is possible to retain variables and their values.

However, we wish to incorporate one more feature in our notion of context. This is taken from logic, where the notion of a context is our inspiration. Indeed the symbol Γ above stands for context. Besides definitions, it contains statements which are interpreted as 'the truth' (or axioms, for that matter). This means that theorems, lemmas, conjectures, and so on, may be thrown in, and are all interpreted as 'facts'. We stress that there may very well be assumptions in the context, so that it might be possible to derive a contradiction. It would not be desirable to have the starting context of an interactive book be self-contradictory, but, in the course of a user developed proof by contradiction, there is nothing against a set of assumptions from which the user can derive $0 = 1$.

It is such a list of definitions of objects and statements, which is called context in the case of theorem provers, that gives a good starting point to what we consider to be the context of a mathematical session. It will be clear that the context is highly dynamic: for instance, if, in the example of the matrix A above, the user wants to consider the matrix over $\mathrm{GF}(11)(x, y, z)$ rather than $\mathbb{Q}[x, y, z]$, a change of the coefficient ring should be the corresponding action on the context.

So, what is needed is a way to exploit such context data whenever a server providing a service to the user needs more knowledge. We have only made a modest beginning with the study of context, and we foresee that substantial research is needed for a successful implementation.

3 The Mathematical Document Server

In the previous section we have explained how we envision smooth communication using OpenMath with several mathematical services on the web. These services will enrich mathematical documents considerably. In this section we present a general model for a highly interactive mathematical environment embodying such features.

The heart of our architecture is a *mathematical document server*. In our approach, this server takes input from mathematical source documents, mathematical (web) services and users, and serves a view on the interactive doc-

ument to the user. The document server takes care of the presentation of the document to the user, it handles the communication between user and several mathematical services. It also manages the (mathematical) context in which presentation and communication take place. Figure 3 displays the essential parts of the proposed architecture and their dependencies.

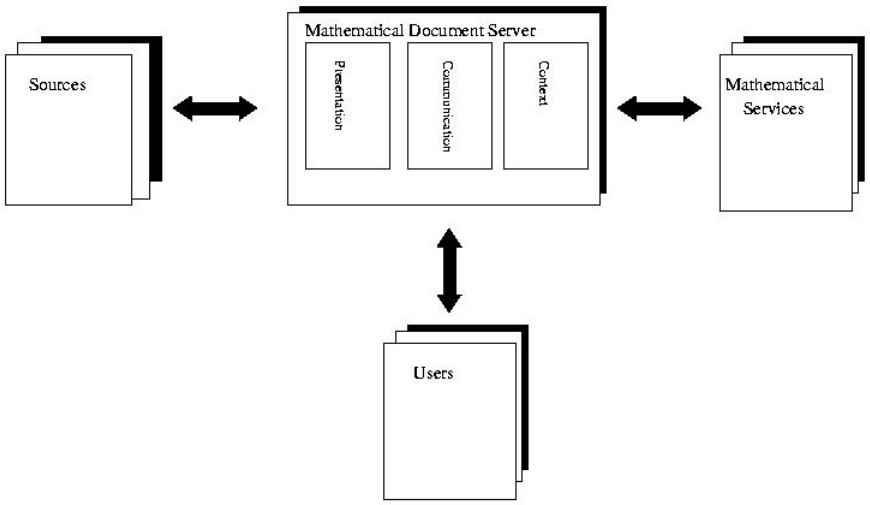

Fig. 3. General architecture

The architecture we have chosen for an interactive mathematical document is based on the idea of an interactive book: the (static) mathematics is included in a source document (or *source*, for short). It is highly structured and semantically sufficiently rich to create an exact mathematical description of the content and to allow actions (see also Subsection 4.2). The source document indicates the kind of action that is supposed to be offered in the interactive environment. The actions themselves however are realized by the document server. The document source is written by an author.

The document server on the other hand, is written by tool developers. It uses the mathematical content from the sources together with input from the user and mathematical services to specify the *context* of the interactive document. The context certainly depends on user actions; a jump from one entry in the source to another may alter the context. But also results from queries to mathematical services are input to the creation of the context. Within this context a presentation of the content relevant to the mathematical setting in which the user 'resides', is realized and can be presented to the user via an interface. In line with the discussion of §2.2, the context consists of

- assignments to variables of OpenMath objects (interpreted as definitions),
- OpenMath objects representing mathematical assertions,
- logistic information, for example, the user's id, mathematical background, permissions to use commercial services, etc.

At any given time, the context gives a precise description of the state the user is in by means of this data.

A simple example of this model is realized in a LaTeX environment. Here the document server produces, on user's demand, a dvi or postscript file from a LaTeX source and serves it using a dvi or postscript viewer to the user. Here the context is just given by the user's request to create a dvi or postscript file to view on the screen or send it to a printer, etc. In this simple example, the logistic data are relevant, but not the mathematical context.

A more advanced example can be realized in an XML-Java setting. Here the source consists of an XML-source. The document server creates, for example by XSL-transformations, an Html or XML document and serves it as a web page to the user. Using a web browser as an interface, the user can view a presentation of the document. Interactivity and communication with mathematical services can be realized inside the web server using Java-applets or servlets. Our present approach to realizing interactive mathematical documents is based on this example and will be discussed in the next section.

Creation and bookkeeping of the context as well as presentation of the content is taken care of by the document server. This server also handles *communication* between the source, the user and mathematical services. It stores presentation information and the context as dynamic data. The context is relevant in communication with the outside world. Using the model of communication with a mathematical service, the provider of the service may be aware of the context of the user's mathematics. This can take place by means of incremental steps (loading the context at the initial stage and translating the user defined changes one by one), or by means of downloading the entire context (or relevant portions thereof) upon receipt of each new query.

Of course, our primary target is a mathematical context, where, for example, in a chapter on ring theory of an algebra book, the field of coefficients might be specified to be a finite field. By interaction of the user interface with the user, this context can be further specialized to, say, the field of order eleven GF(11).

In an example on irreducible polynomials in a polynomial ring, the document server will take care of choosing the polynomial ring $GF(11)[X]$ over GF(11). Within this context the reader can now verify that the polynomial X^2+2X-2 is reducible, whereas the polynomial X^2+2X+2 is irreducible.

Some variables in the context can also be of a logistic nature. For instance the user name might help to create or recognize an individual version of the

context. This might be of relevance, for instance, for tracking the way a student reads an interactive text book.

4 MathBook, our implementation

The discussion of §3 regards our conceptual framework for interactive mathematical documents. In this section we discuss our progress in implementing this architecture within a JAVA-XML set-up. Our motivating example is a forthcoming new edition of the interactive book *Algebra Interactive!* (see [7]), which is interactive course material for undergraduate algebra. We shall use the word *MathBook* for the ensemble of software tools we are building for the construction of interactive mathematical documents such as, but not limited to, 'Algebra Interactive'. The distinct components of the architecture are displayed in Figure 4. We shall deal with them separately.

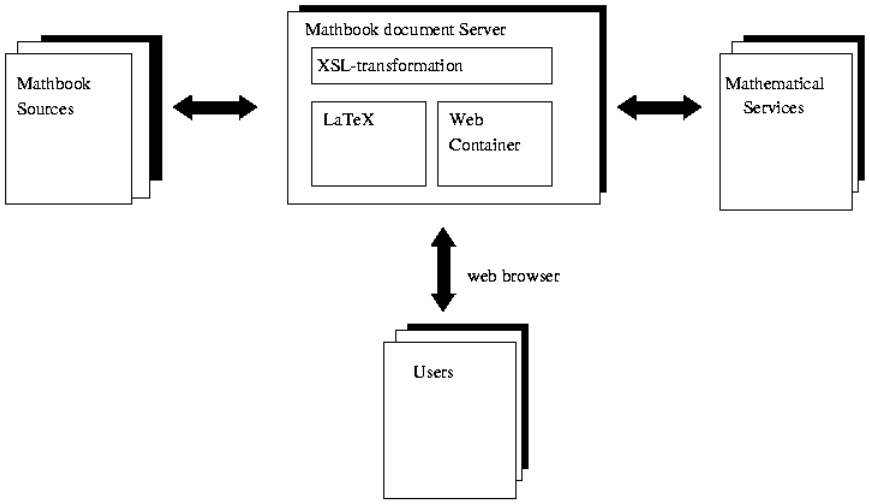

Fig. 4. MATHBOOK implementation

4.1 The MathBook Source

We have derived our own experimental grammar in the guise of a document type definitions (DTD) for the MATHBOOK source, an XML document. As a result, there is an XML based markup language (the MATHBOOK DTD) for the creation of interactive mathematical documents.

In creating a DTD for MathBook, we have been influenced by both DocBook [8] and OMDoc [24]. The former is a fairly general standard for structuring (into chapters, sections, etc.) electronic documents, the latter is a very rich, and strongly logic-oriented standard for mathematical documents. We intend to maintain a close link with OMDoc, but found the overall machinery involved too heavy for our purposes. The connection with DocBook is of importance to us, since we expect several authoring tools for it to emerge in the coming years, tools that could be of use to us in one form or another. MathBook deviates in various respects from OMDoc and DocBook and contains new features, like support for actions.

The mathematics in the source is given by means of OpenMath objects. This feature has clear advantages in terms of portability. The DocBook type grammar sees to it that there are natural scopes, where mathematical objects 'live'. For instance, when a chapter begins with "Let $\mathbb{F}$ be a field", the scope of the variable $\mathbb{F}$ is assumed to be the whole chapter (although, somewhere further down the hierarchy, say in a section of the chapter, this assignment can be overridden).

```
<OMOBJ>
 <OMA>
  <OMATTR>
   <OMATP>
    <OMS name="pres" cd="ida"/> <OMSTR "frac"/>
   </OMATP>
   <OMS name="divide" cd="arith1"/>
  </OMATTR>
  <OMA>
   <OMS name="plus" cd="arith1"/>
   <OMA> <OMS name="divide" cd="arith1"/> <OMI>3</OMI> <OMI>4</OMI> </OMA>
   <OMA> <OMS name="divide" cd="arith1"/> <OMI>2</OMI> <OMI>3</OMI> </OMA>
  </OMA>
 </OMA>
</OMOBJ>
```

Fig. 5. An attributed OpenMath object.

The mathematical content is represented in OpenMath. This means that the semantics is taken care of satisfactorily, but that no attention is being paid to presentation. In general, this is in line with the idea that presentation should be taken care of by the document server rather than the source. There are however some clear exceptions. Let us give two examples. In LaTeX, for each individual fraction, the author has a choice between a slash and a fraction display. In

$$\frac{3/4 + 2/3}{5}$$

we have used both. The other example concerns the statement "$3, 4 \in \mathbb{Z}$". The corresponding OpenMath expression would be the equivalent of "$3 \in \mathbb{Z}$ and $4 \in \mathbb{Z}$", whereas the presentation in the first form is highly desirable from an esthetic point of view.

In order to have such a flexible presentation, we are using presentation annotated OpenMath. This means, that in our MathBook source we allow style attributes inside OpenMath objects. Figure 5 shows an attributed expression corresponding to the LaTeX macro `\frac`, in which the fraction display is forced. It is assumed here that the default presentation is 'slash' so that the two other `divide`s need not be attributed. Of course, the author can also force the slash presentation of these by a similar attribution. By discarding these style attributes, regular OpenMath is obtained. So, one can easily go from annotated OpenMath to 'bare' OpenMath.

Within the MathBook grammar, special attention is also given to interactivity. For this purpose a whole range of tags (that is, structuring elements defined in DTDs and appearing in XML documents between pointed brackets) have been introduced. We will give two snippets of code appearing in the MathBook source to illustrate some of these tags and to give the reader an idea of how an author may create interactivity.

```
<eval scope="session">
   <OMOBJ>
    <OMA>
     <OMS cd="univpoly1" name="expand"/>
     <OMA>
      <OMS cd="univpoly1" name="gcd"/>
      <getomcontent> <getvarvalue name="poly_a"/> </getomcontent>
      <getomcontent> <getvarvalue name="poly_b"/> </getomcontent>
     </OMA>
    </OMA>
   </OMOBJ>
</eval>
```

Fig. 6. Some MathBook tags for interactivity.

The code in Figure 6 uses the combined effects of the following tags.

- getvarvalue: Read two strings representing OpenMath objects that were previously stored in the variables `poly_a` and `poly_b`, respectively. Note that the scope is set to session. This implies that, at the time the user visits this particular part of the source, the context will have the variables poly_a and poly_b, but when the user leaves it, these will no longer stay alive. The scope is introduced by a command like
  `<enablescope scope="session"/>`
  (not displayed in the figure). The above code then creates an OpenMath object (in fact, a univariate polynomial) that is placed in the session scope.
- getomcontent: Get the content of the OpenMath object, i.e., remove the markers `<OMOBJ>` and `</OMOBJ>` at the beginning and the end of an OpenMath object.

- eval: this tag indicates that in a realization of the source as an interactive document, the constructed OpenMath object is sent to a computational backengine, like *Mathematica*, for evaluation.

```
<addtoscope name="matrixsquared" scope="session">
<OMOBJ>
 <OMA>
  <OMS cd="arith1" name="times"/>
  <getomcontent> <getfromscope name="matrix"/> </getomcontent>
  <getomcontent> <getfromscope name="matrix"/> </getomcontent>
 </OMA>
</OMOBJ>
</ida:addtoscope>
```

Fig. 7. Some MathBook tags for content control.

The snippet in Figure 7 shows how objects in a context can be created. Here, the OpenMath object named `matrix` is read from the session scope (by means of the `getfromscope` tag). This object is used to create a new OpenMath object that is placed in the session scope (by means of the `addtoscope` tag) with name `matrixsquared`.

4.2 The MathBook server

As mentioned in Section 3, the mathematical document server, called the MathBook *server*, should cater for presentation, communication, and context in our implementation.

One part of our MathBook server consists of an XSL transformer together with a set of XSL stylesheets. The transformer picks up the MathBook sources and transforms them into LaTeX files for creating printouts or JavaServer Pages (JSP) to create an interactive realization of the source. JSP technology [17] is designed to develop dynamic web pages easily. A JavaServer Page is a template containing standard Html code, user defined tags, and Java scriptlets encoding the logic and the required behaviour of the dynamic web page.

The JavaServer Pages together with our Java tools form a Web application residing in a Web container of a standard (JSP/Servlet) server, allowing us to extend the functionalities of any such server. Note that, as opposed to Web*Mathematica*, we are not modifying the server itself.

So far, besides ROML (discussed at the end of §2.1), our Java tools include phrasebooks and a (JSP based) tag mechanism for bringing to life the interaction specified in the MathBook source. The phrasebooks deal with the following kinds of action.

- Sending an OpenMath object to a backengine (e.g. Mathematica) for evaluation and returning an OpenMath object.

- Retrieving the answer to a mathematical query from a web service and reacting on the outcome.
- Transforming OpenMath into MathML presentation.

```
<phreval id="result" name="GapPhrasebook" method="EVAL" scope="session">
 <OMOBJ>
  <OMA>
   <OMS cd="integer1" name="factorof"/>
   <OMI> <expression>b</expression> </OMI>
   <OMI> <expression>a</expression> </OMI>
  </OMA>
 </OMOBJ>
</phreval>
<if> <condition> <expression>result</expression> </condition>
 <then>
  <para> Answer:
   <expression>b</expression> divides <expression>a</expression>.
  </para>
 </then>
 <else>
  <para> Answer:
   <expression>b</expression> does not divide <expression>a</expression>.
  </para>
 </else>
</if>
```

Fig. 8. Retrieving an answer.

As an example of the first two features, consider the code displayed in the beginning of Figure 8. This is part of a JSP page obtained from a MathBook source. There, the OpenMath object contained in the `phreval` tags is sent to the GAP Phrasebook and passed to GAP for evaluation, and the response from GAP and the GAP Phrasebook is an OpenMath object (a Boolean) assigned to the variable `result` which lives inside the scope called `session`.

Communication is governed by Java servlets and phrasebooks; the actions defined within the MathBook sources are mapped onto and taken care of by a Java tag library, called the MathBook *tag library*.

The tag library is the tool that allows a practical implementation for actions in MathBook grammar. As a side issue, we mention that the library can also be used independently by someone who is just interested in developing his/her own JSP pages.

In the above example, the phrasebooks are invoked by the `phreval` tag. Furthermore, the tag mechanism handles

- the flow within a document, like if/then/else (see Figure 8), for loops, etc.
- the context. For example, objects can be stored and retrieved from the context.
- Casting OpenMath objects to OpenMath objects of another (often more structured) kind. This mechanism is especially useful for software systems

that do not type their objects very strongly. For instance, GAP does not distinguish a list of lists from a matrix, so when we expect a matrix to be returned (a fact that is noticeable in the presence of a context), we cast the list of lists onto a matrix of the right kind. Observe that this cast indeed belongs to the MathBook server and not to the source.

In particular, the tags in the library deal with two of the three features of a mathematical document server: communication, and context. The remaining feature, presentation, is dealt with by a separate Java program that translates the OpenMath objects of the source into MathML. It keeps track of the attributes for presentation such as the one for fraction discussed in §4.1. The MathML appearing in a JSP page can be rendered by a browser like Mozilla or Amaya, cf. [23,1].

Experimental MathBook servers for 'Algebra Interactive', with both *Mathematica* and GAP as backengine, have been realized. We intend to experiment further with CoCoA, Maple, and formal automated proof assistants such as COQ.

At the moment we are investigating the possible extension of the tag library in such a way that we are able to interface with other more geometry or visualisation oriented packages. We have started work on interfacing to the geometry package Cinderella [29].

4.3 Examples

We make the picture described above more concrete by considering three scenarios. In each of these scenarios a suitable interactive mathematical document can offer the appropriate mathematical services via the internet. In [12] we have described a way to provide the computing facilities of various mathematical software packages via OpenMath servers to the internet community. However, in these scenarios the mathematical services cannot consist solely of web interfaces with computational backengines, but ask for more specialized activities.

1. An author of a book on mathematical analysis has used both Maple [19] and *Mathematica* [20] to write algorithms discussed in his/her book. At times, the results of one system are fed into the other. Preferably, the author would like to write the code only once.

By use of the MathBook tools, the algorithms written in either system can be made to run virtually within the electronic version of the book. The MathBook tag library then takes care of communication with the backengines Maple and *Mathematica* and the computer algebra code is stored in the source. An alternative to sending native code to the backengines is to work with OpenMath. If the commands are confined to standard applications such as factorization of polynomials, the EVAL interpretation of the phrasebooks suffice (currently, a Maple phrasebook based on ROML does not exist,

but one based on [26] could probably be used). In this case, we can express input and output as well-understood mathematical objects (using the cast of the tag library, if necessary); moreover, we can ask for an evaluation by any third computer algebra system for which a phrasebook exists. For the author, the implementation has been reduced to writing a simple `phreval` tag. There is a third option in which more elaborate commands can be run on back engines. It uses a first version of an algorithm CD. We expect to be able to write most of the 130 gapplets (i.e., interactive examples using GAP) from the former edition of 'Algebra Interactive', in this OpenMath code, in such a way that each of the systems GAP, CoCoA and *Mathematica* will be able to run the code at the server end.

2. At a high school, students have been assigned a project on cryptography. In this context, information about prime numbers is required. They need to know the definition of a prime number, to find a few prime numbers of 200 digits and to compute related encoding and decoding keys.

There are many home pages about prime numbers, see e.g. [27] for an interesting one. Most of these sites contain a lot of static information, but lack available computation power, for instance to check primality of a given number. As part of the ESPRIT OpenMath project, we have made sample pages on prime numbers, backed up by GAP and *Mathematica*, in which the students can actually profit from the computation power of these backengines without having to know anything from the syntax of these backengines. They can retrieve primes with 200 or more digits to build a realistic and safe RSA cryptosystem, they can break such systems using too small primes, they can search for Mersenne primes, etc.

Upon request, calling a 'Pocklington' server (cf. [6]), the students can obtain a full proof (in words) of the primality of a given number. This works in much the same way as the stabilizer subgroup example discussed in §2.2.

3. Cinderella [29] is a beautiful program for exploring traditional planar geometry. Configurations can be constructed corresponding to classical theorems such as Pappus' Theorem, in which the conclusion is that three points are on a line. Once the configuration of points and lines is drawn, the fact will present itself 'automatically'. The user can drag and rescale the configuration while the three points stay on a line. An OpenMath representation of this configuration, using the OpenMath CD 'plangeo1', see Figure 2, can be translated into a formal description, a presentation in words, or to Cinderella input. Conversely, Cinderella (at least an experimental version) is able to provide such OpenMath expressions. We intend to explore these interactions further in collaboration with Ulrich Kortenkamp.

5 Conclusion

We have argued that OpenMath objects suffice to communicate mathematics in a rigorous way between software systems, but that two more features are

of immediate need: query facilities and management of the context of the mathematics in which the user is immersed. A solution of the query problem seems feasible on a fundamental level within the OpenMath framework, but the context problem requires more experimentation. We expect that the MathBook tag library will solve some of the most urgent matters in this respect. Authors can use it to augment their xml sources (in MathBook format), so as to obtain a high degree of structured mathematical interactivity.

A major obstacle to authoring an interactive document is the inaccessibility of xml source code, the enormous number of brackets and labels, such as in the examples of code in Figure 8. The general expectation is that, once good special purpose editors have been developed, no author will need to work with the elaborate xml sources. However, currently there is no alternative at hand. There are two editors for OpenMath objects, viz. [18,22], but these do not suffice for the more elaborate source documents described in §4.1. By means of the MathBook tag library, we have tried to reduce the difficulties of authoring as far as possible, but some xml editing remains necessary.

Another issue to be explored is 'searching for mathematical content'. Standard xml techniques might work on CDs. Although the interdependence of CDs is rather loosely organized (there is a `CDUses` field in a CD indicating on which other CDs the definition of symbols contained in it depend), standard xml tools will be able to produce the dependence trees. For example, via the `CDUses` construct we will be able to unravel that `times` in the core CD `group` refers to `times` in the core CD `monoid`, which in turn refers to `times` in `arith1`. Mathematical knowledge always has a hierarchical structure. It is the question whether the `CDUses` construct will suffice for an efficient implementation of the full hierarchy and the related searches.

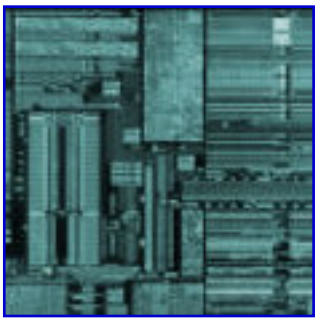
Machine Head -- David Cohen -- New Scientist -- February 24, 2001 -- [Comments]



Computers, commonly perceived as little more than ultra-fast calculators, are suggesting new ideas in medicine and chemistry, determining the roles of genes and proposing and testing new mathematical theorems. They are even helping with the choice of embryos for IVF implantation. Computers have been promoted from dumb tools to full research partners, and people working without digital colleagues may soon begin to fall behind. "The future lies in human-computer collaboration," Srinivasan says.

Concepts and Algorithms for Polygonal Simplification

Jonathan D. Cohen

Department of Computer Science, The Johns Hopkins University

1. INTRODUCTION

1.1 Motivation

In 3D computer graphics, polygonal models are often used to represent individual objects and entire environments. Planar polygons, especially triangles, are used primarily because they are easy and efficient to render. Their simple geometry has enabled the development of custom graphics hardware, currently capable of rendering millions or even tens of millions of triangles per second. In recent years, such hardware has become available even for personal computers. Due to the availability of such rendering hardware and of software to generate polygonal models, polygons will continue to play an important role in 3D computer graphics for many years to come.

However, the simplicity of the triangle is not only its main advantage, but its main disadvantage as well. It takes many triangles to represent a smooth surface, and environments of tens or hundreds of millions of triangles or more are becoming quite common in the fields of industrial design and scientific visualization. For instance, in 1994, the UNC Department of Computer Science received a model of a notional submarine from the Electric Boat division

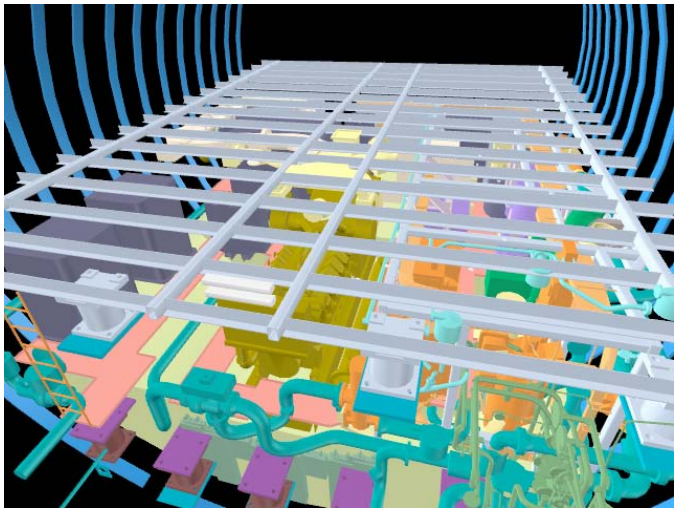

Figure 1: The auxiliary machine room of a notional submarine model: 250,000 triangles

of General Dynamics, including an auxiliary machine room composed of 250,000 triangles (see Figure 1) and a torpedo room composed of 800,000 triangles. In 1997, we received from ABB Engineering a coarsely-tessellated model of an entire coal-fired power plant, composed of over 13,000,000 triangles. It seems that the remarkable performance increases of 3D graphics hardware systems cannot yet match the desire and ability to generate detailed and realistic 3D polygonal models.

1.2 Polygonal Simplification

This imbalance of 3D rendering performance to 3D model size makes it difficult for graphics applications to achieve *interactive* frame rates (10-20 frames per second or more). Interactivity is an important property for applications such as architectural walkthrough, industrial design, scientific visualization, and virtual reality. To achieve this interactivity in spite of the enormity of data, it is often necessary to trade fidelity for speed.

We can enable this speed/fidelity tradeoff by creating a *multi-resolution* representation of our models. Given such a representation, we can render smaller or less important objects in the scene at a lower resolution (i.e. using fewer triangles) than the larger or more important objects, and thus we render fewer triangles overall. Figure 2 shows a widely-used test model: the Stanford bunny. This model was acquired using a laser range-scanning device; it contains over 69,000 triangles. When the 2D image of this model has a fairly large area, this may be a reasonable number of triangles to use for rendering the image. However, if the image is smaller, like Figure 3 or Figure 4, this number of triangles is probably too large. The right-most image in each of these figures shows a bunny with fewer triangles. These complexities are often more appropriate for image of these sizes. Each of these images is typically some small piece of a much larger image of a complex scene.

For CAD models, such representations could be created as part of the process of building the original model. Unfortunately, the robust modeling of 3D objects and environments is already a difficult task, so we would like to explore solutions that do not add extra burdens to the original modeling process. Also, we would like to create such representations for models acquired by other means (e.g. laser scanning), models that already exist, and models in the process of being built.

Figure 2: The Stanford bunny model: 69,451 triangles

69,451 triangles

2,204 triangles

Figure 3: Medium-sized bunnies.

69,451 triangles

575 triangles

Figure 4: Small-sized bunnies.

Simplification is the process of automatically reducing the complexity of a given model. By creating one or more simpler representations of the input model (generally called *levels of detail*), we convert it to a multi-resolution form. This problem of automatic simplification is rich enough to provide many interesting and useful avenues of research. There are many issues related to how we represent these multi-resolution models, how we create them, and how we manage them within an interactive graphics application. This dissertation is concerned primarily with the issues of level-of-detail quality and rendering performance. In particular, we explore the question of how to preserve the appearance of the input models to within an intuitive, user-specified tolerance and still achieve a significant increase in rendering performance.

1.3 Topics Covered

This paper reviews some fundamental concepts necessary to understand algorithms for simplification of polygonal models at a high level. These concepts include optimal/near-optimal solutions for the simplification problem, the use of local simplification operations, topology preservation, level-of-detail representations for polygonal models, error measures for surface deviation, and the preservation of appearance attributes. This is not a complete survey of the field of polygonal model simplification, which has grown to be quite large (for more information, several survey papers are available [Erikson 1996, Heckbert and Garland 1997]). In particular, this paper does *not* provide much coverage of algorithms specialized for simplifying polygonal terrains, nor does it cover simplification and compression algorithms geared towards progressive transmission applications.

2. OPTIMALITY

There are two common formulations of the simplification problem, described in [Varshney 1994], to which we may seek optimal solutions:

- **Min-# Problem**: Given some error bound, ε, and an input model, *I*, compute the minimum complexity approximation, *A*, such that no point of *A* is farther than ε distance away from *I* and vice versa (the complexity of *A* is measured in terms of number of vertices or faces).

- **Min-ε Problem**: Given some target complexity, n, and an input model, I, compute the approximation, A, with the minimum error, ε, described above.

In computational geometry, it has been shown that computing the min-# problem is NP-hard for both convex polytopes [Das and Joseph 1990] and polyhedral terrains [Agarwal and Suri 1994]. Thus, algorithms to solve these problems have evolved around finding polynomial-time approximations that are *close* to the optimal.

Let k_0 be the size of a min-# approximation. An algorithm has been given in [Mitchell and Suri 1992] for computing an ε-approximation of size $O(k_0 \log n)$ for convex polytopes of initial complexity n. This has been improved by Clarkson in [Clarkson 1993]; he proposes a randomized algorithm for computing an approximation of size $O(k_0 \log k_0)$ in expected time $O(k_0 n^{1+\delta})$ for any $\delta > 0$ (the constant of proportionality depends on δ, and tends to $+\infty$ as δ tends to 0). In [Brönnimann and Goodrich 1994] Brönnimann and Goodrich observed that a variant of Clarkson's algorithm yields a polynomial-time deterministic algorithm that computes an approximation of size $O(k_0)$. Working with polyhedral terrains, [Agarwal and Suri 1994] present a polynomial-time algorithm that computes an ε-approximation of size $O(k_0 \log k_0)$ to a polyhedral terrain.

Because the surfaces requiring simplification may be quite complex (tens of thousands to millions of triangles), the simplification algorithms used in practice must be $o(n^2)$ (typically $O(n \log n)$) for the running time to be reasonable. Due to the difficulty of computing near-optimal solutions for general polygonal meshes and the required efficiency, most of the algorithms described in the computer graphics literature employ local, greedy heuristics to achieve what appear to be reasonably good simplifications with no guarantees with respect to the optimal solution.

3. LOCAL SIMPLIFICATION OPERATIONS

Simplification is often achieved by performing a series of local operations. Each such operation serves to coarsen the polygonal model by some small amount. A simplification algorithm generally chooses one of these operation types and applies it repeatedly to its input surface until the desired complexity is achieved for the output surface.

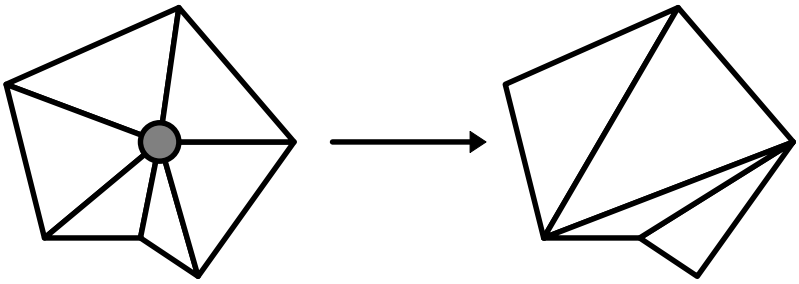

Figure 5: Vertex remove operation

3.1 Vertex Remove

The vertex remove operation involves removing from the surface mesh a single vertex and all the triangles touching it. This removal process creates a hole that we then fill with a new set of triangles. Given a vertex with *n* adjacent triangles, the removal process creates a hole with *n* sides. The hole filling problem involves a discrete choice from among a finite number of possible retriangulations for the hole. The *n* triangles around the vertex are replaced by this new triangulation with *n*-2 triangles. The Catalan sequence,

$$C(i) = \frac{1}{i+1} * \binom{2i}{i} = \frac{1}{i+1} * \frac{(2i)!}{i!(2i-i)!} = \frac{1}{i+1} * \frac{(2i)!}{i!i!} = \frac{(2i)!}{(i+1)!i!}\ , \qquad (1)$$

describes the number of unique ways to triangulate a convex, planar polygon with *i*+2 sides [Dörrie 1965, Plouffe and Sloan 1995]. This provides an upper bound on the number of non-self-intersecting triangulations of a hole in 3D. For example, holes with 3 sides have only 1 triangulation, and holes with 4, 5, 6, 7, 8, and 9 sides have up to 2, 5, 14, 42, 132, and 429 triangulations, respectively.

Both [Turk 1992] and [Schroeder et al. 1992] apply the vertex remove approach as part of their simplification algorithms. Turk uses point repulsion (weighted according to curvature) to distribute some number of new vertices across the original surface, then applies vertex remove operations to remove most of the original vertices. Holes are retriangulated using a planar projection approach. Schroeder also uses vertex remove operations to reduce mesh complexity, employing a recursive loop splitting algorithm to fill the necessary holes.

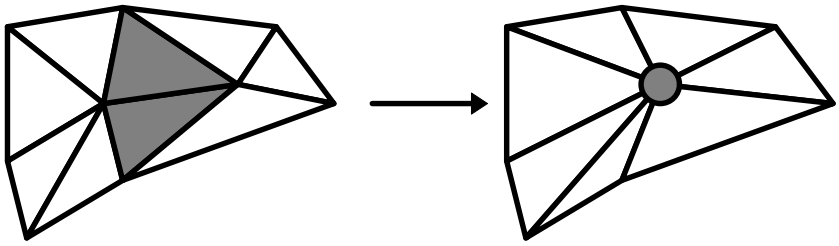

Figure 6: Edge collapse operation

3.2 Edge Collapse

The edge collapse operation has become popular in the graphics community in the last several years. The two vertices of an edge are merged into a single vertex. This process distorts all the neighboring triangles. The triangles that contain both of the vertices (i.e. those that touch the entire edge) degenerate into 1-dimensional edges and are removed from the mesh. This typically reduces the mesh complexity by 2 triangles.

Whereas the vertex remove operation amounts to making a discrete choice of triangulations, the edge collapse operation requires us to choose the coordinates of the new vertex from a continuous domain. Common choices for these new coordinates include the coordinates of one of the two original vertices, the midpoint of the collapsed edge, arbitrary points along the collapsed edge, or arbitrary points in the neighborhood of the collapsed edge.

Not only is the choice of new vertex coordinates for the edge collapse a continuous problem, but the actual edge collapse operation may be performed continuously in time. We can linearly interpolate the two vertices from their original positions to the final position of the new vertex. This allows us to create smooth transitions as we change the mesh complexity. As described in [Hoppe 1996], we can even perform *geomorphs*, which smoothly transition between versions of the model with widely varying complexity by performing many of these interpolations simultaneously.

In terms of the ability to create identical simplifications, the vertex removal and edge collapse operations are not equivalent. If we collapse an edge to one of its original vertices, we can create n of the triangulations possible with the vertex remove, but there are still $C(n+2)-n$ triangulations that the edge collapse cannot create. Of course, if we allow the edge collapse to choose arbitrary coordinates for its new vertex, it can create infinitely many simplifications that the vertex remove operation cannot create. For a given input model and

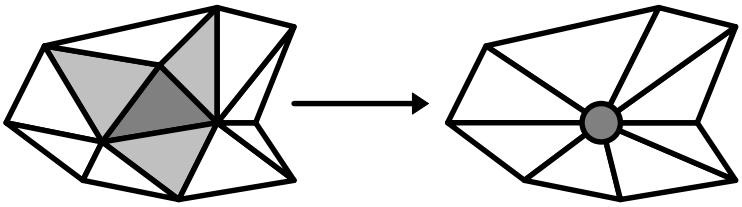

Figure 7: Face collapse operation

desired output complexity, it is not clear which type of operation can achieve a closer approximation to the input model.

The edge collapse was used by [Hoppe et al. 1993] as part of a mesh optimization process that employed the vertex remove and edge swap operations as well (the edge swap is a discrete operation that takes two triangles sharing an edge and swaps which pair of opposite vertices are connected by the edge). In [Hoppe 1996], the vertex remove and edge swaps are discarded, and the edge collapse alone is chosen as the simplification operation, allowing a simpler system that can take advantage of the features of the edge collapse. Although systems employing multiple simplification operations might possibly result in better simplifications, they are generally more complex and cannot typically take advantage of the inherent features of any one operation.

3.3 Face Collapse

The face collapse operation is similar to the edge collapse operation, except that it is more coarse-grained. All three vertices of a triangular face are merged into a single vertex. This causes the original face to degenerate into a point and three adjacent faces to degenerate into line segments, removing a total of four triangles from the model. The coarser granularity of this operation may allow the simplification process to proceed more quickly, at the expense of the fine-grained local control of the edge collapse operation. Thus, the error is likely to accumulate more quickly for a comparable reduction in complexity. [Hamann 1994, Gieng et al. 1997] use the face collapse operation in their simplification systems. The new vertex coordinates are chosen to lie on a local quadratic approximation to the mesh. Naturally, it is possibly to further generalize these collapse operations to collapse even larger connected portions of the input model. It may even be possible to reduce storage requirements by grouping nearby collapse operations with similar error bounds into larger collapse operations.

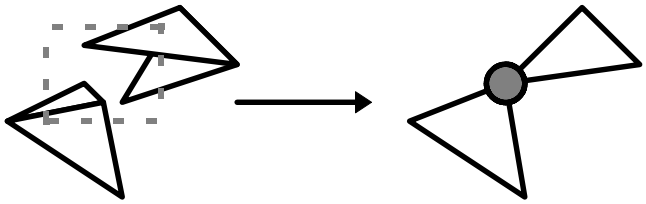

Figure 8: Vertex Cluster operation

Thus, the fine-grained control may be traded for reduced storage and other overhead requirements in certain regions of the model.

3.4 Vertex Cluster

Unlike the preceding simplification operations, the vertex cluster operation relies solely on the geometry of the input (i.e. the vertex coordinates) rather than the topology (i.e. the adjacency information) to reduce the complexity. Like the edge and face collapses, several vertices are merged into a single vertex. However, rather than merging a set of topologically adjacent vertices, a set of "nearby" vertices are merged [Rossignac and Borrel 1992]. For instance, one possibility is to merge all vertices that lie within a particular 3D axis-aligned box. The new, merged vertex may be one of the original vertices that "best represents" the entire set, or it may be placed arbitrarily to minimize some error bound. An important property of this operation is that it can be robustly applied to arbitrary sets of triangles, whereas all the preceding operations assume that the triangles form a connected, manifold mesh.

The effects of this vertex cluster are similar to those of the collapse operations. Some triangles are distorted, whereas others degenerate to a line segment or a point. In addition, there may be coincident triangles, line segments, and points originating from non-coincident geometry. One may choose to render the degenerate triangles as line segments and points, or one may simply not render them at all. Depending on the particular graphics engine, rendering a line or a point may not be much faster than rendering a triangle. This is an important consideration, because achieving a speed-up is one of the primary motivations for simplification.

There is no point in rendering several coincident primitives, so multiple copies are filtered down to a single copy. However, the question of how to render coincident geometry is complicated by the existence of other surface attributes, such as normals and colors. For

instance, suppose two triangles of wildly different colors become coincident. No matter what color we render the triangle, it may be noticeably incorrect.

[Rossignac and Borrel 1992] use the vertex clustering operation in their simplification system to perform very fast simplification on arbitrary polygonal models. They partition the model space with a uniform grid, and vertices are collapsed within each grid cell. [Luebke and Erikson 1997] build an octree hierarchy rather than a grid at a single resolution. They dynamically collapse and split the vertices within an octree cell depending on the current size of the cell in screen space as well as silhouette criteria.

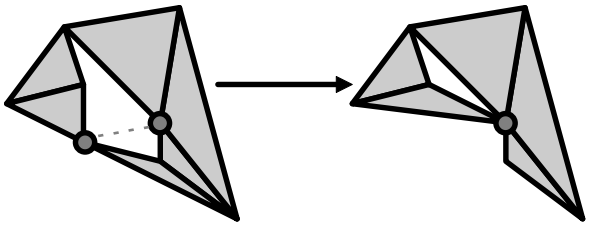

Figure 9: Generalized edge collapse operation

3.5 Generalized Edge Collapse

The generalized edge collapse (or vertex pair) operation combines the fine-grained control of the edge collapse operation with the generality of the vertex cluster operation. Like the edge collapse operation, it involves the merging of two vertices and the removal of degenerate triangles. However, like the vertex cluster operation, it does not require that the merged vertices be topologically connected (by a topological edge), nor does it require that topological edges be manifold.

[Garland and Heckbert 1997] apply the generalized edge collapse in conjunction with error quadrics to achieve simplification that gives preference to the collapse of topological edges, but also allows the collapse of virtual edges (arbitrary pairs of vertices). These virtual edges are chosen somewhat heuristically, based on proximity relationships in the original mesh.

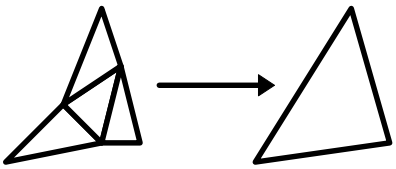

Figure 10: Unsubdivide operation

3.6 Unsubdivide

Subdivision surface representations have also been proposed as a solution to the multi-resolution problem. In the context of simplification operations, we can think of the "unsubdivide" operation (the inverse of a subdivision refinement) as our simplification operation. A common form of subdivision refinement is to split one triangle into four triangles. Thus the unsubdivide operation merges four triangles of a particular configuration into a single triangle, reducing the triangle count by three triangles.

[DeRose et al. 1993] shows how to represent a subdivision surface at some finite resolution as a sequence of wavelet coefficients. The sequence of coefficients is ordered from lower to higher frequency content, so truncating the sequence at a particular point determines a particular mesh resolution. [Eck et al. 1995] presents an algorithm to turn an arbitrary topology mesh into one with the necessary subdivision connectivity. They construct a base mesh of minimal resolution and guide its refinement to come within some tolerance of the original mesh. This new refined subdivision mesh is used in place of the original mesh, and its resolution is controlled according to the wavelet formulation.

4. TOPOLOGICAL CONSIDERATIONS

4.1 Manifold vs. Non-manifold Meshes

Polygonal simplification algorithms may be distinguished according to the type of input they accept. Some algorithms require the input to be a *manifold* triangle mesh, while others accept more general triangle sets. In the continuous domain, a manifold surface is one that is everywhere homeomorphic to an open disc. In the discrete domain of triangle meshes, such a surface has two topological properties. First, every vertex is adjacent to a set of triangles that form a single, complete cycle around the vertex. Second, each edge is adjacent to exactly two triangles. For a manifold mesh with *borders*, these restrictions are slightly relaxed. A border is simply a chain of edges with adjacent triangles only to one side. In a manifold mesh with borders, a vertex may be surrounded by a single, incomplete cycle (i.e. the beginning need not meet the end). Also, an edge may be adjacent to either one or two triangles.

A mesh that does not have the above properties is said to be *non-manifold*. Such meshes may occur in practice by accident or by design. Accidents are possible, for example, during either the creation of the mesh or during conversions between representation, such as the conversion from a solid to a boundary representation. The correction of such accidents is a subject of much interest [Barequet and Kumar 1997, Murali and Funkhouser 1997]. They may occur by design because such a mesh may require fewer triangles to render than a visually-comparable manifold mesh or because such a mesh may be easier to create in some situations. If the non-manifold portions of a mesh are few and far between, we may refer to the mesh as *mostly manifold*.

At the extreme, some data sets take the form of a set of triangles, with no connectivity information whatsoever (sometimes referred to as a "triangle soup"). Such data might turn out to be manifold or non-manifold if we were to attempt to reconstruct the connectivity information. In general, if any conversion has been performed on the original data, it's safe to assume that a naïve reconstruction will result in at least some non-manifold regions.

The most robust algorithms, based on vertex clusters, operate as easily on a triangle soup as on a perfectly manifold mesh [Rossignac and Borrel 1992], [Luebke and Erikson 1997]. This advantage cannot be stressed enough and is extremely important in the case where the simplification user has no control over the data. The ability to view an large, unfamiliar data set interactively is invaluable in the process of learning its ins and outs, and these algorithms allow one to get up and running quickly.

However, these very general algorithms do not typically create simplifications that look as attractive as those produced by algorithms that operate on manifold meshes. These algorithms, which rely on operations such as the vertex remove or edge collapse, respect the topology of the original mesh and avoid catastrophic changes to the surface and its appearance. The manifold input criterion does limit the applicability of these algorithms to some real-world models, but many of these algorithms may be modified to handle mostly manifold meshes by avoiding simplification of the non-manifold regions. This can be an effective strategy until the non-manifold regions begin to dominate the surface complexity.

The vertex pair and edge collapse operations can both operate on non-manifold meshes as well as manifold ones. Vertex-pair algorithms must deal with the non-manifold meshes they are bound to create by merging non-adjacent vertices. Edge collapse algorithms can operate on non-manifold meshes, but it may be difficult to adapt the most rigorous error metrics for manifold meshes to use on non-manifold meshes.

4.2 Topology Preservation

The topological structure of a polygonal surface typically refers to features such as its *genus* (number of topological holes, e.g. 0 for a sphere, 1 for a torus or coffee mug) and the number and arrangement of its borders. These features are fully determined by the adjacency graph of the vertices, edges, and faces of a polygonal mesh. For manifold meshes with no borders (i.e. closed surfaces), the Euler equation holds:

$$F - E + V = 2 - G, \tag{2}$$

where F is the number of faces, E is the number of edges, V is the number of vertices, and G is the genus.

In addition to this combinatorial description of the topological structure, the embedding of the surface in 3-space impacts its perceived topology in 3D renderings. Generally, we expect the faces of a surface to intersect only at their shared edges and vertices.

Most of the simplification operations described in section 3 (all except the vertex cluster and the generalized edge collapse) preserve the connectivity structure of the mesh. If a simplification algorithm uses such an operation and also prevents local self-intersections (intersections within the adjacent neighborhood of the operation), we say the algorithm *preserves local topology*. If the algorithm prevents any self-intersections in the entire mesh, we say it *preserves global topology*.

If the simplified surface is to be used for purposes other than rendering (e.g. finite element computations), topology preservation may be essential. For rendering applications, however, it is not always necessary. In fact, it is often possible to construct simplifications with fewer polygons for a given error bound if topological modifications are allowed.

However, some types of topological modifications may have a dramatic impact on the appearance of the surface. For instance, many meshes are the surfaces of solid objects. For example, consider the surface of a thin, hollow cylinder. When the surface is modified by more than the thickness of the cylinder wall, the interior surface will intersect the outer surface. This can cause artifacts that cover a large area on the screen. Problems also occur when polygons with different color attributes become coincident.

Certain types of topological changes are clearly beneficial in reducing complexity, and have a smaller impact on the rendered image. These include the removal of topological holes and thin features (such as the antenna of a car). Topological modifications are encouraged in [Rossignac and Borrel 1992], [Luebke and Erikson 1997], [Garland and Heckbert 1997] and [Erikson and Manocha 1998] and controlled modifications are performed in [He et al. 1996] and [El-Sana and Varshney 1997].

5. LEVEL-OF-DETAIL REPRESENTATIONS

We can classify the possible representations for level-of-detail models into two broad categories: *static* and *dynamic*. Static levels of details are computed totally off-line. They are fully determined as a pre-process to the visualization program. Dynamic levels of detail are typically computed partially off-line and partially on-line within the visualization program. We now discuss these representations in more detail.

5.1 Static Levels of Detail

The most straightforward level-of-detail representation for an object is a set of independent meshes, where each mesh has a different number of triangles. A common heuristic for the generation of these meshes is that the complexity of each mesh should be reduced by a factor of two from the previous mesh. Such a heuristic generates a reasonable range of complexities, and requires only twice as much total memory as the original representation.

It is common to organize the objects in a virtual environment into a hierarchical *scene graph* [van Dam 1988, Rohlf and Helman 1994]. Such a scene graph may have a special type of node for representing an object with levels of detail. When the graph is traversed, this

level-of-detail node is evaluated to determine which child branch to traverse (each branch represents one of the levels of detail). In most static level-of-detail schemes, the children of the level-of-detail nodes are the leaves of the graph. [Erikson and Manocha 1998] presents a scheme for generating *hierarchical levels of detail*. This scheme generates level-of-detail nodes throughout the hierarchy rather than just at the leaves. Each such interior level-of-detail node involves the merging of objects to generate even simpler geometric representations. This overcomes one of the previous limitations of static levels of detail — the necessity for choosing a single scale at which objects are identified and simplified.

The transitions between these levels of detail are typically handled in one of three ways: discrete, blended, or morphed. The discrete transitions are instantaneous switches; one level of detail is rendered during one frame, and a different level of detail is rendered during the following frame. The frame at which this transition occurs is typically determined based on the distance from the object to the viewpoint. This technique is the most efficient of the three transition types, but also results in the most noticeable artifacts.

Blended transitions employ alpha-blending to fade between the two levels of detail in question. For several frames, both levels of detail are rendered (increasing the rendering cost during these frames), and their colors are blended. The blending coefficients change gradually to fade from one level of detail to the other. It is possible to blend over a fixed number of frames when the object reaches a particular distance from the viewpoint, or to fade over a fixed range of distances [Rohlf and Helman 1994]. If the footprints of the objects on the screen are not identical, blending artifacts may still occur at the silhouettes.

Morphed transitions involve gradually changing the shape of the surface as the transition occurs. This requires the use of some correspondence between the two levels of detail. Only one representation must be rendered for each frame of the transition, but the vertices require some interpolation each frame. For instance, [Hoppe 1996] describes the *geomorph* transition for levels of detail created by a sequence of edge collapses. The simpler level of detail was originally generated by collapsing some number of vertices, and we can create a transition by simultaneously interpolating these vertices from their positions on one level of detail to their positions on the other level of detail. Thus the number of triangles we render during the

transition is equal to the maximum of the numbers of triangles in the two levels of detail. It is also possible to morph using a mutual tessellation of the two levels of detail, as in [Turk 1992], but this requires the rendering of more triangles during the transition frames.

5.2 Dynamic Levels of Detail

Dynamic levels of detail provide representations that are more carefully tuned to the viewing parameters of each particular rendered frame. Due to the sheer number of distinct representations this requires, each representation cannot simply created and stored independently. The common information among these representations is used to create a single representation for each simplified object. From this unified representation, a geometric representation that is tuned to the current viewing parameters is extracted. The coherence of the viewing parameters enables incremental modifications to the geometry rendered in the previous frame; this makes the extraction process feasible at interactive frame rates.

[Hoppe 1996] presents a representation called the *progressive mesh*. This representation is simply the original object plus an ordered list of the simplification operations performed on the object. It is generally more convenient to reverse the order of this intuitive representation, representing the simplest *base mesh* plus the inverse of each of the simplification operations. Applying all of these inverse operations to the base mesh will result in the original object representation. A particular level of detail of this progressive mesh is generated by performing some number of these operations.

In [Hoppe 1997], the progressive mesh is reorganized into a vertex hierarchy. This hierarchy is a tree that captures the dependency of each simplification operation on certain previous operations. Similar representations include the *merge tree* of [Xia et al. 1997], the *multiresolution model* of [Klein and Krämer 1997], the *vertex tree* of [Luebke and Erikson 1997], and the *multi-triangulation* of [DeFloriani et al. 1997]. Such hierarchies allow selective refinement of the geometry based on various metrics for screen-space deviation, normal deviation, color deviation, and other important features such as silhouettes and specular highlights. A particular level of detail may be expressed as a *cut* through these graphs, or a *front* of vertex nodes. Each frame, the nodes on the current front are examined, and may cause the graph to be refined at some of these nodes.

[DeFloriani et al. 1997] discuss the properties of such hierarchies in terms of graph characteristics. Examples of these properties include compression ratio, linear growth, logarithmic height, and bounded width. They discuss several different methods of constructing such hierarchies and test these methods on several benchmarks. For example, one common heuristic for building these hierarchies is to choose simplification operations in a greedy fashion according to an error metric. Another method is to choose a set of operations with disjoint areas of influence on the surface and apply this entire set before choosing the next set. The former method does not guarantee logarithmic height, whereas the latter does. Such height guarantees can have practical implications in terms of the length of the chain of dependent operations that must be performed in order to achieve some particular desired refinement.

[DeRose et al. 1993] present a wavelet-based representation for surfaces constructed with subdivision connectivity. [Eck et al. 1995] make this formulation applicable to arbitrary triangular meshes by providing a remeshing algorithm to approximate an arbitrary mesh by one with the necessary subdivision connectivity. Both the remeshing and the filtering/reconstruction of the wavelet representation provide bounded error on the surfaces generated. [Lee et al. 1998] provide an alternate remeshing algorithm based on a smooth, global parameterization of the input mesh. Their approach also allows the user to constrain the parameterization at vertices or along edges of the original mesh to better preserve important features of the input.

5.3 Comparison

Static levels of detail allow us to perform simplification entirely as a pre-process. The real-time visualization system performs only minimal work to select which level of detail to render at any given time. Because the geometry does not change, it may be rendered in retained mode (i.e. from cached, optimized *display lists*). Retained-mode rendering should always be at least as fast as immediate mode rendering, and is much faster on most current high-end hardware. Perhaps the biggest shortcoming of using static levels of detail is that they require that we partition the model into independent “objects” for the purpose of simplification. If an object is large with respect to the user or the environment, especially if the viewpoint is often contained inside the object, little or no simplification may be possible.

This may require that such objects be subdivided into smaller objects, but switching the levels of detail of these objects independently causes visible cracks, which are non-trivial to deal with.

Dynamic levels of detail perform some of simplification as a pre-process, but defer some of the work to be computed by the real-time visualization system at run time. This allows us to provide more fine-tuning of the exact tessellation to be used, and allows us to incorporate more view-dependent criteria into the determination of this tessellation. The shortcoming of such dynamic representations is that they require more computation in the visualization system as well as the use of immediate mode rendering. Also, the memory requirements for such representations are often somewhat larger than for the static levels of detail.

6. SURFACE DEVIATION ERROR BOUNDS

Measuring the deviation of a polygonal surface as a result of simplification is an important component of the simplification process. This surface deviation error gives us an idea of the quality of a particular simplification. It helps guide the simplification process to produce levels of detail with low error, determine when it is appropriate to show a particular level of detail of a given surface, and optimize the levels of detail for an entire scene to achieve a high overall image quality for the complexity of the models actually rendered.

6.1 Distance Metrics

Before discussing the precise metrics and methods used by several researchers for measuring surface deviation, we consider two formulations of the distance between two surfaces. These are the Hausdorff distance and the mapping distance. The Hausdorff distance is a well-known concept from topology, used in image processing as well as surface modeling, and the mapping distance is a commonly used metric for parametric surfaces.

6.1.1 Hausdorff Distance

The Hausdorff distance is a distance metric between point sets. Given two sets of points, *A* and *B*, the Hausdorff distance is defined as

$$H(A,B) = \max(h(A,B), h(B,A)), \tag{3}$$

where

$$h(A,B) = \max_{a \in A} \min_{b \in B} \| a - b \| . \quad (4)$$

Thus the Hausdorff distance measures the farthest distance from a point in one point set to its closest point in the other point set (notice that $h(A,B) \neq h(B,A)$). Because a surface is a particular type of continuous point set, the Hausdorff distance provides a useful measure of the distance between two surfaces.

6.1.2 Mapping Distance

The biggest shortcoming of the Hausdorff distance metric for measuring the distance between surfaces is that it makes no use of the point neighborhood information inherent in the surfaces. The function $h(A,B)$ implicitly assigns to each point of surface A the closest point of surface B. However, this mapping may have discontinuities. If points i and j are "neighboring" points on surface A (i.e. there is a path on the surface of length no greater than ε that connects them), their corresponding points, i' and j', on surface B may not be neighboring points. In addition, the mapping implied by $h(A,B)$ is not identical to the mapping implied by $h(B,A)$.

For the purpose of simplification, we would like to establish a continuous mapping between the surface's levels of detail. Ideally, the correspondences described by this mapping should coincide with a viewer's perception of which points are "the same" on the surfaces. Given such a continuous mapping

$$F: A \rightarrow B$$

the mapping distance is defined as

$$D(F) = \max_{a \in A} \| a - F(a) \| . \quad (5)$$

Because there are many such mappings, there are many possible mapping distances. The minimum mapping distance is simply

$$D_{min} = \min_{F \in M} D(F) , \quad (6)$$

where *M* is the set of all such continuous mapping functions. Note that although D_{min} and its associated mapping function may be difficult to compute, all continuous mapping functions provide an upper bound on D_{min}.

6.2 Surface Deviation Algorithms

We now classify several simplification algorithms according to how they measure the surface deviation error of their levels of detail.

6.2.1 Mesh Optimization

[Hoppe et al. 1993] pose the simplification problem in terms of optimizing an energy function. This function has terms corresponding to number of triangles, surface deviation error, and a heuristic spring energy. To quantify surface deviation error, they maintain a set of point samples from the original surface and their closest distance to the simplified surface. The sum of squares of these distances is used as the surface deviation component of the energy function. The spring energy term is required because the surface deviation error is only measured in one direction: it approximates the closest distance from the original surface to the simplified surface, but not vice versa. Without this term, small portions of the simplified surface can deviate quite far from the original surface, as long as all the point samples are near to some portion of the simplified surface.

6.2.2 Vertex Clustering

[Rossignac and Borrel 1993] present a simple and general algorithm for simplification using vertex clustering. The vertices of each object are clustered using several different sizes of uniform grid. The surface deviation in this case is a Hausdorff distance and must be less than or equal to the size of grid cell used in determining the vertex clusters. This is a very conservative bound, however. A slightly less conservative bound is the maximum distance from a vertex in the original cluster to the single representative vertex after the cluster is collapsed. Even this bound is quite conservative in many cases; the actual maximum deviation from the original surface to the simplified surface may be considerably smaller than the distance the original vertices travel during the cluster operation.

[Luebke and Erikson 1997] take a similar approach, but their system uses an octree instead of a single-resolution uniform grid. This allows them to take a more dynamic approach, folding and unfolding octree cells at run-time and freely merging nearby objects. The measure of surface deviation remains the same, but they allow a more flexible choice of error tolerances in their run-time system. In particular, they use different tolerances for silhouette and non-silhouette clusters.

6.2.3 Superfaces

[Kalvin and Taylor 1996] present an efficient simplification algorithm based on merging adjacent triangles to form polygonal patches, simplifying the boundaries of these patches, and finally retriangulating the patches themselves. This algorithm guarantees a maximum deviation from vertices of the original surface to the simplified surface and from vertices of the simplified surface to the original surface. Unfortunately, even this bidirectional bound does not guarantee a maximum deviation between points on the simplified surface and points on the original surface. For instance, suppose we have two adjacent triangles that share an edge, forming a non-planar quadrilateral. If we retriangulate this quadrilateral by performing an edge swap operation, the maximum deviation between these two surfaces is non-zero, even though their four vertices are unchanged (thus the distance measured from vertex to surface is zero).

6.2.4 Error Tolerance Volumes

[Guéziec 1995] presents a simplification system that measures surface deviation using error volumes built around the simplified surface. These volumes are defined by spheres, specified by their radii, centered at each of the simplified surface's vertices. We can associate with any point in a triangle a sphere whose radius is a weighted average of the spheres of the triangle's vertices. The error volume of an entire triangle is the union of the spheres of all the points on the triangle, and the error volume of a simplified surface is the union of the error volumes of its triangles. As edge collapses are performed, not only are the coordinates of the new vertex computed, but new sphere radii are computed such that the new error volume contains the previous error volume. The maximum sphere radius is a bound on the Hausdorff

distance of the simplified surface from the original, and thus provides a bound for surface deviation in both 3D and 2D (after perspective projection).

6.2.5 Simplification Envelopes

The simplification envelopes technique of [Cohen and Varshney et al. 1996] bounds the Hausdorff distance between the original and simplified surfaces without actually making measurements during the simplification process. For a particular simplification, the input surface is surrounded by two envelope surfaces, which are constructed to deviate by no more than a specified tolerance, ε, from the input surface. As the simplification progresses, the modified triangles are tested for intersection with these envelopes. If no intersections occur, the simplified surface is within distance ε from the input surface. Similar constructions are built to constrain error around the borders of bordered surfaces. By including extensive self-intersection testing as well, the algorithm provides complete global topology preservation. This algorithm does an excellent job at generating small-triangle-count surface approximations for a given error bound. The biggest limitations are the up-front processing costs required for envelope construction (for each level of detail to be generated) and the conservative nature of the envelopes themselves, which do not expand beyond the point of self-intersection.

6.2.6 Error Quadrics

[Ronfard and Rossignac 1996] describe a fast method for approximating surface deviation. They represent surface deviation error for each vertex as a sum of squared distances to a set of planes. The initial set of planes for each vertex are the planes of its adjacent faces. As vertices are merged, the sets of planes are unioned. This metric provides a useful and efficient heuristic for choosing an ordering of edge collapse operations, but it does not provide any guarantees about the maximum or average deviation of the simplified surface from the original.

[Garland and Heckbert 1997] present some improvements over [Ronfard and Rossignac 1996]. The error metric is essentially the same, but they show how to approximate a vertex's set of planes by a quadric form (represented by a single 4x4 matrix). These matrices are simply added to propagate the error as vertices are merged. Using this metric, it is possible to

choose an optimal vertex placement that minimizes the error. In addition, they allow the merging of vertices that are not joined by an edge, allowing increased topological modification. [Erikson and Manocha 1998] further improve this technique by automating the process of choosing which non-edge vertices to collapse and by encouraging such merging to preserve the local surface area.

6.2.7 Mapping Error

[Bajaj and Schikore 1996] perform simplification using the vertex remove operation, and measure surface deviation using local, bijective (one-to-one and onto) mappings in the plane between points on the surface just before and just after the simplification operation. This approach provides a fairly tight bound on the maximum deviation over all points on the surface, not just the vertices (as does [Guéziec 1995]) and provides pointwise mappings between the original and simplified surfaces.

A similar technique is employed by [Cohen et al. 1997], who perform mappings in the plane for the edge collapse operation. They present rigorous and efficient techniques for finding a plane in which to perform the mapping, as well as applying the mapping and propagating error from operation to operation. The computed mappings are used not only to guide the simplification process in its choice of operations, but also to assign texture coordinates to the post-collapse vertices and to control the switching of levels of detail in interactive graphics applications.

6.2.8 Hausdorff Error

[Klein et al. 1996] measure a one-sided Hausdorff distance (with appropriate locality restrictions) between the original surface and the simplified surface. By definition, this approach produces the smallest possible bound on maximum one-sided surface deviation, but the one-sided formulation does not guarantee a true bound on overall maximum deviation. At each step of the simplification process, the Hausdorff distance must be measured for each of the original triangles mapping to the modified portion of the surface. The computation time for each simplification operation grows as the simplified triangles cover more and more of the mesh, but of course, there are also fewer and fewer triangles to simplify. [Klein and Krämer 1997] present an efficient implementation of this algorithm.

6.2.9 Memory-efficient Simplification

[Lindstrom and Turk 1998] demonstrate the surprising result that good simplifications are possible without measuring anything with respect to the original model. All errors in this method are measured purely as incremental changes in the local surface. The error metric used preserves the total volume while minimizing volume changes of each triangle. Another interesting aspect of this work is that they perform after-the-fact measurements to compare the "actual" mean and maximum simplification errors of several algorithm implementations. These measurement use the *Metro* geometric comparison tool [Cignoni et al. 1996], which uniformly samples the simplified surface, computes correspondences with the original surface, and measures the error of the samples.

7. APPEARANCE ATTRIBUTE PRESERVATION

We now classify several algorithms according to how they preserve the appearance attributes of their input models.

7.1 Scalar Field Deviation

The mapping algorithm presented in [Bajaj and Schikore 1996] allows the preservation of arbitrary scalar fields across a surface. Such scalar fields are specified at the mesh vertices and linearly interpolated across the triangles. Their approach computes a bound on the maximum deviation of the scalar field values between corresponding points on the original surface and the simplified surface.

7.2 Color Preservation

[Hughes et al. 1996] describes a technique for simplifying colored meshes resulting from global illumination algorithms. They use a logarithmic function to transform the vertex colors into a more perceptually linear space before applying simplification. They also experiment with producing mesh elements that are quadratically- or cubically-shaded in addition to the usual linearly-shaded elements.

[Hoppe 1996] extends the error metric of [Hoppe et al. 1993] to include error terms for scalar attributes and discontinuities as well as surface deviation. Like the surface deviation,

the scalar attribute deviation is measured as a sum of squared Euclidean distances in the attribute space (e.g. the RGB color cube). The distances are again measured between sampled points on the original surface and their closest points on the simplified surface. This metric is useful for prioritizing simplification operations in order of increasing error. However, it does not provide much information about the true impact of attribute error on the final appearance of the simplified object on the screen. A better metric should incorporate some degree of area weighting to indicate how the overall illuminance of the final pixels may be affected.

[Erikson and Manocha 1998] present a method for measuring the maximum attribute deviation in Euclidean attribute spaces. Associated with each vertex is an attribute volume for each attribute being measured. The volume is a disc of the appropriate dimension (i.e. an interval in 1D, a circle in 2D, a sphere in 3D, etc.). Each attribute volumes is initially a point in the attribute space (an *n*-disk with radius zero). As vertex pairs are merged, the volumes grow to contain the volumes of both vertices.

[Garland and Heckbert 1998] extend the algorithm of [Garland and Heckbert 1997] to consider color and texture coordinate error as well as geometry. The error quadrics are lifted to higher dimensions to accommodate the combined attribute spaces (e.g. 3 dimensions for RGB color and 2 dimensions for texture coordinates). The associated form matrices grow quadratically with the dimension, but standard hardware-accelerated rendering models typically require a dimension of 9 or less. The error is thus measured and optimized for all attributes simultaneously. The method makes the simplifying assumption that the errors in all these attribute values may be measured as in a Euclidean space.

[Certain et al. 1996] present a method for preserving vertex colors in conjunction with the wavelet representation for subdivision surfaces [DeRose et al. 1993]. The geometry and color information are stored as two separate lists of wavelet coefficients. Coefficients may be added or deleted from either of these lists to adjust the complexity of the surface and its geometric and color errors. They also use the surface parameterization induced by the subdivision to store colors in texture maps to render as textured triangles for machines that support texture mapping in hardware.

[Bastos et al. 1997] use texture maps with bicubic filtering to render the complex solutions to radiosity illumination computations. The radiosity computation often dramatically increases the number of polygons in the input mesh in order to create enough vertices to store the resulting colors. Storing the colors instead in texture maps removes unnecessary geometry, reducing storing requirements and rasterization overhead.

The appearance-preserving simplification technique of [Cohen et al. 1998] is in some sense a generalization of this "radiosity as textures" work. Colors are stored as texture maps before the simplification is applied. Mappings are computed as in [Cohen et al. 1997], but this time in the 2D texture domain, effectively measuring the 3D displacements of a texture map as a surface is simplified. Whereas [Bastos et al. 1997] reduces geometry complexity to that of the pre-radiositized mesh, [Cohen et al. 1998] simplify complex geometry much farther, quantifying the distortions caused by the simplification of non-planar, textured surfaces. [Cignoni et al. 98] describe a method for compactly storing attribute values into map structures that are customized to a particular simplified mesh.

7.3 Normal Vector Preservation

[Xia et al. 1997] associate a cone of normal vectors with each vertex during their simplification preprocess. These cones initially have an angle of zero, and grow to contain the cones of the two vertices merged in an edge collapse. Their run-time, dynamic simplification scheme uses this range of normals and the light direction to compute a range of reflectance vectors. When this range includes the viewing direction, the mesh is refined, adapting the simplification to the specular highlights. The results of this approach are visually quite compelling, though they do not allow increased simplification of the highlight area as it gets smaller on the screen (i.e. as the object gets farther from the viewpoint).

[Klein 1998] maintains similar information about the cone of normal deviation associated with each vertex. The refinement criterion takes into account the spread of reflected normals (i.e. the specular exponent, or shininess) in addition to the reflectance vectors themselves. Also, refinement is performed in the neighborhood of silhouettes with respect to the light sources as well as specular highlights. Again, this normal deviation metric does not allow

increased simplification in the neighborhood of the highlights and light silhouettes as the object gets smaller on the screen.

[Cohen et al. 1998] apply their appearance-preserving technique to normals as well as colors by storing normal vectors in normal maps. Figure 11 shows a view of a complex "armadillo" model. Applying the appearance-preserving algorithm to this model generates the simplified versions of Figure 12 and Figure 13, in which it is nearly impossible to distinguish the simplifications from the original. Compared this to the bunnies in Figure 3 and Figure 4. Although the positions of the surfaces are preserved quite well, as evidenced by the similarity of the silhouettes of the bunnies, the shading makes it quite easy to tell which bunnies have been simplified and which have not (i.e. the appearance has not been totally preserved).

The appearance-preserving approach to normal preservation has the advantage that the normal values need not be considered in the simplification process – only texture distortion error constrains the simplification process. In fact, the error in the resulting images can be characterized entirely by the number of pixels of deviation of the textured surface on the screen. The major disadvantage to this approach is that it assumes a per-pixel lighting model is applied to shade the normal-mapped triangles. Per-pixel lighting is still too computationally expensive for most graphics hardware, though support for such lighting is making its way into standard graphics APIs such as OpenGL.

Figure 11: "Armadillo" model: 249,924 triangles

249,924 triangles

7,809 triangles

Figure 12: Medium-sized "armadillos"

249,924 triangles

975 triangles

Figure 13: Small-sized "armadillos"

8. CONCLUSIONS

As is the case for many classes of geometric algorithms, there does not seem to be any single best simplification algorithm or scheme. An appropriate scheme depends not only on the characteristics of the input models, but also the final application to which the multi-resolution output will be applied.

For poorly-behaved input data (mostly non-manifold or triangle soups), the vertex clustering algorithms [Rossignac and Borrel 1992], [Luebke and Erikson 1997] should yield the fastest and most painless success. For cleaner input data, one of the many methods which respect topology will likely produce more appealing results.

When even pre-computation time is of the essence, a fast algorithm such as [Garland and Heckbert 1997] may be appropriate, while applications required better-controlled visual fidelity should invest some extra pre-computation time in an algorithm such as [Cohen et al. 1998], [Guéziec 1995], or [Hoppe 1996], to achieve guaranteed or at least higher quality.

For applications and machines with extra processing power to spare, dynamic level of detail techniques such as [Hoppe 1997] and [Luebke and Erikson 1997] can provide smooth level-of-detail transitions with minimal triangle counts. However, for applications requiring maximal triangle throughput (including display lists) or need to actually employ their CPU(s) for application-related processing, static levels of detail (possibly with geomorphs between levels of detail) are often preferable (they also add less complexity to application code).

The construction and use of levels of detail have become essential tools for accelerating the rendering process. The field has now reached a level of maturity at which there is a rich "bag of tricks" from which to choose when considering the use of levels of detail for a particular application. Making sense of the available techniques as well as when and how well they work is perhaps the next step towards answering the question, "What is a good simplification?", both statically, and over the course of an interactive application.

9. ACKNOWLEDGMENTS

We gratefully acknowledge Greg Angelini, Jim Boudreaux, and Ken Fast at the Electric Boat division of General Dynamics for the submarine model; the Stanford Computer Graphics Laboratory for the bunny and model; and Venkat Krishnamurthy and Marc Levoy at the Stanford Computer Graphics Laboratory and Peter Schröder for the "armadillo" model. Thanks to Amitabh Varshney of the State University of New York at Stonybrook for the original material for the section on optimality. Finally, thanks to Dinesh Manocha, my advisor, for the continued guidance that led to the completion of my dissertation.

ACMS Seminar

Applied and Computational Mathematical Sciences

Speaker: Shawn Cokus, Mathematics

Title: Summing Sums Symbolically: How Computers Revolutionized the Field of Combinatorial Identities

Date: Friday, January 19, 2001

Time: 3:30 - 5:00pm

Place: Loew 102

Not long ago, there was a considerable sub-industry of combinatorics dedicated to proving combinatorial identities such as

$$\sum_{k=0}^{\infty} \frac{(-4)^k \binom{n}{k}}{\binom{2k}{k}} = \frac{1}{1-2n}$$

These kinds of sums come up all the time in probability, analysis of computer algorithms, and many other areas. One used to have to know a lot of tricks and often make up sophisticated ad-hoc arguments to prove each identity.

Recently, however, a very large class of such sums and identities have been shown to be completely routine! That is, for a certain well-defined space of sums, there exists computer algorithms that are guaranteed to find a closed form answer if one exists. Even when a closed form answer does not exist, for this class of sums the algorithms are guaranteed to find a recurrence that the sum satisfies, which is often useful in its own right.

I'll try to give a good overview of these algorithms, and there will be plenty of examples of using Mathematica and Maple packages that implement them. There will be handouts so you can go home, get

on the web, download the packages, and try them on your own problems. (Or keep them at hand so when one of these problems comes up, you'll be ready!)

Handout from the talk: pdf file

For more information: **http://www.ms.washington.edu/acms/seminar.html**

The level of talks is aimed at undergraduates and grad students in mathematical sciences

Everyone welcome!

AlgoVista - A Search Engine for Computer Scientists

Redmond, WA.

Abstract

We describe AlgoVista , a web-based search engine designed to allow applied computer scientists to classify problems and find algorithms and implementations that solve these problems. Unlike other search engines, AlgoVista is not keyword based. Rather, users provide a set of input==>output samples that describe the behavior of the problem they wish to classify. This type of *query-by-example* requires no knowledge of specialized terminology, only an ability to formalize the problem. The search mechanism of AlgoVista is based on a novel application of *program checking*, a technique developed as an alternative to program verification and testing.

DEDICATED TO H. S. M. COXETER

ABSTRACT

Partial answers are given to two questions.
When does a lattice Lambda contain a sublattice Lambda'
of index N that is geometrically similar to Lambda?
When is the sublattice "clean", in the sense that the boundary of the
Voronoi cells for Lambda ' do not intersect Lambda?

ABSTRACT

The coordination sequence {S(n)} of a lattice or net gives the number of nodes that are n bonds away from a given node.
S(1) is the familiar coordination number.

Extending work of O'Keeffe and others, we give explicit formulae for the coordination sequences of the root lattices A_d, D_d, E_6, E_7, E_8 and their duals.

Proofs are given for many of the formulae, and for the fact that in every case S(n) is a polynomial in n, although some of the individual formulae are conjectural.

In the majority of cases the set of nodes that are at most n bonds away from a given node form a polytopal cluster whose shape is the same as that of the contact polytope for the lattice.

It is also shown that among all the Barlow packings in three dimensions the hexagonal close packing has the greatest coordination sequence, and the face-centered cubic lattice the smallest, as conjectured by O'Keeffe.

This paper was published (in a somewhat different form) in
Proc. Royal Soc. London, Series A, Vol. 453 (1997), 2369-2389.

Work: High-School Algebra, Backwards

Jeffreys Copeland & Haemer

(*Server/Workstation Expert*, February 2001)

Nature has... some sort of arithmetical-geometical coordinate system, because nature has all kinds of models.

--- R. Buckminster Fuller

Why is it that we entertain the belief that for every purpose odd numbers are the most effectual?

--- Pliny the Elder

You know how to write programs to do high-school algebra. For example, you could use *bc* to compute the sequence generated by $y=x2$

```
$ bc
for (i=0; i<10; i++)
 i^2
 0
 1
 4
 9
 16
 25
 36
 49
 64
 81
```

That wasn't hard.

 <P> Work: High-School Algebra, Backwards

But suppose you're given the problem backwards. Suppose someone gives you the sequence 0,1,4,9,16,25,36,49,64,81,... and asks you for the equation, or for its 51*st* term. You can look at it and say, ``That's the squares, and the 51*st* term is 2500."

Trivial, we admit, but now suppose someone gives you the sequence 5,4,5,14,37,80,149,250,389,572,... . Quickly now -- what equation generates this sequence? What's the 51*st* term?

Our first attack is to look it up in Sloane's On-Line Encyclopedia of Integer Sequences, http://www.research.att.com/~njas/sequences/.

Unfortunately, it's not there.

Now what? Amazingly, there is a general method to attack this problem, with several wonderful (to us, anyway) properties:

- It's easy to do
- It's easy to remember
- It makes sense
- It's not widely known
- It's useful
- It gives us an excuse to write some code that will fit in a single column

The code isn't actually needed, it's just fun, so we'll start with the math.

Actually, the math is fun, too, but the math requires some familiarity with that advanced mathematical technique, high-school algebra; if that scares you off, just skip to another article. In case you're still on the fence, you'll need to know how to multiply out and simplify equations like $y=(x+1)(x-1)$.

It's Easy To Do

Let's start by going back to the squares

y:0,1,4,9,16,25,36,49,64,81,...

Gillian Haemer once told us, when she was a little girl, that the differences between these numbers were just the odd numbers

/\y:1,3,5,7,9,11,13,15,17,...

and that the differences between *those* were always the same

/\2*y*:2,2,2,2,2,2,2,2,...

and that the differences between *those* were always zero

/\3*y*:0,0,0,0,0,0,0,0,...

It should be clear that we can use this process to generate even the 51*st* term of *y*=*x*2, by taking the 50*th* term and adding the 50*th* odd number. And we could get the 50*th* odd number by taking the 49*th* odd number and adding 2. This sort of building-up process will work for many sequences. Let's try our mystery sequence:

y:5,4,5,14,37,80,149,250,389,572,...

/*y*:-1,1,9,23,43,69,101,139,183,...

/\2*y*:2,8,14,20,26,32,38,44,...

/\3*y*:6,6,6,6,6,6,6,6,...

/\4*y*:0,0,0,0,0,0,0,...

It should be clear that we could calculate the 51st term of this series the same way we sketched for *x*2; it would just be tedious. With only a little math, we can cut down on the calculation and get a closed-form solution.

It's Easy To Remember

With no justification, we're going to introduce an idea and a notation.

Suppose *y*=*x*(*x*-1)(*x*-2)...(*x*-*n*+1) [*n* terms]. We could write this with factorials *y*=<I>__-<I>_<I>_<I>_<I>_. Instead, we're going to call this function a *factorial power*, which we'll write like this: *x*<B>_*n*=*x(x-1)(x-2)...(x-n+1). (We could, we suppose, now write 5!=5_**5** but we personally still like 5! better.)*

 <P> Work: High-School Algebra, Backwards

*Just as with regular powers, we'll let x_**0**=1.*

Why this new notation? It makes our method easy to remember and understand. We're about to use factorial powers in Gregory's Theorem:

> *If y=y0,y1,y2,... is a sequence, then the sequence is generated by the polynomial*
>
> *_ y=f(x)=f(0)+/\f(0)x+__<I>_**2**<I>_<I>_<I>_<I>_x_**2**+__<I>_**6**<I>_<I>_<I>_<I>_x_**3** +...=>____**!**_**<I>_<I>_x<B>_*i***

Here, by /\if(0) we mean ``find the ith set of differences, then take the zeroeth term."

Looks complex, but perhaps oddly familiar. Remember this?

*_ y=f(x)=f(0)+f'(0)x+_<I>_<I>_**2_<I>_<I>_x2+_<I>_<I>_6_<I>_<I>_<I>_x3+...=>___! _<I>_<I>_xi**

where *Dnf*=___. That's just Taylor's theorem, from elementary calculus.

So, we have a mnemonic: our formula is just like the Taylor-Maclaurin series, but with differences instead of derivatives and with factorial powers instead of regular powers.

Shall we try it? Let's do *y=x*2, just for Gillian. Gilly noticed that /\3 and all higher differences are 0. This leaves us with

y=f*(*x*)=*f*(0)+/*f*(0)*x*+__<I>_*2*<I>_<I>_<I>_<I>_x_*2

Plugging in, we get

y=f(x)=0+1x+2_x_2=x+x_2=x+x(x-1)=x2

Eureka.

And it's easy to remember.

It Makes Sense

 <P> Work: High-School Algebra, Backwards

Let's digress again for a few seconds. Be patient with us.

Suppose we have a sequence generated by a factorial power: y=x<B>_n*=x(x-1)(x-2)...(x-n+1). Can we write an equation that generates differences between pairs of successive terms, /\y=f(x+1)-f(x)? Sure. It's just high-school math:*

/\y=(x+1)(x)(x-1)...(x-n)-x(x-1)(x-2)...(x-n+1)=

x(x-1)...(x-n)[(x+1)-(x-n+1)]=

*x(x-1)...(x-n)[n]=nx_**(**<B>_n_-_1_)*

*What's this result, /\x<B>_n=nx_**(**<B>_n_-_1_), look like? Simple derivatives of polynomials in elementary calculus.*

When working with sequences, factorial powers give you the same kind of easy manipulations that regular powers do in continuous functions. Plus, it's not hard to convince yourself that every polynomial can be expressed as the sum of factorial powers times constant coefficients:

_

y=>Cnx<B>_n

(The ambitious reader can prove from this that /\n for any polynomial of degree n will be 0.)

Let's figure out the coefficients, Cn. Take a polynomial,

*y=C0x_**0**+C1x_**1**+C2x_**2**+...*

What's the first difference?

*/\y=C1x_**0**+2C2x_**1**+3C2x_**2**+...*

What's the first term of that sequence? /\1y(0)=C1.

Likewise, the second difference is

*/\2y=2C2x_**0**+(3x2)C3x_**1**+(4x3)C4x_**2**+...*

And the leading term of that sequence is /\2y(0) = 2C2.

Continuing on this way, we see that the first term of the nth difference is

/\ny(0)=n!Cn.

In other words, Cn=____!_<I>_<I>_ ***-- Gregory's theorem. (The Taylor expansion works for an exactly analogous reason, of course.)***

This, then, shows us why Gregory's theorem makes sense: it creates a sequence whose /\'s match the sequence you started with.

It's Not Widely Known

We didn't learn Gregory's theorem in high school. Did you? It's an elementary result in what's called the ``Calculus of Finite Differences.'' It's not hard to use; it's easy to learn, understand, and remember; it's an answer to what seems like an elementary question; yet no mathematician we've ever asked has even known about Gregory's theorem or factorial powers.

Lots of math is like that: accessible, just not fashionable.

It's not widely known.

It's Useful

We confess that we first learned about finite differences as undergraduates, from a book of Haemer's mother's that we found tucked back on an out-of-the-way bookshelf and mysteriously pierced by a nail hole: Lancelot Hogben's An Introduction to Mathematical Genetics, New York, W. W. Norton & Company, Inc. [1946],

We've never seen another copy of Hogben's book, but you can find a modern treatment of finite differences in Concrete Mathematics, ISBN 0-201-55802-5, another in the long line of amazing books by Don Knuth -- this one coauthored with Ron Graham and Oren Patashnik. The book, typeset by Knuth himself, covers math that the authors believe is accessible and useful to computer programmers, but not typically covered in degree programs because it's out-of-vogue. Unlike Hogben's book, Concrete Mathematics is regularly in stock in our local Barnes and Noble.

We agree with Graham, Patashnik, and Knuth. We've never seen it in any other books, but since

 <P> Work: High-School Algebra, Backwards

reading Hogben, we've used Gregory's theorem to attack everything from genetics problems to Sunday supplement puzzles.

It's useful.

It Gives Us An Excuse ...

``Well, that's nice. Where's your code?''

Impatient, aren't you? Let's go back to our other example:

y:5,4,5,14,37,80,149,250,389,572,...

/\y:-1,1,9,23,43,69,101,139,183,...

/\2y:2,8,14,20,26,32,38,44,...

/\3y:6,6,6,6,6,6,6,...

/\4y:0,0,0,0,0,0,0,...

Fourth-degree terms and above go away, so our equation will be

f(x)=f(0)+/\f(0)x+__<I>_2<I>_<I>_<I>_<I>_x(2)+__<I>_6<I>_<I>_<I>_<I>_x(3)

Plugging in, we get f(x)=5+(-1)x+<I>_!_x_2+<I>_!_x_3

Oh, ugh. We can hardly wait to simplify that.

One alternative would be to use a symbolic mathematics package, like Maple or Mathematica. These aren't free, but an AltaVista search for `+'symbolic algebra' +linux` ***returns a wide range of other open-source offerings that could fit the bill. We haven't tried any of these, but would love to hear reviews from anyone who has.***

 <P> Work: High-School Algebra, Backwards

We need something simple that will fit in our margins. A trip to the CPAN, http://www.cpan.org, leads us to Matz Kindahl's package, `Math::Polynomial`, which lets us create ``polynomial'' objects we can do arithmetic on.

For example, let's multiply (3x+2) by (3x-2):

```
#!/usr/bin/perl -w
# $Id: polytest,v 1.1 2000/11/25 23:39:22 jsh Exp $

use Math::Polynomial;
use strict;

Math::Polynomial->verbose(1);

my $p = Math::Polynomial->new(3,+2); # 3*$X + 2
my $q = Math::Polynomial->new(3,-2); # 3*$X - 2

print "($p)*($q) = ", $p*$q, "\n";
```

Running this gives us the expected result.

```
(3*$X + 2)*(3*$X + -2) = 9*$X**2 + -4
```

We can use `Math::Polynomial`, to write a program that will take a sequence as input and print out the polynomial it comes from.

```
#!/usr/bin/perl -w
# $Id: gregory,v 1.6 2000/11/27 19:54:22 jsh Exp $

use strict;
use Math::Polynomial;

sub delta {    # finite diff of a seq
 my @delta;

 for (my $i = 1; $i < @_; $i++) {
  push @delta, ($_[$i] - $_[$i-1]);
 }
 @delta;
}
```

 <P> Work: High-School Algebra, Backwards

```
sub fact {     # factorial
 return 1 if $_[0] < 2;
 my $f = 1;
 $f *= $_ foreach (2..$_[0]);
 $f;
}

sub fact_pow { # factorial power
 my $f = Math::Polynomial->new(1);
 foreach (1 .. $_[0]) {
  $f *= Math::Polynomial->new(1,1-$_);
 }
 $f;
}

# non-zeroes in seq?
sub non_zero { grep($_ != 0, @_) }

# grab the input sequence

my @s;    # array of finite diffs
  # s[0] is original seq
  # s[1] is 1st f.d.
  # etc.

while (<>) {
 # words from input stream
 my @l = split /\W/, $_;
 # discard non-numbers
 @l = grep /^\d+$/, @l;
 push @s, @l;
}

# calculate coefficients

my @c;    # coefficients of final equation

for (my $i=0; non_zero @s; $i++) {
 $c[$i] = $s[0]/fact $i;
 @s = delta @s;
}
```

 <P> Work: High-School Algebra, Backwards

```
# Gregory's theorem

my $p = Math::Polynomial->new(0);
for (my $i = 0; $i < @c; $i++) {
$p += $c[$i]*(fact_pow $i);
}

Math::Polynomial->verbose(1);

print "$p\n";
```

And here is the result from our mystery sequence.

```
$X**3 + -2*$X**2 + 5
```

If we wanted this to run more quickly, we could tune `fact()` ***and*** `fact_pow()` ***by saving results we already know in an array. Once we know x_2*** *from an earlier calculation, we could look it up in our computation of* ***x_3*** *instead of recalculating it. (This is known as memoizing.)*

On the other hand, this would take more development time, and the program seems fast enough as it is. We chose to use `Math::Polynomial` *instead of investing in an elaborate symbolic math package, or writing our own, for the same reason.*

Still, the reason we spent an hour or so writing a program was because we wanted something that worked faster than a hand-calculation. Okay, if we're not optimizing for development time (zero if we'd done the algebra with pencil-and-paper), and we're not optimizing for program performance, what are we optimizing for?

Our own amusement.

Speaking of which, we're amused by the observation that Gregory's theorem can be rewritten in the following way:

*x _ _ >____****!_<I>_<I>_x<B>_i****=>/\if(0) ( ) i*

This makes us think there might be some nice combinatoric interpretation or application of the formula. Can any reader give us one?

Until next time, happy trails.

Work: Odds and Ends

Jeffreys Copeland & Haemer

(*Server/Workstation Expert*, May 1999)

I beheld the wretch -- the miserable monster whom I created.
--- Mary Wollestonecraft Shelly, *Frankenstein*

How much easier it is to be critical than to be correct.
--- Benjamin Disraeli

Ah, May. We can't help but think of the late Bill Rotsler's cartoon cat sitting in the window distracted by a butterfly above the caption ``if cats had a longer attention span, they could rule the world.'' Just so we don't compete with the short attention span engendered by spring fever, we'll be covering a set of topics we've had kicking around in the attic for a while, none of which are enough to fill a complete column. Thus, we present you with a Franken-column.

But first, we found your reaction to our February column educational. (See ``Differences Among Women,'' *SunExpert*, page 38, or http://swexpert.com/C9/SE.C9.FEB.99.pdf.)

Differences among correspondents.

Sometimes, life imitates that simple harmonic motion experiment from freshman physics. When we wrote our November column on technology and reading, we were surprised that the first two notes we had about it were both from women. We used this as a jumping-off point for our February column. (As you know, there's sufficient publication offset that our observations and counter-observations occur in waves with a period of three months.)

The level of reader interest in the February column was higher than we'd anticipated. We seem to have struck a nerve -- or a pair of nerves, as it turns out.

One reader, Pete Kernan, now has a web page about these four-tuples, http://theory2.phys.cwru.edu/~pete/sequence.html. There is also a related entry, A045794, in the ``On-Line Encyclopedia of Integer Sequences,'' http://www.research.att.com/~njas/sequences/

index.html (look for ``Haemer," ``Copeland," or ``1 1 1 3 3 4 9").

We promised to report on the sex ratio of the responses to our column, and here it is: within a month, we got 61 pieces of email from 34 unsolicited readers. Of these, nine respondants were women, (including Ann Janssen, one of our correspondents on the November column), and 25 were men. The correspondents even included the husband-and-wife pair of Shelly Shumway and Arthur Smith. One (male) reader, Sal Mamone, sent us a pointer to some statistics he'd gathered about sex differences among his computer science students. (See ``Empirical Study of Motivation in a Entry Level Programming Course," *ACM SIGPLAN Notices*, March 1992.) We aren't sure Sal's statistics completely apply, since he was teaching COBOL and we think that puts an entirely different skew into the results, but they're interesting nonetheless.

All the responses were interesting and gratifying, but what jumped out at us was the sexual dimorphism. Women sent mail saying, ``Interesting column, here's my opinion"; men sent mail saying, ``interesting column, here's my code/math." We suspect that we could write a perl script to sort the responses by sex.

One woman sent a technical response (containing math or code); three men sent non-technical responses. The fraction of cross-dressed mail for the two sexes is identical to two decimal places.

But we've still gotten no responses from Antarctica.

Monopolies and You.

It should be apparent by now that we're open-source bigots. We firmly believe in open systems, with commodity hardware and for the most part, with non-proprietary software. But there are forces in the world that disagree with us. The largest of those is currently (and probably still will be, by the time you read this) on trial for violations of the anti-trust laws. We speak, of course, about Microsoft.

We won't go into detail about the trial, because whatever we say will be out of date by the time this sees print, but we'll note some interesting reactions:

- Amid all the calls to break Microsoft into various vertical or horizontal slices, Perl consultant and author Tom Christiansen has suggested a different solution: he'd rather see the government make all Microsoft's source code subject to the GNU Public License.
- An IBM spokesman has suggested that Microsoft being sued for anti-trust will destroy the company. After all, he reasons, once IBM ran into anti-trust trouble -- a lawsuit that lasted for eight years, from the last day of the Johnson adminstration to the first day of the Carter administration -- they started spending all their time consulting with lawyers about their plans rather than making new ones. We aren't sure how lawyers had anything to do with their stupidity about the PC market and relative hardware pricing: that's what actually brought the world's formerly largest computer company to the brink of death.

- There's a movement afoot from Linux users to get Microsoft and the hardware vendors to refund their license fees. In general, the Linux community buys commodity hardware, but never boots the installed versions of Windows which are pre-installed on the machines. Open Source advocate Eric Raymond led a protest march over this issue at Microsoft's Silicon Valley offices in February. See `http://www.netcraft.com.au/geoffrey/toshiba.html` for another example.
- If Microsoft is broken up, we expect that the century's first big forced corporate breakup will be instructive. When Standard Oil was dismembered by the government, conventional wisdom was that John D. Rockefeller's fortune would suffer. Quite the contrary, he was three times richer within five years.
- Our guess is that no matter what Judge Thomas Penfield Jackson decides at the trial itself -- which in early March, during the trial's recess, we expect will be against Microsoft in some form -- Microsoft will appeal the verdict. The applicable appeals court has already demonstrated its computer illiteracy in its imfamous ``the browser is part of the operating system because Microsoft says so'' decision. This means that all bets are off on the final outcome.

Off By One and Other Odd Calculations.

We've tripped over a variety of off-by-one errors in our time. In fact, we've complained about some of these in this column before. How do they show up and how do we prevent them? Some examples of obsfucated code, and the fixes for them, may be instructive.

Taking our cue from Disraeli, we provided an example back in October, 1996, complete with fix, of the `%U` and `%W` specifiers to the `date` command and the `strftime()` interface. These two specifiers return the week number; in the case of `%W`, it's the number of weeks beginning on Sunday since January 1st of the current year. In many (nay, most) implementations, these are calculated incorrectly. Given a populated `tm` structure, and the realization that the number of weeks since the beginning of the year is the same as the number of Sundays, it's pretty easy to calculate:

```
sun_week (tm)
 struct tm *tm;
{
 int lastsun = tm->tm_yday -
  tm->tm_wday;
 return (lastsun+7)/7;
}
```

On the other hand, we've been known to get things wrong, too. We built a routine to over-write a section of a file with `nul`s a while back. Since the files could be large, we wanted the program to print a status bar to tell us how far along it was. Certainly, it could print a dot for each block it wrote, but it would be

far more effective to print a line of fixed length, and then add a dot for each 5% of the write completed.

The code for writing the blocks is pretty obvious:

```
fprintf(stderr, "-20s (%07ld) ",
 filename, size);
/* insert [set up for status bar] here */
while( size > 0L )
{
 if( size >= BUFSIZ )
  write(fp,nullbuf,BUFSIZ);
 else
  write(fp,nullbuf,size);
 size -= BUFSIZ;
 /* insert [show status] here */
}
```

But how do we print the status? Our first cut was something like:

```
#define REPORT 20
/* set up for status bar */
osize = size;
nn = size / REPORT;
cnt = nn * (REPORT-1);

  ...

/* show status */
while( size < cnt )
{
 cnt -= nn;
 fprintf(stderr, ".");
}
```

But this, of course, results in incorrect bar length if `size` is less than 20, or if rounding makes the initial value of `cnt` odd. The correct code is more like:

```
#define REPORT 20
/* set up for status bar */
osize = size;
nn = REPORT;
```

```
  ...

/* show status */
while( nn > 0  && size < (osize*nn/REPORT) )
{
 nn--;
 fprintf(stderr,".");
}
```

An equally odd calculation occurs in the TeX macros for Graham, Knuth and Patashnik's *Concrete Mathematics*. (Addison-Wesley, 1994, ISBN 0-201-55802-5.) TeX provides the time of day in minutes since midnight. (We'll leave alternate implementations as an exercise.) To convert that to traditional hours, colon, minutes format requires a bit of fiddling. Usually, we use code such as the following:

```
\def\formattedtime{\hrs = \time
 \divide \hrs by 60
 \mins = \time
 \divide \mins by 60
 \multiply \mins by -60
 \advance \mins by \time
 \number \hrs
  :\ifnum \mins < 10 0\fi\number \mins
}
```

On the other hand, we spent a bit of head scratching over the following fragment from the *Concrete Mathematics* macros before the inevitable ``aha!'':

```
\def\hours{\count0=\time
  \divide\count0 by60 % find the o'clock
  \multiply\count0 by40
  \advance\count0\time % convert to hhmm
  \advance\count0 10000
  \expandafter\gobbleone\number\count0\relax
}
\def\gobbleone1{}
```

The calculation of time divided by 60 times 40 provides 40 times the hours. Since the number of minutes since midnight already contains the hour times 60, this has the effect of leaving the hours multiplied by 100 in the result. Thus we are left with hours times 100, plus minutes. Adding 10000 guarantees that there is a leading zero, if necessary. Unfortunately, it's preceeded by a leading one; fortunately that

character is eaten by `gobbleone` in a bit of TeX macro legedermain.

HTML and troff.

Let's change gears now: By virtue of our being open-source bigots, we're also in favor of open formats. This means that the proprietary documents produced by the likes of Microsoft Word and the Excel spreadsheet make us see various shades of red. (Okay, they make Haemer see red: Copeland's color blind, so he just sees a darker shade of gray.) It also means we really like markup languages such as `troff` and HTML. In fact, we generally write this column in the first, and then convert it to the other for later consumption.

There are a number of tricks we could use for this conversion, including a variety of public domain tools for conversion. But, we do something that may not be as obvious: we convert our `troff` source to HTML by running it through `nroff` with a special macro package.

This all came to mind a few weeks ago when Softway Systems colleague John McMullen was converting a variety of `troff` documentation to on-line web pages, and asked for some assistance. We won't show you the whole macro package, but just some interesting pieces.

Our replacement for the `-mm` list macros had been the following:

```
.\" ===== LISTS
.de AL \" numbered list
.nr list_type 1
<OL>
..
.de BL \" bullet list
.nr list_type 2
<UL>
..
.de LE
.if \\n[list_type]=1 </OL>
.if \\n[list_type]=2 </UL>
.nr list_type 0
..
.de LI
.if \\n[list_type]=1 <LI>
.if \\n[list_type]=2 <LI>
..
```

John pointed out that we didn't support nested lists, and supplied the following replacement code, which

you'll note actually has comments in it. (For ease of reading, `@br` is a macro that replaces `troff`'s `br` directive; `br` itself becomes a macro that produces an HTML `<BR>` tag.)

```
.\" =====  LISTS
.\" When we enter a new list, we prepend the
.\" correct termination tag to the string
.\" list_end.  When we end a list, we use that
.\" string as the argument list to the .LE
.\" macro, print the first argument and redefine
.\" the string If the string length is zero,
.\" we know there's a problem.
.de AL \" numbered list
.@br

It's just not possible to provide a macro to handle every eventuality in our text, so the HTML macros define `.ds HTML@Printing xx` Since `groff` provides a way to test the existence of a string -- `amp;.if d HTML@Printing`... -- we can provide different coding for the `troff` and HTML versions. For example,

```
.ds rr re\*'sume\*'
.if d HTML@Printing .ds rr r&eacute;sum&eacute;
```

Since most of the use of the `HTML@Printing` flag are related to accents, we finally wrote an accent filter.

```
#! /usr/local/bin/perl -p
#  Accent filter for -mm to HTML conversion.
#  Note this only works for valid combinations.

s/([AEIOUaeiouy])\\\*:/\&$1uml;/g;
s/([AEIOUaeiouy])\\\*;/\&$1uml;/g;
s/([AEIOUaeiou])\\\*`/\&$1grave;/g;
s/([AEIOUYaeiouy])\\\*'/\&$1acute;/g;
s/([AEIOUaeiou])\\\*\^/\&$1circ;/g;
s/([ANOano])\\\*\~/\&$1tilde;/g;
s/([Cc])\\\*,/\&$1cedil;/g;
s/\\\(AE/\Æ/g;
s/\\\(ae/\æ/g;
```

This nicely converts input such as

```
U\*:ber, u\*:ber,
ha\*^t, nin\*~o,
fac\*,ade, \(aeon.
```

into

```
&Uuml;ber, &uuml;ber,
h&acirc;t, ni&ntilde;o,
```

```
fa&ccedil;ade, &aelig;on.
```

for printing as ``Über, über, hât, ninnbsp;o, façade, æon."

We leave it as an exercise to fill in the other interesting `troff` special characters with HTML/8859-1 escape sequences, such as inverted exclamation points, and the common fractions.

Finishing up.

Next time, we'll write a review of I18N tricks and techniques. By the time you read that, the Microsoft trial may be in appeal, all of your off-by-one bugs may be gone, and you may have finished converting all your `troff` documents to HTML.

Until then, happy trails.

Representing Trees with Constraints

[2] Department of Computing, School of Informatics,
City University, Northampton Square, London EC1V 0HB

Abstract. This paper presents a method for representing trees using constraint logic programming over finite domains. We describe a class of trees that is of particular interest to us and how we can represent the set of trees belonging to that class using constraints. The method enables the specification of a set of trees without having to generate all of the members of the set. This allows us to reason about sets of trees that would normally be too large to use. We present this research in the context of a system to generate expressive musical performances and, in particular, how this method can be used to represent musical structure.

1 Introduction

This paper describes how constraints can be used to represent a specific class of trees that have the following properties:

Rooted - each tree has a node distinguished as the root node.
Ordered - the children of each node are distinct and cannot be re-ordered without changing what the tree represents.
Constant depth - the leaf nodes of each tree are all the same distance from the root.
Strict - at each depth, one of the nodes has at least two successors.

The number of distinct trees in this class is large for each n, where n is the number of leaf nodes. If $n \geq 10$ the set of trees described can not easily be manipulated or used within a computer system. We present here an efficient way of representing this large set of trees, using constraint logic programming, that enables us to use this class of trees in our research.

The structure of the paper is as follows. The next section explains why we are interested in representing sets of trees in the context of music. We then present some implementation details including our representation and the constraints used to specify the trees of interest. Some results are presented that illustrate the effectiveness of this method. Finally, we end with our conclusions.

2 Motivation: Grouping Structure

This work forms part of our research into creating an expressive musical performer that is capable of performing a piece of music alongside a human musician in an expressive manner.

An expressive performance is one in which the performer introduces variations in the timing and dynamics of the piece in order to emphasise certain aspects of it. Our hypothesis is that there is a direct correlation between these expressive gestures and the musical structure of the piece and we can use this link to generate expressive performances.

The theory of musical structure we are using is the Generative Theory of Tonal Music (GTTM) by Lerdahl and Jackendoff (1983). The theory is divided into four sections that deal with different aspects of the piece's musical structure. We are particularly interested in the *grouping structure* which corresponds with how we segment a piece of music, as we are listening to it, into a hierarchy of groups. It is this hierarchy of groups that we seek to represent with our trees.

The rules are divided into two types: *well-formedness* rules that specify what structures are possible; and *preference* rules that select, from the set of all possible structures, those that correspond most closely to the score.

The rules defining grouping structures are based on principles of change and difference. Figure 1 shows four places where a grouping boundary may be detected (denoted by a '$*$'). The first case is due to a relatively large leap in pitch between the third and fourth notes in comparison to the pitch leaps between the other notes. The second boundary occurs because there is a change in dynamics from piano to forte. The third and fourth boundaries are due to changes in articulation and duration respectively.

Fig. 1. Points in the score where grouping rules may apply

Figure 2 shows an example of a grouping structure for a small excerpt of music. We can see that the music has been segmented into five different groups, one for each collection of three notes. The musical rest between the third and fourth groups causes a higher level grouping boundary that makes two higher level groups which contain the five groups. These groups are then contained within one large group at the highest level.

The grouping structure can be represented with a tree. Figure 3 shows a tree representation (inverted, to aid comparison) for the grouping structure shown in Fig. 2. The leaf nodes at the top of the tree correspond to the notes in the score, and the branches convey how the notes are grouped together. This is an

example of the class of tree we are trying to represent. From this point onwards the trees will be presented in the more traditional manner, i.e. the leaf nodes at the bottom and the root node at the top.

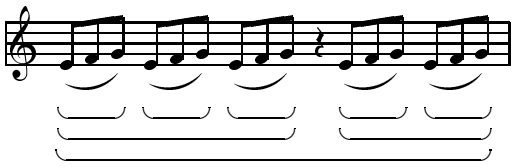

Fig. 2. An example grouping structure

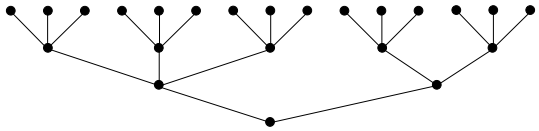

Fig. 3. Tree representing the grouping structure shown in Fig. 2

Although the GTTM grouping rules are presented formally, the preference rules introduce a large amount of ambiguity. For a particular piece of music, there are many possible grouping structures which would satisfy the preference rules. The purpose of the present research is to devise a way to represent this large set of possible structures in an efficient way so that they can be used by a computer system.

Using our hypothesis of the link between musical structure and expressive performance, one of the core ideas of our research is to use rehearsal performances by the human musician to disambiguate the large set of possible grouping trees. The expressive timing used by the musician in these rehearsals provides clues as to how the musician views the structure of the piece. A consistent pattern of timing deviations across a number of performances will enable us to highlight points in the score where the musician agrees with the possible grouping boundaries.

3 Using Constraints

This section of the paper explains how we use constraint logic programming (Van Hentenryck, 1989) to represent sets of trees. Although constraints have been used in the areas of music composition (e.g. Henz 1996) and tree drawing

(e.g. Tsuchida 1997), this research is concerned with an efficient representation of large numbers of tree structures, which is a problem distinct from these.

Constraint logic programming over finite domains enables the specification of a problem in terms of variables with a range of possible values (known as the *domain* of the variable) and equations that specify the relationships between the variables. For example if (1), (2) and (3) hold then we can narrow the domains of x and y as shown in (4):

$$x \in \{1..4\} \tag{1}$$
$$y \in \{3..6\} \tag{2}$$
$$x + y \geq 9 \tag{3}$$
$$x \in \{3..4\} \wedge y \in \{5..6\} \tag{4}$$

The following sections outline the representation and the constraints we use to specify the class of trees. We begin by discussing the representation of the nodes and then present the five types of constraints used to ensure that the trees generated belong to our class.

3.1 Representation

We know that our class of trees will be monotonically decreasing in width from the leaf nodes up to the root and, therefore, we can represent the set of trees by a triangular point lattice of nodes[1]. Figure 4 shows the point lattices for trees of width $n = 3$ and $n = 4$.

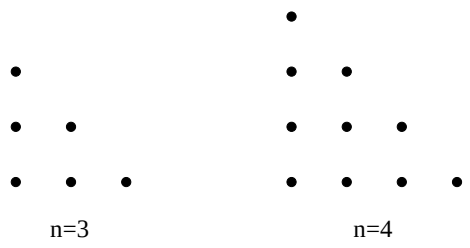

Fig. 4. Point lattices for trees of width 3 and 4

Each node has the following variables (illustrated in Fig. 5):

1. *id*: a unique identifier;
2. *uplink*: a connection to the level above;

[1] An implementation detail means that there is always a path from the highest node of the point lattice to the leaf nodes, but this highest node should not be considered the root node. The root node may occur at any height in the point lattice and is identified as the highest node with more than one child.

3. Downlink values which represent all the nodes on the level below that are connected to this one.

The *id* is specified as an (x,y) coordinate to simplify the implementation details. The *uplink* variable contains an integer that represents the x-coordinate of the node on the level above to which this node is connected i.e. node ($uplink$, $y + 1$). The downlink values, specified by a lower (dl) and upper (du) bound, refer to a continuous range of nodes on the level below that may be connected to this one i.e. nodes (dl, $y - 1$)...(du, $y - 1$).

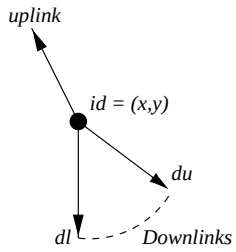

Fig. 5. A typical node

The next sections present the constraints that are applied to the nodes in order to create the specific set of trees in which we are interested. They begin by specifying the domains of the variables and then constraining the nodes so that only those trees that belong to our class can be generated.

3.2 Node Constraints

The first task is to define the domains of the variables for each node. Due to the triangular shape of the point lattice, the uplink for each node is constrained to point either upwards, or up and to the left of the current node. We constrain the downlink for each node to span the nodes directly below, and below and to the right of the current node.

The constraints (given in (5)-(8)) define the domains of the *uplink* and downlink range (i.e. dl and du) for each node[2]. The *uplink* lies in the range $\{0..x\}$ where x is the x-coordinate of the current node. The zero in the range is used when the node is not connected to the level above.

$$domain([uplink]) = \{0..x\} \tag{5}$$

$$domain([dl, du]) = \{0..n\} \tag{6}$$

$$(dl = 0) \oplus (dl \geq x) \tag{7}$$

$$du \geq dl \tag{8}$$

[2] The $\oplus$ in (7) denotes exclusive-or.

The downlink specifiers dl and du are constrained in a similar way to lie in a range from {0..n} with the added constraints that du has to be greater than or equal to dl and that dl either equals zero or is greater than or equal to x. Figure 6 shows how these constraints relate to the direction of the connections to and from each node.

Constraint (9) handles the situation of a node which is not used in a tree. If the *uplink* of the node is zero then the downlinks of the node must also be zero.

$$((dl = 0) \Leftrightarrow (du = 0)) \wedge ((dl = 0) \Leftrightarrow (uplink = 0)) \tag{9}$$

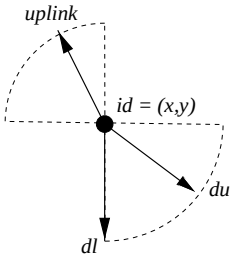

Fig. 6. Constraining the Uplinks and Downlinks

3.3 Level Constraints

To ensure that the connections between two levels do not cross, constraints (10) and (11) are applied to each pair of adjacent nodes. For a pair of nodes A and B, with A directly to the left of B, the $uplink_B$ must either point to the same node as the $uplink_A$ or to the node to the right of it or, if it is unused, be equal to zero (10).

$$(uplink_B = uplink_A) \vee (uplink_B = uplink_A + 1) \vee (uplink_B = 0) \tag{10}$$

Once one of the uplinks on a particular level becomes equal to zero, all the uplinks to the right of it must also be zero (11). This prevents the situation of an unconnected node in the midst of connected ones.

$$(uplink_A = 0) \Rightarrow (uplink_B = 0) \tag{11}$$

Figure 7 shows examples of correct and incorrect mid-sections of a tree under these new constraints. The bottom example is incorrect because it violates constraints (10) and (11).

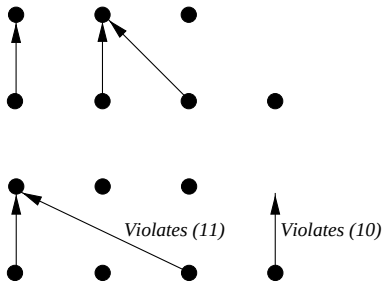

Fig. 7. A correct (*top*) and incorrect (*bottom*) mid-section of a tree

3.4 Consistency Constraints

If the current node refers to a node in the level above, the x-coordinate of this node must appear within its downlink range. Constraint (12) ensures that if this node points to a node on the level above, the downlink range of that node must include this one. Figure 8 shows how this constraint affects two nodes where the lower one is connected to the upper one.

$$(x_{above} = uplink_{this}) \Leftrightarrow ((x_{this} \geq dl_{above}) \wedge (x_{this} \leq du_{above})) \qquad (12)$$

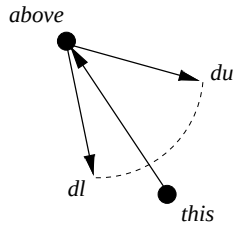

Fig. 8. Ensuring connectivity between nodes

3.5 Width Constraints

We now constrain the trees to decrease in width as we travel from the leaf nodes to the root node. The width of a level is defined as the number of nodes that have a non-zero uplink on that level. Constraint (13) deals with this situation with the precondition that the width of the current level is greater than 1. This precondition is necessary to allow situations such as the first four trees in Fig. 10 where we consider the root node to be at the point where branching begins.

$$(width_i > 1) \Rightarrow (width_j < width_i) \tag{13}$$

We want to ensure that the trees decrease in width to reduce the search space as much as possible. Figure 9 shows an example of a tree which does not decrease in width between two levels, we can remove this tree from our search space as it does not contribute anything new to the grouping structure as we move from level i to level j.

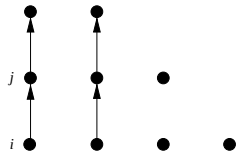

Fig. 9. A section of a tree that does not decrease in width

3.6 Edge Constraints

The last step is to ensure that the uplink of the rightmost[3] node on a level points inwards (the rightmost node in Fig. 7 is an example of this). We find the maximum x of the level above that has a non-zero *uplink* and then ensure that the *uplink* of the rightmost node points to it ((14) and (15)).

$$\mathcal{S} = \{x : id(x, y) \text{ has } uplink_x \neq 0\} \tag{14}$$

$$uplink \leq max(\mathcal{S}) \tag{15}$$

3.7 Valid Trees

The constraints given in §3.2 to §3.6 define the set of trees which belong to our class. Figure 10 shows an example set of width $n = 4$. The white nodes are ones that appear in the generated solutions but are not considered to be part of the tree since the root of the tree is the highest node with more than one child.

3.8 Using the Constraint Representation

The constraints which have been defined in the sections above describe a general class of trees. The next step is to introduce aspects of the grouping structure to

[3] By 'rightmost' we mean the node on the current level with the maximum x-coordinate that has a non-zero uplink.

Fig. 10. All the trees of width four ($n = 4$)

reduce this large set of trees to only those trees that correspond to the piece of music being analysed.

Every point in the musical score where a grouping boundary could occur is identified, for each of these points we then measure the relative strength of this boundary against the surrounding ones. Every boundary point can then be used to determine the shape of the tree by ensuring that every pair of notes intersected by a boundary corresponds to a pair of nodes separated in the tree set.

To separate the nodes in a tree, we need to ensure that the parents of the nodes are not the same, and if we have a measure of relative strength between boundaries, we can specify how far towards the root the nodes need to be separated. The algorithm below shows how this is implemented:

$Repel(id_A, id_B, strength)$
  if $(strength \geq 1)$ **then**
    $parent(id_A) \neq parent(id_B)$
    $Repel(parent(id_A), parent(id_B), strength - 1)$
  endif

This recursive predicate takes two nodes and a strength argument and recursively ensures that the nodes are separated up to a height *strength*. Figure 11 shows an example tree where the tree is divided into two subtrees by a *Repel* constraint that is applied with $strength = 1$ between the second and third leaf nodes.

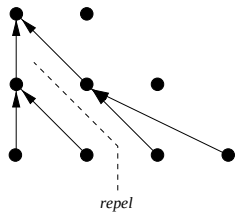

Fig. 11. How *Repel* affects the tree

4 Results

We generated all the trees up to width $n = 7$ and found a similarity with an entry in the Online Encyclopedia of Integer Sequences (Sloane, 2000). It matched a sequence discovered by the mathematician Arthur Cayley (1891) based upon this particular class of trees which has the recurrence shown in (16) and (17)[4]

This recurrence defines the number of trees that belong to our class that are of width n.

$$a(0) = 1 \tag{16}$$

$$a(n) = \sum_{k=1}^{n} \binom{n}{k} a(n-k) \tag{17}$$

Using our representation, the approximate formula, derived experimentally, for the number of constraints to represent the set of all the trees of width n is given in (18).

$$Constraints \approx \frac{2}{3}n^3 + 11n^2 - \frac{2}{3}n - 24 \tag{18}$$

The number of trees of width n grows rapidly (e.g. the number of trees of width 50 is 1.995×10^{72}). By contrast, the number of constraints it takes to represent the same number of trees is 1.1×10^5.

Figure 12 shows how the number of trees grows in comparison to the number of constraints as we increase the width of the tree. The number of trees increases at a greater than exponential rate whereas the number of constraints increases at a low-order polynomial rate.

5 Conclusions

This paper presents our research on representing a specific class of trees with constraint logic programming. Although the number of constraints needed to represent these large sets of trees is comparatively small, the computational time needed to solve the constraints is not.

The representation currently restricts the trees to have leaf nodes at the same depth; however, it does allow the addition of quite simple constraints to change the class of trees represented. For example, to restrict the trees to strictly binary trees we need only add the constraint $du = dl + 1$.

With the use of constraints we have delayed the generation of trees until we have added all the possible restrictions, this offers a great reduction in complexity and allows us to manipulate trees of greater width than would normally be possible.

[4] Where $\binom{n}{k}$ is the standard n choose k formula given by: $\frac{n!}{k!(n-k)!}$

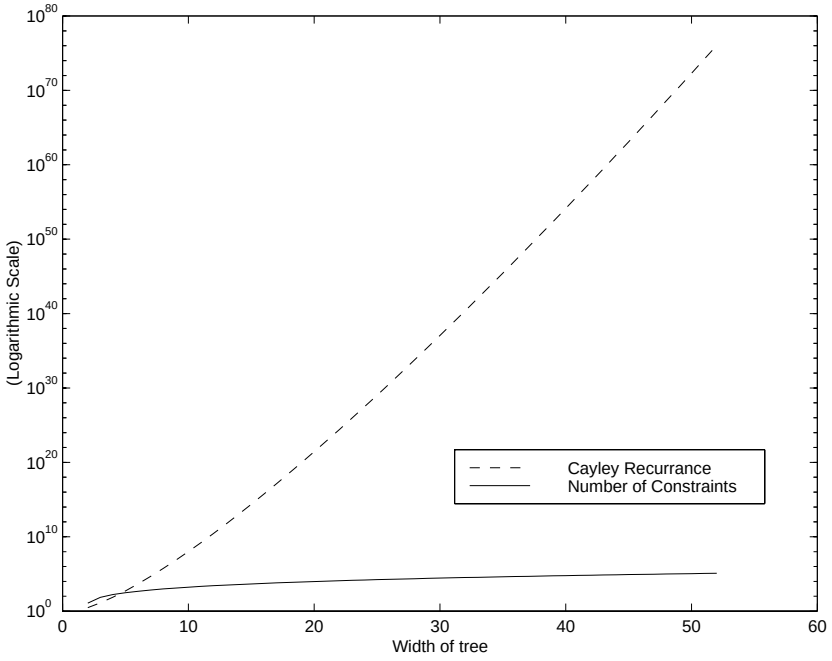

Fig. 12. A graph showing how the number of trees and number of constraints grows with the width of the tree

Alain Darte, Daniel Chavarria-Miranda, Robert Fowler, and John Mellor-Crummey. Latin hyper-rectangles for efficient parallelization of line-sweep computations. Submitted to the *Annals of Operations Research*, December 2001. [ps], [pdf]

Multipartitioning is a strategy for partitioning multi-dimensional arrays among a collection of processors so that line-sweep computations can be performed efficiently. The principal property of a multipartitioned array is that for a line sweep along any array dimension, all processors have the same number of tiles to compute at each step in the sweep, in other words, it describes a *latin hyper-rectangle*, natural extension of the notion of *latin squares*. This property results in full, balanced parallelism. A secondary benefit of multipartitionings is that they induce only coarse-grain communication.

All of the multipartitionings described in the literature to date assign only one tile per processor per hyperplane of a multipartitioning (*latin hyper-cube*). While this class of multipartitionings is optimal for two dimensions, in three dimensions it requires the number of processors to be a perfect square. This paper considers the general problem of computing optimal multipartitionings for multi-dimensional data volumes on an arbitrary number of processors. We describe an algorithm to compute a *d*-dimensional multipartitioning of a multi-dimensional array for an arbitrary number of processors. When using a multipartitioning to parallelize a line sweep computation, the best partitioning is the one that exploits all of the processors and has the smallest communication volume. To compute the best multipartitioning of a multi-dimensional array, we describe a cost model for selecting *d*, the dimensionality of the best partitioning, and the number of cuts along each partitioned dimension. In practice, our technique will choose a 3-dimensional multipartitioning for a 3-dimensional line-sweep computation, except when *p* is a prime; previously, a 3-dimensional multipartitioning could be applied only when sqrt(*p*) is integral.

Finally, we describe a prototype implementation of generalized multipartitioning in the Rice dHPF compiler and performance results obtained when using it to parallelize a line sweep computation for different numbers of processors.

Abstract

Multipartitioning is a strategy for partitioning multi-dimensional arrays among a collection of processors. With multipartitioning, computations that require solving one-dimensional recurrences along each dimension of a multi-dimensional array can be parallelized effectively. Previous techniques for multipartitioning yield efficient parallelizations over three-dimensional domains only when the number of processors is a perfect square. This paper considers the general problem of computing optimal multipartitionings for d-dimensional data volumes on an arbitrary number of processors. We describe an algorithm that computes an optimal multipartitioning for this general case, which enables multipartitioning to be used for performing efficient parallelizations of line-sweep computations under arbitrary conditions.

Finally, we describe a prototype implementation of generalized multipartitioning in the Rice dHPF compiler and performance results obtained when using it to parallelize a line sweep computation for different numbers of processors.

1 Introduction

Line sweeps are used to solve one-dimensional recurrences along each dimension of a multi-dimensional discretized domain. This computational method is the basis for Alternating Direction Implicit (ADI) integration — a widely-used numerical technique for solving partial differential equations such as the Navier-Stokes equation [4, 13, 15] — and is also at the heart of a variety of other numerical methods and solution techniques [15]. Parallelizing computations based on line sweeps is important because these computations address important classes of problems and they are computationally intensive.

Recurrences along a dimension that line sweeps are used solve, serialize computation of each line along that dimension. If a dimension with such recurrences is partitioned, it induces serialization between computations on different processors. Using standard block uni-partitionings, in which each processor is assigned a single hyper-rectangular block of data, there are two classes of alternative partitionings. *Static block unipartitionings* involve partitioning some set of dimensions of the data domain, and assigning each processor one contiguous hyper-rectangular volume. To achieve significant parallelism for a line sweep computation with this type of partitionings requires exploiting wavefront parallelism within each sweep. In wavefront computations, there is a tension between using small messages to maximize parallelism by minimizing the length of pipeline fill and drain phases, and using larger messages to minimize communication overhead in the computation's steady state when the pipeline is full. *Dynamic block unipartitionings* involve partitioning a single data dimension, performing line sweeps in all unpartitioned data dimensions locally, transposing the data to localize the data along the previously partitioned dimension, and then performing the remaining sweep locally. While dynamic block unipartitionings achieve better efficiency during a (local) sweep over a single dimension compared to a (wavefront) sweep using static block unipartitionings, they require transposing *all* of the data to per-

*This research was supported in part by the Los Alamos National Laboratory Computer Science Institute (LACSI) through LANL contract number 03891-99-23 as part of the prime contract (W-7405-ENG-36) between the DOE and the Regents of the University of California.

†This work performed while a visiting scholar at Rice University.

form a complete set of sweeps, whereas static block unipartitionings communicate only data at partition boundaries.

To support better parallelization of line sweep computations, a third sophisticated strategy for partitioning data and computation known as *multipartitioning* was developed [4, 13, 15]. Multipartitioning distributes arrays of two or more dimensions among a set of processors so that for computations performing a directional sweep along any one of the array's data dimensions, (1) all processors are active in each step of the computation, (2) load-balance is nearly perfect, and (3) only a modest amount of coarse-grain communication is needed. These properties are achieved by carefully assigning each processor a balanced number of tiles between each pair of adjacent hyperplanes that are defined by the cuts along any partitioned data dimension. We describe multipartitionings in detail in Section 2. A study by van der Wijngaart [18] of implementation strategies for hand-coded parallelizations of ADI Integration found that 3D multipartitionings yield better performance than both static block unipartitionings and dynamic block unipartitionings.

All of the multipartitionings described in the literature to date consider only one tile per processor per hyperplane of a multipartitioning. The most general class of multipartitionings described in the literature is known as *diagonal multipartitionings*. While diagonal multipartitionings are optimal in two dimensions, for three dimensions diagonal multipartitionings are optimal only when the number of processors is a prime or a perfect square. This paper considers the general problem of computing optimal multipartitionings for d-dimensional data volumes on an arbitrary number of processors. We describe an algorithm that computes an optimal multipartitioning for this general case, which enables multipartitioning to be used for performing efficient parallelizations of line-sweep computations under arbitrary conditions.

In the next section, we describe prior work in multipartitioning. Then, we present our strategy for computing generalized multipartitionings. This has three parts: an objective function for computing the cost of a line sweep computation for a given multipartitioning, a cost-model-driven algorithm for computing the dimensionality and tile size of the best multipartitioning, and an algorithm for computing a mapping of tiles to processors. Finally, we describe a prototype implementation of generalized multipartitioning in the Rice dHPF compiler for High Performance Fortran. We report preliminary performance results obtained using it to parallelize a computational fluid dynamics benchmark.

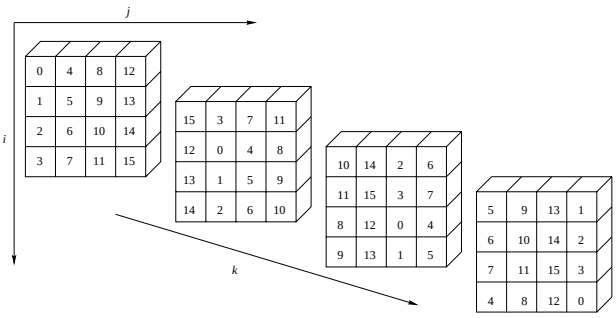

Figure 1: 3D Multipartitioning on 16 processors.

2 Background

Johnsson *et al.* [13] describe a two-dimensional domain decomposition strategy, now known as a multipartitioning, for parallel implementation of ADI integration on a multiprocessor ring. They partition both dimensions of a two-dimensional domain to form a $p \times p$ grid of tiles. They use a tile-to-processor mapping $\theta(i, j) = (i - j) \bmod p$, where $0 \leq i, j < p$. Using this mapping for an ADI computation requires each processor to exchange data with only its two neighbors in a linear ordering of the processors, which maps nicely to a ring.

Bruno and Cappello [4] devised a three-dimensional partitioning for parallelizing three-dimensional ADI integration computations on a hypercube architecture. They describe how to map a three-dimensional domain cut into $2^d \times 2^d \times 2^d$ tiles on to 2^{2d} processors. They use a tile to processor mapping $\theta(i, j, k)$ based on Gray codes. A Gray code $g_s(r)$ denotes a one-to-one function defined for all integers r and s where $0 \leq r < 2^s$, that has the property that $g_s(r)$ and $g_s((r + 1) \bmod 2^s)$ differ in exactly one bit position. They define $\theta(i, j, k) = g_d((j + k) \bmod 2^d) \cdot g_d((i + k) \bmod 2^d)$, where $0 \leq i, j, k < 2^d$ and $\cdot$ denotes bitwise concatenation. This θ maps tiles adjacent along the i or j dimension to adjacent processors in the hypercube, whereas tiles adjacent along the k dimension map to processors that are exactly two hops distant. They also show that no hypercube embedding is possible in which adjacent tiles always map to adjacent processors.

Naik *et al.* [15] describe *diagonal multipartitionings* for two and three dimensional problems. Diagonal multipartitionings are a generalization of Johnsson *et al*'s two dimensional partitioning strategy. This

class of multipartitionings is also more broadly applicable than the Gray code based mapping described by Bruno and Cappello. The three-dimensional diagonal multipartitionings described by Naik *et al.* partition data into $p^{\frac{3}{2}}$ tiles arranged along diagonals through each of the partitioned dimensions. Figure 1 shows a three-dimensional multipartitioning of this style for 16 processors; the number in each tile indicates the processor that owns the block. In three dimensions, a diagonal multipartitioning is specified by the tile to processor mapping $\theta(i,j,k) = ((i-k) \bmod \sqrt{p})\sqrt{p} + ((j-k) \bmod \sqrt{p})$ for a domain of $\sqrt{p} \times \sqrt{p} \times \sqrt{p}$ tiles where $0 \leq i,j,k < \sqrt{p}$.

More generally, we observe that diagonal multipartitionings can be applied to partition d-dimensional data onto an arbitrary number of processors p by cutting the data into an array of p^d tiles. For two dimensions, this yields a unique optimal multipartitioning (equivalent to the class of partitionings described by Johnsson *et al.* [13]). However, for $d > 2$, cutting data into so many tiles yields inefficient partitionings with excess communication. For three or more dimensions, diagonal multipartitioning is optimal only when $p^{\frac{1}{d-1}}$ is integral.

3 General Multipartitioning

Bruno and Cappello noted that multipartitionings need not be restricted to having only one tile per processor per hyperplane of a multipartitioning [4]. How general can multipartitioning mappings be? A sufficient condition to support load-balanced line-sweep computation is that in any hyperplane of the partitioning, each processor must have the same number of tiles. We call any hyperplane in which each processor has the same number of tiles *balanced*. This raises the question: can we find a way to partition a d-dimensional array into tiles and assign the tiles to processors so that each hyperplane is balanced? The answer is yes. However, such an assignment is possible if and only if the number of tiles in each hyperplane along any dimension is a multiple of p. We describe a "regular" solution (regular to be defined) to this general problem that enables us to guarantee that the neighboring tiles of a processor's tiles along a direction of a data dimension all belong to a single processor — an important property for efficient computation on a multipartitioned distribution.

In Section 4, we define an objective function that represents the execution time of a line-sweep computation over a multipartitioned array. In Section 5, we present an algorithm that computes a partitioning of a multidimensional array into tiles that is optimal with respect to this objective. In Section 6, we develop a general theory of modular mappings for multipartitioning. We apply this theory to define a mapping of tiles to processors so that each line sweep is perfectly balanced over the processors.

We use the following notations in the subsequent sections:

- p denotes the number of processors. We write $p = \prod_{j=1}^{s} \alpha_j^{r_j}$, to represent the decomposition of p into prime factors.
- d is the number of dimensions of the array to be partitioned. The array is of size $n_1, \ldots, n_d$. The total number of array elements $n = \prod_{i=1}^{d} n_i$.
- γ_i, for $1 \leq i \leq d$, is the number of tiles into which the array is cut along its i-th dimension. We consider the d-dimensional array as a $\gamma_1 \times \ldots \times \gamma_d$ array of tiles. In our analysis, we assume γ_i divides n_i evenly and do not consider alignment or boundary problems that must be handled when applying our mappings in practice if this assumption is not valid.

To ensure each hyperplane is balanced, the number of tiles it contains must be a multiple of p; namely, for each $1 \leq i \leq d$, p should divide $\prod_{j \neq i} \gamma_j$.

4 Objective Function

We consider the cost of performing a line sweep computation along each dimension of a multipartitioned array. The total computation cost is proportional to the number of elements in the array, n. A sweep along the i-th dimension consists of a sequence of γ_i computation phases (one for each hyperplane of tiles along dimension i), separated by $\gamma_i - 1$ communication phases. The work in each hyperplane is perfectly balanced, with each processor performing the computation for its own tiles. The total computational work for each processor is roughly $\frac{1}{p}$ of the total work in the sequential computation. The communication overhead is a function of the number of communication phases and the communication volume. Between two computation phases, a hyperplane of array elements is transmitted – the boundary layer for all tiles computed in first phase. The total communication volume for a phase communicated along dimension i is $\prod_{j \neq i} n_j$ elements, i.e., $\frac{n}{n_i}$. Therefore, the total execution time for a sweep along dimension i can be approximated by the following formula:

$$T_i(p) = K_1 \frac{n}{p} + (\gamma_i - 1)(K_2 + K_3 \frac{n}{n_i})$$

where K_1 is a constant that depends on the sequential computation time, K_2 is a constant that depends on the cost of initiating one communication phase (start-up), and K_3 is a constant that depends of the cost of transmitting one array element. Define $\lambda_i = K_2 + K_3 \frac{n}{n_i}$, λ_i depends on the domain size, number of processors and machine's communication parameters. The total cost of the algorithm, sweeping in all dimensions, is thus

$$T(p) = d\left(K_1 \frac{n}{p} - K_2 - K_3 \sum_{i=1}^{d} \frac{n}{n_i}\right) + \sum_{i=1}^{d} \gamma_i \lambda_i$$

Remark: if all communications are performed with perfect parallelism, with no overhead, then the term with K_3 is actually divided by p. We assume here that, in general, the cost of one communication phase is an affine function of the volume of transmitted data.

Assuming that p, n, and the n_i's are given, what we can try to minimize is $\sum_{i=1}^{d} \gamma_i \lambda_i$.

There are several cases to consider. If the number of phases is the critical term, the objective function can be simplified to $\sum_i \gamma_i$. If the volume of communications is the critical term, the objective function can be simplified to $\sum_i \frac{\gamma_i}{n_i}$, which means it is preferable to partition dimensions that are larger into relatively more pieces. For example, in 3D, even for a square number of processors (e.g., $p = 4$), if the data domain has one very small dimension, then it is preferable to use a 2D partitioning with the two larger ones rather than a 3D partitioning. Indeed, if n_1 and n_2 are at least 4 times larger than n_3, then cutting each of the first two dimensions into 4 pieces ($\gamma_1 = \gamma_2 = 4$, $\gamma_3 = 1$) leads to a smaller volume of communication than a "classical" 3D partitioning in which each dimension is cut into 2 pieces ($\gamma_1 = \gamma_2 = \gamma_3 = 2$). The extra communication while sweeping along the first two dimensions is offset by the absence of communication in the local sweep along the last dimension.

5 Finding the Partitioning

In this section, we address the problem of minimizing $\sum_i \gamma_i \lambda_i$ for general λ_i's, with the constraint that, for any fixed i, p divides the product of the γ_j's excluding γ_i. We give a practical algorithm, based on an exhaustive search, exponential in s (the number of factors) and the r_i's (see the decomposition of p into prime factors), but whose complexity in p grows slowly.

From a theoretical point of view, we do not know whether this minimization problem is NP-complete, even for a fixed dimension $d \geq 3$, even if all λ_i are equal to 1, or if there is an algorithm polynomial in $\log p$ or even in $\log s$ and the $\log r_i$'s. We suspect that our problem is strongly NP-complete, even if the input is s and the r_i's, instead of p. If p has only one prime factor, we point out that a greedy approach leads to a polynomial (i.e., polynomial in $\log r$) algorithm (see [10]). However, we do not know if an extension of this greedy approach can lead to a polynomial algorithm for an optimal solution in the general case.

5.1 Properties of Potentially Optimal Partitionings

We say that $(\gamma_i)_{1 \leq i \leq d}$ – or (γ_i) for short – is a **valid solution** if, for each $1 \leq i \leq d$, p divides $\prod_{j \neq i} \gamma_j$. Furthermore, if $\sum_i \gamma_i \lambda_i$ is minimized, we say that (γ_i) is an **optimal solution**. We start with some basic properties of valid and optimal solutions.

Lemma 1 *Let (γ_i) be given. Then, (γ_i) is a valid solution if and only if, for each factor α of p, appearing r_α times in the decomposition of p, the total number of occurrences of α in all γ_i is at least $r_\alpha + m_\alpha$, where m_α is the maximum number of occurrences of α in any γ_i.*

Proof: Suppose that (γ_i) is a valid solution. Let α be a factor of p appearing r_α times in the decomposition of p, let m_α be the maximum number of occurrences of α in any γ_i, and let i_0 be such that α appears m_α times in γ_{i_0}. Since p divides the product of all γ_i excluding γ_{i_0}, α appears at least r_α times in this product. The total number of occurrences of α in all of the γ_i is thus at least $r_\alpha + m_\alpha$. Conversely, if this property is true for any factor α, then for any product of $(d-1)$ different γ_i's, the number of occurrences of α is at least $r_\alpha + m_\alpha$ minus the number of occurrences in the γ_i that is not part of the product, and thus must be at least r_α. Therefore, p divides this product and (γ_i) is a valid solution. ■

Thanks to Lemma 1, we can interpret (and manipulate) a valid solution (γ_i) as a distribution of the factors of p into d bins. If a factor α appears r_α times in p, it must appear $(r_\alpha + m_\alpha)$ times in the d bins, where m_α is the maximal number of occurrences of α in a bin. As far as the minimization of $\sum_i \lambda_i \gamma_i$ is concerned, no other prime number can appear in the γ_i without increasing the objective function. The following lemma refines the result of Lemma 1 for a potentially optimal solution.

Lemma 2 *Let (γ_i) be an optimal solution. Then, each factor α of p, appearing r_α times in the decomposition of p, appears exactly $(r_\alpha + m_\alpha)$ times in (γ_i), where m_α is the maximum number of occurrences of α in any γ_i. Furthermore, the number of occurrences of α is m_α in at least two γ_i's.*

Proof: Let (γ_i) be an optimal solution. By Lemma 1, each factor α, $0 \leq j < s$, that appears r_α times in p, appears at least $(r_\alpha + m_\alpha)$ times in (γ_i). The following arguments hold independently for each factor α.

Suppose m_α occurrences of α appear in some γ_{i_0} and no other γ_i. Remove one α from γ_{i_0}. Now, the maximum number of occurrences of α in any γ_i is $m_\alpha - 1$ and we have $(r_\alpha + m_\alpha) - 1 = r_\alpha + (m_\alpha - 1)$ occurrences of α. By Lemma 1, we still have a valid solution, and with a smaller cost. This contradicts the optimality of (γ_i). Thus, there are at least two bins with m_α occurrences of α.

If c, the number of occurrences of α in (γ_i), is such that $c > r_\alpha + m_\alpha$, then we can remove one α from any nonempty bin, containing fewer than m_α occurrences. We now have $c-1 \geq r_\alpha + m_\alpha$ occurrences of α and the maximum is still m_α (since at least two bins had m_α occurrences of α). Therefore, according to Lemma 1, we still have a valid solution, and with smaller cost, again a contradiction. ■

We can now give some upper and lower bounds for the maximal number of occurrences of a given factor in any bin.

Lemma 3 *In any optimal solution, for any factor α appearing r_α times in the decomposition of p, we have $\lceil \frac{r_\alpha}{d-1} \rceil \leq m_\alpha \leq r_\alpha \leq (d-1)m_\alpha$ where m_α is the maximal number of occurrences of α in any bin and d is the number of bins.*

Proof: By Lemma 2, we know that the number of occurrences of α is exactly $r_\alpha + m_\alpha$, and at least two bins contain m_α elements. Thus, $r_\alpha + m_\alpha = 2 * m_\alpha + e$ where e is the total number of elements in $(d-2)$ bins, excluding two bins of maximal size m_α. Since $0 \leq e \leq (d-2)m_\alpha$, then $m_\alpha \leq r_\alpha \leq (d-1)m_\alpha$. Finally, any valid solution requires that p divides the product of all of the factor instances in each group of $d-1$ bins. Thus, there must be r_α instances of α in $d-1$ bins, and thus $m_\alpha \geq \lceil \frac{r_\alpha}{d-1} \rceil$. ■

5.2 Exhaustive Enumeration of Potentially Optimal Partitionings

We now give an algorithm that finds an optimal solution by generating all possible partitionings (γ_i) that satisfy the necessary optimality conditions given by Lemma 2, and determining which one yields the lowest cost partitioning. We also evaluate how many candidate partitions there are and present the complexity of our algorithm. For the complexity, we are not interested in the exact number of solutions that respect the conditions of Lemma 2, but in the order of magnitude, especially when the number of bins d is fixed (and small, equal to 3, 4, or 5), but when p can be large (up to 1000 for example), since this is the situation we expect to encounter in practice when computing multipartitionings.

The C program of Figure 2 generates, in linear time, all possible distributions into d bins, satisfying the $(r+m)$ optimality condition of Lemma 2, of a given factor appearing r times in the decomposition of p. It is inspired by a program [16] for generating all partitions of a number, which is a well-studied problem (see [17]) since the mathematical work of Euler and Ramanujam. The procedure `Partitions` first selects the maximal number m in a bin, and uses the recursive procedure `P(n,m,c,t,d)` that generates all distributions of n elements in $(d-t+1)$ bins (from index t to index d), where each bin can have at most m elements and at least c bins should have m elements. Therefore the initial call is `P(r+m,m,2,1,d)`.

We now prove the correctness of the program. The procedure `P` selects a number of elements for the bin number t and makes a recursive call with parameter $t+1$ for the selection in the next bin. It is thus clear that all generated solutions are different since each iteration of a loop selects a different number of elements for each bin. It remains to prove that all solutions generated by `P` are valid (the total number of elements should be $r+m$, each bin should have less than m elements, and there should be at least c bins with m elements), and that all solutions are generated. For that we prove that `P(n,m,c,t,d)` is always called with parameters for which there exists at least a valid solution, that all possible numbers of elements are selected and only those.

Let us first consider the loop in function `Partitions`. Thanks to Lemma 3, we know that the maximal number of elements in a bin is between $\lceil \frac{r}{d-1} \rceil$ and r. Furthermore, for each such m, there is indeed at least one valid solution with $(r+m)$ elements and two maxima equal to m (if $d \geq 2$), for example the solution where the first two bins have m elements and the $(d-2)$ other bins contain a total

```
// Precondition: d >= 2
void Partitions(int r, int d) {
  int m;
  for (m = (r+d-2)/(d-1); m <= r; m++)
    P(r+m,m,2,1,d);
}

void P(int n, int m, int c, int t, int d) {
  int i;
  if (t==d)
    bin[t] = n;
  else {
    for (i=max(0,n-(d-t)*m);
              i<=min(m-1,n-c*m); i++) {
      bin[t] = i;
      P(n-i,m,c,t+1,d);
    }
    if (n>=m) {
      bin[t] = m;
      P(n-m,m,max(0,c-1),t+1,d);
    }
  }
}
```

Figure 2: Program for generating all possible distributions for one factor.

of $(r-m)$ elements, one possibility being with the $r-m$ elements distributed so that $q = \lfloor \frac{r-m}{m} \rfloor$ bins contain m elements and one contains $(r-m-mq)$ elements. Therefore, if the function `P` is correct, the function `Partitions` is also correct.

To prove the correctness of the function `P` we prove by induction on $d-t+1$ (the number of bins) that there is at least one valid solution if and only if $c \leq d-t+1$ and $cm \leq n \leq (d-t+1)m$ and that `P` generates all of them if these conditions are satisfied. These conditions are simple to understand: we need at least cm elements (so that at least c bins have m elements) and at most $(d-t+1)m$ elements, otherwise at least one bin will contain more than m elements.

The terminal case is clear: if we have only one bin and n elements to distribute, the bin should contain n elements. Furthermore, if there is a solution, we should have $c \leq 1$ and $n = m$ if $c = 1$, i.e., $c \leq d-t+1$ and $cm \leq n \leq (d-t+1)m$.

The general case is more tricky. We first select the number of elements i in the bin number t and recursively call `P` for the remaining bins. If we select strictly less than m elements (this selection is in the loop), we will still have to select c bins with m elements for the remaining $(d-t)$ bins, with $(n-i)$ elements. Therefore, the number i that we select should not be too small, nor too large, and we should have $cm \leq n-i \leq m(d-t)$, i.e., $n-(d-t)m \leq i \leq n-cm$. Furthermore, i should be strictly less than m, nonnegative, and less than n. Since c is always positive, the constraint $i \leq n-cm$ ensures $i \leq n$. If the parameters are correct for the bin number t, we also have $c \leq d-t+1$ and if $c = d-t+1$, then the loop has no iteration, thus for an i selected in the loop, we have $c \leq d-t$. Therefore the recursive call `P(n-i,m,c,t+1,d)` has correct parameters. Finally, if we select m elements for the bin t (after the loop), this is possible only if m is less than n of course, and then it remains to put $(n-m)$ elements into $(d-t)$ bins, with a maximum of m, and at least $\max(0, c-1)$ maxima. Again, the recursive call has correct parameters since we decreased both c and $(d-t)$ and removed m elements.

5.3 Complexity of the Exhaustive Enumeration

For generating all optimal solutions to our minimization problem, we first decompose p into prime factors (complexity $O(\sqrt{p})$ by a standard algorithm, but could be less), we then generate all potentially optimal solutions that satisfy Lemma 2 for each factor (with the function `Partitions`), and we combine them while keeping track of the best overall solution. For evaluating each solution, we need to build the corresponding (γ_i)'s and add them. Each γ_i is at most p and is obtained by at most $\sum_i r_i \leq \log_2 p$ multiplications of numbers less than p. Therefore, building each γ_i costs at most $(\log_2 p)^3$. The overall complexity (excluding the cost of the decomposition of p into prime factors) is thus the product of the complexity of the function `Partitions` (which is the number of solutions generated by the algorithm) times $(\log_2 p)^3$. Therefore, it remains to evaluate the number of solutions generated by the function `Partitions`.

Consider first the case of a number p, product of simple prime factors, in particular the product of the first s prime numbers: $p = \prod_{i=1}^{s} \pi_i$ where π_i is the i-th prime number. For each factor, there are $\frac{d(d-1)}{2}$ possible distributions (picking two bins where to put one copy of each element), so the total number of solutions is $\left(\frac{d(d-1)}{2}\right)^s$. Now, the i-th prime number is approximated by $i \log i$ (see for example the Prime Pages [5]). Therefore, when p grows, we have

$$\begin{aligned} \log p &= \sum_{i=1}^{s} \log \pi_i \sim \sum_{i=1}^{s} \log(i \log i) \\ &\sim \sum_{i=1}^{s} \log i \sim \int_1^s \log x \, \mathrm{d}x \sim s \log s \end{aligned}$$

since divergent series with equivalent nonnegative terms are equivalent. Therefore $\log p \sim s \log s$ and $\frac{\log p}{\log\log p} \sim s$. The total number of solutions for p is thus $\left(\frac{d(d-1)}{2}\right)^{\frac{\log p}{\log\log p}(1+o(1))}$, thus at least of order $p^{\frac{f(d)(1+o(1))}{\log\log p}}$, for a small function $f(d)$ of d. We can prove that this situation (when p is the product of single prime factors) is actually representative of the worst case (in order of magnitude). The proof is too long to be provided here but is available in the extended version of this paper [10].

Theorem 1 *When p grows, the total number of generated solutions is less than $p^{\frac{f(d)(1+o(1))}{\log\log p}}$ where $f(d)$ is a small function of d.*

6 Finding the Mapping

In Section 5, we determined a particular way of cutting the array so as to optimize communications: after partitioning, we get an array (of tiles) whose size is (γ_i) for which the objective is minimized. But until now, we made the assumption that we will be indeed able to assign tiles to processors so that each slice of the array contains exactly the same number of tiles per processor (load-balancing property). This is not certain yet.

The only property we have until now is that the (γ_i) form is a **valid solution**: for each $1 \leq i \leq d$, p divides $\prod_{j \neq i} \gamma_j$, the defining property of a completely balanced multipartitioning. Our main result is that this condition is sufficient to guarantee a mapping of processors to tiles. Our proof is constructive. For any valid solution (γ_i), optimal or not, with or without the additional property of Lemma 2, we give an automatic way to assign a processor number to each tile so that the load-balancing property is satisfied. This assignment is done through the use of modular mappings, defined below. The proof of our construction is much too long to be given here. We refer the reader to the extended version of this paper [10] for details of the proof and interesting properties of modular mappings.

The solution we build is one particular assignment, out of a set of legal mappings. It is not unique, and more experiments might show that they are not all equivalent in terms of execution time, for example because of communication patterns. But, currently, with our objective function (Section 4), the network topology is not taken into account yet and all valid mappings are considered equally good.

6.1 Modular Mappings

Consider the assignment in Figure 1. Can we give a formula that describes it? There are 16 processors that can be represented as a 2-dimensional grid of size 4×4. For example the processor number $7 = 4 + 3$ can be represented as the vector $(3, 1)$, in general (r, q) where r and q are the remainder and the quotient of the Euclidean division by 16. The assignment in the figure corresponds to the assignment $(i - k \bmod 4, j - k \bmod 4)$, which is what we call a **multi-dimensional modular mapping**.

Definition 1 *A mapping $M_m : \mathbb{Z}^d \longrightarrow \mathbb{Z}^{d'}$ defined by $M_m(\vec{i}) = (M\vec{i}) \bmod \vec{m}$ where M is an integral $d \times d'$ matrix and $\vec{m}$ is an integral positive vector of dimension d' is a* **modular mapping**.

With a multi-dimensional mapping, each tile is assigned to a "processor number" in the form of a vector. The product of the components of $\vec{m}$ is equal to the number of processors. It then remains to define a one-to-one mapping from the hyper-rectangle $\{\vec{j} \in \mathbb{Z}^{d'} \mid \vec{0} \leq \vec{j} < \vec{m}\}$ (inequalities component-wise) onto the processor numbers. This can be done by viewing the processors as a virtual grid of dimension d' of size $\vec{m}$. The mapping $M_{\vec{m}}$ is then an assignment of each tile (described by its coordinates in the d-dimensional array of tiles) to a processor (described by its coordinates in the d'-dimensional virtual grid). (Note: in our construction, we will need only the case $d' = d - 1$.)

The following definitions summarize the notions of modular mappings and of modular mappings that satisfy the load-balancing property.

Definition 2 *Given a positive integral vector $\vec{b}$, the* **rectangular index set** *defined by $\vec{b}$ is the set $\mathcal{I}_b = \{\vec{i} \in \mathbb{Z}^n \mid 0 \leq \vec{i} < \vec{b}\}$ (component-wise) where n is the dimension of $\vec{b}$.*

Definition 3 *Given a rectangular index set $\mathcal{I}_b$, a* **slice** *$\mathcal{I}_b(i, k_i)$ of $\mathcal{I}_b$ is defined as the set of all elements of $\mathcal{I}$ whose i-th component is equal to k_i (an integer between 0 and $b_i - 1$).*

Definition 4 *Given an hyper-rectangle (or any more general set) $\mathcal{I}_b$, a modular mapping M_m is a* **one-to-one** *mapping* **from** *$\mathcal{I}_b$* **onto** *$\mathcal{I}_m$ if and only if for each $\vec{j} \in \mathcal{I}_m$ there is one and only one $\vec{i} \in \mathcal{I}_b$ such that $M_m(\vec{i}) = \vec{j}$.*

Definition 5 *Given an hyper-rectangle (or any more general set) $\mathcal{I}_b$, a modular mapping M_m is a* **many-to-one** *modular mapping* **from** *$\mathcal{I}_b$* **onto** *$\mathcal{I}_m$ if and only if the number of $\vec{i} \in \mathcal{I}_b$ such that $M_m(\vec{i}) = \vec{j}$ does not depend on $\vec{j}$.*

Definition 6 *Given a rectangular index set $\mathcal{I}_b$, a modular mapping M_m has the* **load-balancing property** *for $\mathcal{I}_b$ if and only if for any slice $\mathcal{I}_b(i, k_i)$, the restriction of M_m to $\mathcal{I}_b(i, k_i)$ is a many-to-one mapping onto $\mathcal{I}_m$.*

Because a modular mapping is linear, it is easy to see that the load-balancing property can be checked only for the slices that contain 0 (the slices $\mathcal{I}_b(i, 0)$). Furthermore, if $\vec{b}[i]$ denotes the vector obtained from $\vec{b}$ by removing the i-th component and $M[i]$ denotes the matrix obtained from M by removing the i-th column, then the images of $\mathcal{I}_b(i, 0)$ under M_m are the images of $\mathcal{I}_{b[i]}$ under the modular mapping $M[i]_m$. We therefore have the following property.

Lemma 4 *Given an hyper-rectangle $\mathcal{I}_b$, a modular mapping M_m has the load-balancing property for $\mathcal{I}_b$ if and only if each mapping $M[i]_m$ is a many-to-one modular mapping from $\mathcal{I}_{b[i]}$ to $\mathcal{I}_m$.*

We also have the following straightforward result.

Lemma 5 *If M_m is a one-to-one modular mapping from $\mathcal{I}_{b'}$ onto $\mathcal{I}_m$, then M_m is a many-to-one modular mapping from any multiple $\mathcal{I}_b$ of $\mathcal{I}_{b'}$ onto $\mathcal{I}_m$.*

Lemmas 4 and 5 explain why we focus on one-to-one modular mappings first, then on many-to-one modular mappings, and finally on modular mappings with the load-balancing property. In the extended version of this paper [10], we explore the properties of such modular mappings, in order to define a provably adequate matrix M and shape $\vec{m}$ for the virtual grid of processors. Our results are linked to previous works by Lee and Fortes [14] and Darte, Dion, and Robert [9] to the case of one-to-one modular mappings. As in [9], the theory we developed is linked to a famous (in covering/packing theory) theorem due to Hajos [12]. Our results are also connected (through the use of Hajos' theorem) to scheduling techniques used in systolic-like array design (see [8] and [11]) for generating "juggling schedules". However, unlike these two works, which are "one-to-one"-like problems, many questions remain open in the many-to-one case because the extension of Hajos' theorem to a similar "many-to-one" case is true only up to dimension 3 included. Also, while it is easy to build a one-to-one mapping (just take $\vec{m} = \vec{b}$ and the identity matrix!), here we need a much more constrained matrix, such that any submatrix obtained by removing one column is many-to-one for the corresponding $\vec{b}$ and $\vec{m}$. In other words, to use the terminology [11], we need to juggle simultaneously in all dimensions!

We just give here the steps of our construction. We build a modular mapping M_m with the load-balancing property for an index set $\mathcal{I}_b$ (which is given, $\vec{b}$ is the vector whose components are the γ_i's of Section 5). The freedom we have is that we can choose the matrix M and the modulo vector $\vec{m}$, but with the constraint that the cardinality of $\mathcal{I}_m$ (the product of the components of $\vec{m}$) is also given, (equal to the number of processors p). The only property of $\vec{b}$ we exploit is that $\vec{b}$ is a valid solution (with the meaning of Section 5), which means that the product of any $(d-1)$ components of $\vec{b}$ is a multiple of p.

We choose the matrix M with the following form:

$$M = \begin{pmatrix} N & 0 \\ \vec{\lambda} & 1 \end{pmatrix}$$

where N will be computed by induction. Therefore, finally, M will be even triangular, with 1's on the diagonal. We have the following preliminary result.

Lemma 6 *Suppose that m_d divides b_d, and that the modular mapping $N_{m'}$ – in dimension $(d-1)$ – defined by N and $\vec{m}'$ has the load-balancing property for $I_{b'}$, where $\vec{b}'$ and $\vec{m}'$ are the vectors defined by the $(d-1)$ first components of $\vec{b}$ and $\vec{m}$. Then, the modular mapping M_m defined by M and $\vec{m}$ has the load-balancing property for $\mathcal{I}_b$ if it is many-to-one from the last slice $\mathcal{I}_b(0, d)$ onto $\mathcal{I}_m$.*

Proof: In order to check that the mapping defined by M and $\vec{m}$ has the load-balancing property for the rectangular index set $\mathcal{I}_b$, we have to make sure that it is many-to-one for all slices $\mathcal{I}_b(0, i)$, $1 \leq i \leq d$ (Lemma 4). To prove this lemma, we only have to prove that this is true for the slices $\mathcal{I}_b(0, i)$, $i < d$ if N has the properties stated.

Without loss of generality, let us consider the first dimension, i.e., the first slice $\mathcal{I}_b(0, 1)$. Given $\vec{j} \in \mathbb{Z}^d/\vec{m}\mathbb{Z}$, let us count the number of vectors $\vec{i} \in \mathcal{I}_b$, such that $M\vec{i} = \vec{j} \bmod \vec{m}$ and $i_1 = 0$. Now $(M\vec{i} = \vec{j} \bmod \vec{m}) \Leftrightarrow (N\vec{i}' = \vec{j}' \bmod \vec{m}'$ and $\vec{\lambda}.\vec{i}' + i_d = j_d \bmod m_d)$, where $\vec{i}'$ and $\vec{j}'$ are defined the same way as $\vec{b}'$ and $\vec{m}'$, and $\vec{\lambda}$ is the row vector formed by the first $(d-1)$ component of the last row of M. Now, because of the load-balancing property of $N_{m'}$, there are exactly n vectors $\vec{i}' \in \mathcal{I}_{b'}$ such that $i_1 = 0$ and $N\vec{i}' = \vec{j}' \bmod \vec{m}'$, where n is a positive integer that does not depend on $\vec{j}'$. It remains to count the number of values i_d, between 0 and $b_d - 1$, such that $i_d = j_d - \vec{\lambda}.\vec{i}' \bmod m_d$. Since m_d divides b_d, there are exactly b_d/m_d such values, whatever the value $x = (j_d - \vec{\lambda}.\vec{i}' \bmod m_d)$. These are the values $x + km_d$,

with $0 \leq k < b_d/m_d$. Therefore, $\vec{j}$ has $(nb_d)/m_d$ preimages in $\mathcal{I}_b$ and this number does not depend on $\vec{j}$. ■

We define the vector $\vec{m}$ according to the following formula:

$$\forall i,\ 1 \leq i \leq d,\ m_i = \frac{\gcd\left(p, \prod_{j=i}^{d} b_j\right)}{\gcd\left(p, \prod_{j=i+1}^{d} b_j\right)} \qquad (1)$$

(By convention, an "empty" product is equal to 1). The vector $\vec{m}$ defined this way has several properties that will make a recursive construction of M possible (see [10] again).

Because $m_1 = 1$, we will be able to drop, at the end of the construction, the first component of the mapping, and end up with a mapping from $\mathbb{Z}^d$ into a subgroup of $\mathbb{Z}^{d-1}$ (or of smaller dimension if some other components of m are equal to 1). Once N is built, we write:

$$M = \begin{pmatrix} N & 0 \\ \vec{\lambda} & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ \vec{u} & T & 0 \\ \rho & \vec{z} & 1 \end{pmatrix}$$

and we define ρ and $\vec{z}$ such that $\vec{z} = -\vec{t}T$ and $\rho = 1 - \vec{t}.\vec{u}$, where the row vector $\vec{t}$, with $(d-2)$ components, is defined by the following (decreasing) recurrence:

- $r_{d-1} = m_d$,
- for $1 \leq i \leq d-2$, $t_i = \frac{r_{i+1}}{\gcd(b_{i+1}, r_{i+1})}$ and $r_i = \gcd(t_i m_{i+1}, r_{i+1})$.

This schema corresponds to the C program of Figure 3 (where the matrix M has rows and columns from 1 to d as in the presentation of this paper). In our current implementation, we of course take the final matrix modulo the corresponding values of $\vec{m}$. We also play some tricks, variants of the previous program (alternating signs of t for example, or prepermuting the components of $\vec{b}$) to make coefficients smaller. We also use Theorem 3 in [9] (injectivity of $M_{\lambda m}$ for $\mathcal{I}_{\lambda b}$) to reduce the components of M, dividing the components of $\vec{b}$ by their gcd. But the basic kernel is the one presented in Figure 3.

```
// Precondition: d >= 2
void ModularMapping(int d) {

  for (i=1; i<=d; i++)
    for (j=1; j<=d; j++)
      if ((i==1) || (i==j)) M[i][j] = 1;
      else M[i][j] = 0;

  for (i=2; i<=d; i++) {
    r = m[i];
    for (j=i-1; j>=2; j--) {
      t = r/gcd(r, b[j]);
      for (k=1; k<=i-1; k++) {
        M[i][k] -= t*M[j][k];
      }
      r = gcd(t*m[j],r);
    }
  }
}
```

7 Multipartitionings in dHPF

We have implemented preliminary support for *generalized* multipartitionings in the Rice dHPF compiler for High Performance Fortran.

Multipartitioning within the dHPF compiler is implemented as a generalization of `BLOCK`-style HPF partitioning [6, 7]. The partitioned dimensions of the template are distributed onto a virtual array of processors that has the correct size for the rank of the multipartitioning. Internally, the compiler analyzes communication and loop bounds reduction as if the multipartitioned template was a standard `BLOCK` partitioned template onto a larger array of processors. The main difference comes in the interpretation that the compiler gives to the `PROCESSORS` directive. For a `BLOCK` partitioned template, the number of processors onto which each dimension is partitioned determines the data sizes of the tiles. The number of processors may be different for each dimension (i.e. `processors p(2, 3); distribute t(block, block) onto p`).

In the case of multipartitionings, the number of processors cannot be specified on a per dimension basis. All multipartitioned dimensions are distributed onto the number of processors corresponding to the leftmost dimension of the `PROCESSORS` directive. The tiles are partitioned according to the rank of the multipartitioning and then assigned in a skewed-cyclic fashion to the processors (as presented in section 2). Figure 1 illustrates a 3D diagonal multipartitioning on 16 processors.

There are several important issues for correctly generating efficient code for diagonal multipartitioned distributions:

- **Tile Iteration Order**: The order in which a processor's tiles are enumerated has to satisfy any loop-carried dependences present in the orig-

inal loop from which the multipartitioned loop has been generated. If the tiles are not enumerated in the order indicated by the loop-carried dependences, then it is possible to execute the loop correctly, but in a serialized manner induced by data exchange-related synchronization.

- **Inter-loop nest Communication Aggregation**: Communication, which has effectively been vectorized out of a loop nest, should not be performed on a tile-by-tile basis, but instead should be executed once for all of a processor's tiles. This is possible because multipartitioning guarantees that the neighboring tiles for a particular processor will be the same for all of its owned tiles.

In the case of generalized multipartitionings, we might have distributions in which we have more than one tile per processor on a single hyperplane. In order to generate high-performance code, we had to address these challenges:

- **Extended Tile Iteration Order**: For a single hyperplane, a processor may need to enumerate several tiles. The enumeration order does not have any bearing on correctness because dependences are being carried across hyperplanes instead of within a single hyperplane.

- **Intra-loop nest Communication Aggregation**: Communication caused by a loop-carried dependence may require several of a processor's tiles on a single hyperplane to send or receive data. We desire that this communication event should be executed as a single unit, instead of once per tile. This is possible because generalized multipartitionings provide the same neighborhood guarantee as simpler, diagonal multipartitionings.

8 Preliminary Results

Our implementation of multipartitioning in dHPF currently supports generalized multipartitionings. By using a multipartitioned data distribution in conjunction with sophisticated data-parallel compiler optimizations, we are closing the performance gap between compiler-generated and hand-coded implementations of line-sweep computations. Earlier results and details about dHPF's compilation techniques can be found elsewhere [7, 6, 1, 2]. Here we present some preliminary results applying generalized multipartitioning in a compiler-based parallelization of the NAS SP application benchmark [3, 7], a computational fluid dynamics code.

Table 1: Comparison of hand-coded and dHPF speedups for NAS SP (class B).

The most important analysis and code generation techniques used to obtain high-performance multipartitioned applications by the dHPF compiler are:

- partial replication of computation to reduce communication frequency and volume,
- communication vectorization,
- aggressive communication placement, and
- intra-variable and inter-variable communication aggregation.

We performed these experiments on a SGI Origin 2000 with 128 250MHz R10000 CPUs, each CPU has 32KB of L1 instruction cache, 32KB of L1 data cache and an unified, two-way set associative L2 cache of 4MB.

Table 1 shows the speedups obtained for both the dHPF-generated and hand-coded versions of the NAS SP benchmark using the class 'B' problem size (102^3). The hand-coded version implements three-dimensional diagonal multipartitionings, thus its results are only available for numbers of processors which are perfect squares. The compiler-generated version uses generalized multipartitioning to execute on other numbers of processors. The table presents the speedups for the hand-coded version (where available), the dHPF version and the differences between

them. All speedups presented are relative to the sequential version of NAS SP. Overall, the performance of the compiler-generated code is similar to that of the hand-coded versions with the exception of the gap between the versions for a 49 processor execution, which is wider for reasons that are currently unknown.

The performance differences observed between the hand-coded and compiler-generated versions are due in large part to a difference how off-processor values are stored and accessed in the two versions. In the dHPF-generated code, each data tile is extended with overlap areas (ghost regions around the tile's boundary) into which off-processor data is unpacked. Overlap areas enable a loop operating on the tile to reference all data uniformly without having to distinguish between local and off-processor data. The hand-coded version uses a clever buffering scheme in which iterations of a loop that need off-processer data are peeled off the main body of the loop. Then, in the peeled loop references to off-processor data read their values directly out of a message buffer without having to unpack it. In the dHPF-generated code, the use of extra data space for overlap areas degrades data cache efficiency, which appears to account for most of the observed performance differences.

One other factor that effects the execution efficiency of the dHPF-generated code when the number of tiles per hyperplane of a multipartitioning is greater than one (e.g., when the number of processors in a 3D partitioning is not a perfect square) is that the dHPF-generated code fails to effectively exploit reuse of data tiles across multiple loop nests. Currently, for a sequence of loop nests, dHPF-generated code executes one loop nest for each of the data tiles in a hyperplane of the data and then advances to the next loop nest. For a sequence of loop nests with compatible tile enumeration order, the tile enumeration loops could be fused so that all of the compatible loop nests in the sequence are performed on one tile before advancing to the next tile. When data tiles are small enough to fit into one or more caches, this strategy this would improve cache utilization by facilitating reuse of tile data among multiple loop nests.

9 Conclusions

The paper describes an algorithm for computing multipartitioned data distributions. These distributions are important because they support fully parallel execution of line-sweep computations. For arrays of two or more dimensions, our algorithm will compute an optimal multipartitioning that minimizes cost according to an objective function that measures communication in line sweep computations. Previously, optimal multipartitionings could be computed for d dimensional data only when $p^{\frac{1}{d-1}}$ is integral. Our extensions enable optimal multipartitionings to be computed for d dimensions.

We have shown that, having a partitioning in which the number of tiles in each slice is a multiple of the number of processors — an obvious necessary condition — is also a sufficient condition for a balanced mapping of tiles to processors. We also give a constructive method for building this mapping using new techniques based on modular mappings. This method assigns the tiles defined by the partitioning algorithm to the physical processors that should compute upon them.

One currently unresolved issue is that when we compute a multipartitioning for p processors, we force all processors to participate in the computation. In some cases, it might be more efficient to simply drop back to the nearest perfect square number of processors and let others sit idle. The extra communication overhead incurred by including them might dominate benefit of computation they could perform.

We have constructed a prototype code generator that exploits generalized multipartitionings in the Rice dHPF compiler; however, these partitionings could be exploited by hand-coded implementations as well. Preliminary performance results for generalized multipartitioning code generated by dHPF show encouraging scalability for small numbers of processors.

Abstract

Multipartitioning is a strategy for parallelizing computations that require solving 1D recurrences along each dimension of a multi-dimensional array. Previous techniques for multipartitioning yield efficient parallelizations over 3D domains only when the number of processors is a perfect square. This paper considers the general problem of computing multipartitionings for d-dimensional data volumes on an arbitrary number of processors. We describe an algorithm that computes an optimal multipartitioning onto all of the processors for this general case. Finally, we describe how we extended the Rice dHPF compiler for High Performance Fortran to generate code that exploits generalized multipartitioning and show that the compiler's generated code for the NAS SP computational fluid dynamics benchmark achieves scalable high performance.

1. Introduction

Line sweeps are used to solve one-dimensional recurrences along each dimension of a multi-dimensional discretized domain. This computational method is the basis for Alternating Direction Implicit (ADI) integration – a widely-used numerical technique for solving partial differential equations such as the Navier-Stokes equation [4, 13, 15] – and is also at the heart of a variety of other numerical methods and solution techniques [15]. Parallelizing computations based on line sweeps is important because these computations address important classes of problems and they are computationally intensive.

However, parallelizing multi-dimensional line sweep computations is difficult because for each of multiple data dimensions, recurrences serialize computation along that dimension. Using standard block partitionings, which assign a single hyper-rectangular volume of data to each processor, there are two reasonable parallelization strategies. A **static block unipartitioning** partitions one of the array dimensions for the entire computation. To achieve significant parallelism with this type of partitioning, one must exploit wavefront parallelism within each sweep. In wavefront computations, there is a tension between using small messages to maximize parallelism by minimizing the length of pipeline fill and drain phases, and using larger messages to minimize communication overhead in the computation's steady state when the pipeline is full. A **dynamic block partitioning** involves partitioning some subset of the dimensions, performing line sweeps in all unpartitioned dimensions locally, and then transposing the data (when necessary) between sweeps so that each of the sweeps, in turn, can be performed locally. While a dynamic block partitioning achieves better efficiency during a (local) sweep over a single dimension compared to a (wavefront) sweep using a static block unipartitioning, the cost of its data transposes can be substantial.

To support better parallelization of line sweep computations, a third sophisticated strategy for partitioning data and computation known as **multipartitioning** was developed [4, 13, 15]. This strategy partitions arrays of $d \geq 2$ dimensions among a set of proces-

†This work performed while a visiting scholar at Rice University.

sors so that for a line sweep computation along any dimension of an array, all processors are active in each step of the computation, load-balance is nearly perfect, and only coarse-grain communication is needed. These properties are achieved by (1) assigning each processor a balanced number of tiles in each hyper-rectangular slab defined by a pair of adjacent cuts along a partitioned data dimension and (2) ensuring that for all tiles mapped to a processor, their immediate tile neighbors in any one coordinate direction are all mapped to some other single processor. We later refer to these two properties as the **balance** property, and the **neighbor** property respectively. A study by van der Wijngaart [18] of strategies for hand-coded parallelizations of ADI Integration found that 3D multipartitionings yield better performance than static block or dynamic block partitionings.

All of the multipartitionings described in the literature to date consider only one tile per processor per hyper-rectangular slab along a partitioned dimension. The most broadly applicable of the multipartitioning strategies in the literature is known as **diagonal multipartitioning**. In 2D, these partitionings can be performed on any number of processors, p; however, in 3D they are only useful if p is a perfect square. We consider the general problem of computing optimal multipartitionings for d-dimensional data volumes for an arbitrary number of processors.

In the next section, we describe prior work in multipartitioning. Then, we present our strategy for computing generalized multipartitionings. This has three parts: an objective function for computing the cost of a line sweep computation for a given multipartitioning, a cost-model-driven algorithm for computing the dimensionality and tile size of the best multipartitioning, and an algorithm for computing a mapping of tiles to processors. Finally, we describe an implementation of generalized multipartitioning in the Rice dHPF compiler for High Performance Fortran. We show that it yields scalable high performance when used to parallelize the NAS SP [3] computational fluid dynamics benchmark.

2. Background

Johnsson *et al.* [13] describe a 2D domain decomposition strategy, now known as a multipartitioning, for parallel implementation of ADI integration on a multiprocessor ring. They partition both dimensions of a 2D domain to form a $p \times p$ grid of tiles. They use a tile-to-processor mapping $\theta(i,j) \equiv (i-j) \bmod p$, $0 \le i,j < p$, to map from the $[i,j]$ coordinates of

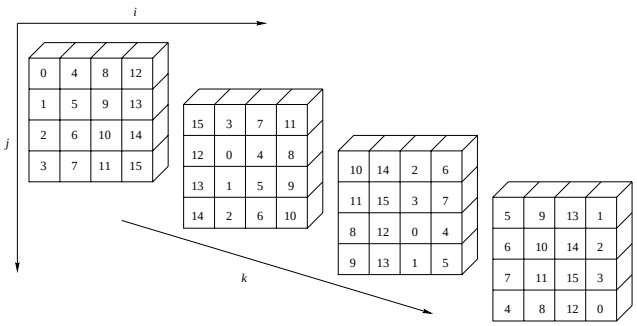

Figure 1. A 3D Multipartitioning.

each tile to its corresponding processor. This partitioning is an instance of a **latin square** [10]. Using this mapping for an ADI computation, each processor exchanges data with only its 2 neighbors in a linear ordering of the processors, which maps nicely to a ring.

Bruno and Cappello [4] devised a 3D partitioning for parallelizing 3D ADI integration computations on a hypercube architecture. They describe how to map a 3D domain cut into $2^d \times 2^d \times 2^d$ tiles on to 2^{2d} processors with a tile-to-processor mapping $\theta(i,j,k)$ based on Gray codes: θ maps tiles adjacent along the i or j dimension to adjacent processors in the hypercube, whereas tiles adjacent along the k dimension map to processors that are exactly two hops distant. They also show that no hypercube embedding is possible in which adjacent tiles always map to adjacent processors.

Naik *et al.* [15] describe **diagonal multipartitionings** for 2D or 3D problems. Diagonal multipartitionings are a generalization of Johnsson *et al.*'s 2D partitioning strategy that are more broadly applicable than the Gray code based mapping described by Bruno and Cappello. The 3D diagonal multipartitionings described by Naik *et al.* partition the data into $p^{\frac{3}{2}}$ tiles, with each processor's tiles arranged along wrapped diagonals through the 3D volume. Figure 1 shows a 3D multipartitioning of this style for 16 processors; the number in each tile indicates the processor that owns the block. This 3D diagonal multipartitioning (there are many) is specified by the tile to processor mapping $\theta(i,j,k) \equiv ((i-k) \bmod \sqrt{p})\sqrt{p} + ((j-k) \bmod \sqrt{p})$ for a domain of $\sqrt{p} \times \sqrt{p} \times \sqrt{p}$ tiles where $0 \le i,j,k < \sqrt{p}$, where $\sqrt{p} = 4$.

More generally, we observe that diagonal multipartitionings can be applied to partition d-dimensional data onto an arbitrary number of processors p by cutting the data into p slices in each dimension, *i.e.,* into an array of p^d tiles. In 2D, this yields an *optimal* multipartitioning (equivalent to those described by Johnsson *et al.*). We call a multipartitioning optimal for a particu-

lar number of processors if no other multipartitioning exists that has lower communication cost according to a cost model that considers both fixed overhead for communicating and overhead proportional to the size of the hyper-surfaces that must be communicated. For $d > 2$, diagonal multipartitionings are only optimal and efficient when $p^{\frac{1}{d-1}}$ is integral.

Bruno and Cappello noted that multipartitionings need not be restricted to having only one tile per processor per hyper-rectangular slab of a multipartitioning [4]. How general can multipartitioning mappings be? A necessary condition to support load-balanced line-sweep computation is that in any hyper-rectangular slab defined by adjacent cuts along a partitioned dimension, each processor must have the same number of tiles. We call any such slab in which each processor has the same number of tiles **balanced**. This raises the question: can we find a way to partition a d-dimensional array into tiles and assign the tiles to processors so that the mapping possesses the **balance** and **neighbor** properties of a multipartitioning? The answer is yes. We show that such an assignment is possible if and only if the number of tiles in each hyper-rectangular slab along any partitioned dimension is a multiple of p ("if" being the difficult part of the proof). We describe a "regular" solution (regular to be defined) that enables us to guarantee that the neighboring tiles along any one coordinate direction of all tiles mapped to a processor all belong to a single processor. This property of multipartitionings is essential for fully-vectorized, directional-shift communication to be efficient.

In Section 3.1, we define an objective function that represents the execution time of a line-sweep computation over a multipartitioned array, and in Section 3.3, we present an algorithm that computes a partitioning of a multi-dimensional array into tiles that is optimal with respect to this objective. In Section 4, we develop a general theory of modular mappings for multipartitioning. We apply this theory to define a mapping of tiles to processors so that each line sweep is perfectly balanced over the processors.

We use the following notation:

- p denotes the number of processors. We write $p = \prod_{j=1}^{s} \alpha_j^{r_j}$ to represent the decomposition of p into prime factors, α_j.
- d is the number of dimensions of the array to be partitioned. The array is of size $\eta_1, \ldots, \eta_d$. The total number of array elements $\eta = \prod_{i=1}^{d} \eta_i$.
- γ_i is the number of tiles into which the array is cut along its i-th dimension. We consider the array of elements as a $\gamma_1 \times \ldots \times \gamma_d$ array of tiles. In our analysis, we assume that γ_i divides η_i evenly and do not consider alignment or boundary problems that must be handled when applying our mappings in practice if this assumption is not valid.

To ensure that each slab is balanced, the number of tiles it contains must be a multiple of p; namely, for each $1 \leq i \leq d$, p should divide $\prod_{j \neq i} \gamma_j$. When this is true, we say that (γ_i) is a **valid partitioning**.

3. Finding the Partitioning

3.1. Objective Function

We consider the cost of performing a line sweep computation along each dimension of a multipartitioned array. The total computation cost is proportional to η, the number of elements in the array. A sweep along the i-th dimension consists of a sequence of γ_i computation phases (one for each hyper-rectangular slab of tiles along dimension i), separated by $\gamma_i - 1$ communication phases. The work in each slab is perfectly balanced, with each processor performing the computation for its own tiles. The total computational work for each processor is roughly $\frac{1}{p}$ of the total work in the sequential computation. The communication overhead is a function of the number of communication phases and the communication volume. Between two computation phases, a hyperplane of array elements is transmitted – the boundary layer for all tiles computed in first phase. The total communication volume for a phase communicated along dimension i is $\prod_{j \neq i} \eta_j$ elements, i.e., $\frac{\eta}{\eta_i}$, yielding a communication volume per processor of $\frac{\eta}{p\eta_i}$. The total execution time for a sweep along dimension i can be approximated by:

$$T_i(p) = K_1 \frac{\eta}{p} + (\gamma_i - 1)(K_2 + K_3(p)\frac{\eta}{\eta_i})$$

where K_1 is a constant that depends on the sequential computation time per data element, K_2 is a constant that depends on the cost of initiating one communication phase (start-up), and $K_3(p)$ is a function of p that reflects the bandwidth-sensitive communication cost per element of hyper-surface area along a cut in dimension i.[1] Define $\lambda_i = K_2 + K_3(p)\frac{\eta}{\eta_i}$; λ_i depends on the domain size, number of processors and machine's communication parameters. The total cost, sweeping

[1] On a parallel machine in which the network bandwidth available is directly proportional to the number of processors, $K_3(p)$ would be proportional to $\frac{1}{p}$, whereas on a bus-based system for which available bandwidth is fixed, $K_3(p)$ would be a constant.

in all dimensions, is thus

$$T(p) = d\left(K_1\frac{\eta}{p} - \sum_{i=1}^{d}\lambda_i\right) + \sum_{i=1}^{d}\gamma_i\lambda_i$$

Assuming that p, η, and the η_i's are given, the first term is a constant, and what we want to minimize is the second term $\sum_{i=1}^{d}\gamma_i\lambda_i$.

Remark: If the number of phases is the critical term, the objective function can be simplified to $\sum_i \gamma_i$. If the volume of communications is the critical term, the objective function can be simplified to $\sum_i \frac{\gamma_i}{\eta_i}$, which means it is preferable to partition dimensions that are larger into relatively more pieces. For example, in 3D, even for a square number of processors (e.g., $p = 4$), if the data domain has a short extent in one dimension, it is preferable to use a 2D partitioning of the other 2 dimensions rather than a 3D partitioning. Indeed, if η_1 and η_2 are at least 4 times larger than η_3, then cutting each of the first 2 dimensions into 4 pieces ($\gamma_1 = \gamma_2 = 4$, $\gamma_3 = 1$) leads to a smaller volume of communication than a "classical" 3D partitioning in which each dimension is cut into 2 pieces ($\forall i$, $\gamma_i = 2$). The extra communication while sweeping along the first 2 dimensions is offset by the absence of communication in the local sweep along the last one.

We now address the problem of minimizing $\sum_i \gamma_i\lambda_i$ with the constraint that, for any fixed i, p divides the product of the γ_j's, $j \neq i$. We give a practical algorithm, based on an (optimized) exhaustive search, exponential in s (the number of distinct factors) and the r_i's (see the decomposition of p into prime factors), but whose complexity in p grows slowly. From a theoretical point of view, we do not know whether this minimization problem is NP-complete, even for a fixed dimension $d \geq 3$, even if $\forall i$, $\lambda_i = 1$, or if there is an algorithm polynomial in $\log p$ or even in the s values $\log r_i$. If p has only one prime factor, a greedy approach leads to a polynomial (polynomial in $\log p$) algorithm (see [8]). However, we do not know if an extension of this greedy approach can lead to a polynomial algorithm for an optimal partitioning in the general case.

3.2. Elementary Partitionings

If (γ_i) is a valid partitioning such that $\sum_i \gamma_i\lambda_i$ is minimized, we say that (γ_i) is an **optimal partitioning**. Using the fact that for each $1 \leq i \leq d$, p divides $\prod_{j\neq i}\gamma_j$ and that the objective function increases when the γ_i increase (the λ_i are positive), we can show the following result. (The proof is not difficult, we omit it due to space constraints.)

Lemma 1 *Let (γ_i) be an optimal partitioning. Then, each factor α_j of p, appearing r_j times in the decomposition of p, appears exactly $(r_j + m_j)$ times in (γ_i), where m_j is the maximum number of occurrences of α_j in any γ_i. Furthermore, the number of occurrences of α_j is m_j in at least two γ_i's.*

We can thus restrict to **elementary partitionings**, those that satisfy the conditions of Lemma 1. We can interpret (and manipulate) an elementary partitioning as a distribution of the factors of p into d bins, satisfying a particular constraint on the number of occurrences. Elementary partitionings are those which are not a "multiple" of another possible size; in other words, these are the sizes for which a multipartitioning exists that cannot be obtained by composing it (by paving) from multiple instances of a smaller multipartitioning. For example, in 3D, with 8 processors, only the partitionings $4\times4\times2$, $8\times8\times1$, and their permutations are elementary. With $p = 5\times3\times2$, only the partitionings $10\times15\times6$, $15\times30\times2$, $10\times30\times3$, $5\times30\times6$, $30\times30\times1$ (and permutations) are elementary.

3.3. Exhaustive Enumeration

We now give an algorithm that finds an optimal partitioning by generating all possible elementary partitionings (γ_i), which satisfy the necessary optimality conditions given by Lemma 1, and determining which one yields the lowest cost partitioning. We also evaluate how many candidate partitions there are to give the complexity of our algorithm. For the complexity, we are not interested in the exact number of elementary partitionings, but in the order of magnitude, especially when the number of bins d is fixed (and small, equal to 3, 4, or 5), but when p can be large (up to 1000 for example), since this is the situation we expect to encounter in practice when computing multipartitionings.

The C program shown in Figure 2 generates, in linear time, all possible distributions of r_j instances of a factor α_j of p into d bins that satisfy the $(r_j + m_j)$ optimality condition of Lemma 1. This program is inspired by a program [16] for generating all partitions of a number, which is a well-studied problem (see [17]) since the mathematical work of Euler and Ramanujam. The procedure `Partitions` first selects the maximal multiplicity m of the factor under consideration that may appear in any bin, and uses the recursive procedure `P(n,m,c,t,d)` to generate all distributions of n elements in $(d - t + 1)$ bins (from index t to index d), where each bin can have at most m instances of the factor and at least c bins must have m instances of the factor. Therefore, the initial call is `P(r+m,m,2,1,d)`.

```
// Precondition: d >= 2
void Partitions(int r, int d) {
  int m;
  for (m = (r+d-2)/(d-1); m <= r; m++)
    P(r+m,m,2,1,d);
}

void P(int n, int m, int c, int t, int d) {
  int i;
  if (t==d)
    bin[t] = n;
  else {
    for (i=max(0,n-(d-t)*m);
              i<=min(m-1,n-c*m); i++) {
      bin[t] = i;
      P(n-i,m,c,t+1,d);
    }
    if (n>=m) {
      bin[t] = m;
      P(n-m,m,max(0,c-1),t+1,d);
    }
  }
}
```

Figure 2. Program for generating all possible distributions for one factor.

We now prove the correctness of the program. The procedure `P` selects a number of elements for the bin number t and makes a recursive call with parameter $t+1$ for the selection in the next bin. It is thus clear that all generated solutions are different since each iteration of the loop selects a different number of elements for the current bin. It remains to prove that all solutions generated by `P` are valid (the total number of elements should be $r+m$, each bin should have at most m elements, and there should be at least c bins with m elements), and that all solutions are generated. For that, we prove that `P(n,m,c,t,d)` is always called with parameters for which there exists at least one valid partitioning, that all possible numbers of elements are selected and only those.

Let us first consider the loop in function `Partitions`. Thanks to Lemma 1, it is easy to see that the maximal number of elements in a bin is between $\lceil \frac{r}{d-1} \rceil$ and r. Furthermore, for each such m, there is indeed at least one valid solution with $(r+m)$ elements and two maxima equal to m (if $d \geq 2$), for example the solution where the first two bins have m elements and the $(d-2)$ other bins contain a total of $(r-m)$ elements; for instance, the $r-m$ elements could be distributed so that $q = \lfloor \frac{r-m}{m} \rfloor$ bins contain m elements and one contains $(r-m-mq)$ elements. Thus, if the function `P` is correct, `Partitions` is also correct.

To prove the correctness of the function `P`, we prove by induction on $d-t+1$ (the number of bins) that there is at least one valid solution if and only if $c \leq d-t+1$ and $cm \leq n \leq (d-t+1)m$ and that `P` generates all of them if these conditions are satisfied. These conditions are simple to understand: we need at least cm elements (so that at least c bins have m elements) and at most $(d-t+1)m$ elements, otherwise at least one bin will contain more than m elements.

The terminal case is clear: if we have only one bin and n elements to distribute, the bin should contain n elements. Furthermore, if there is a solution, we should have $c \leq 1$ and $n = m$ if $c = 1$, i.e., $c \leq d-t+1$ and $cm \leq n \leq (d-t+1)m$.

The general case is more tricky. We first select the number of elements i in the bin number t and recursively call `P` for the remaining bins. If we select strictly less than m elements (this selection is in the loop), we will still have to select c bins with m elements for the remaining $(d-t)$ bins, with $(n-i)$ elements. Therefore, the number i that we select should not be too small, nor too large, and we should have $cm \leq n-i \leq (d-t)m$, i.e., $n-(d-t)m \leq i \leq n-cm$. Furthermore, i should be strictly less than m, nonnegative, and at most n. Since c is always positive, the constraint $i \leq n-cm$ ensures $i \leq n$. If the parameters are correct for the bin number t, we also have $c \leq d-t+1$ and if $c = d-t+1$, then the loop has no iteration, thus for an i selected in the loop, we have $c \leq d-t$. Therefore, the recursive call `P(n-i,m,c,t+1,d)` has correct parameters. Finally, if we select m elements for the bin t (after the loop), this is possible only if m is at most n of course, and then it remains to put $(n-m)$ elements into $(d-t)$ bins, with a maximum of m, and at least $\max(0, c-1)$ maxima. Again, the recursive call has correct parameters since we decreased both c and $(d-t)$ and removed m elements.

For generating all optimal solutions to our minimization problem, we first decompose p into prime factors (complexity $O(\sqrt{p})$ by a standard algorithm, but could be less), we then generate all elementary partitionings, which satisfy Lemma 1 for each factor, with the function `Partitions` and we combine them while keeping track of the best overall solution. The overall complexity (excluding the cost of the decomposition of p into prime factors) is the product of the complexity of the function `Partitions` (which is the number of solutions generated by the algorithm) times $(\log_2 p)^3$ (to built the γ_i's and evaluate them). We proved that the total number of generated solutions (i.e., the number of elementary partitionings) is $O\left(\left(\frac{d(d-1)}{2}\right)^{\frac{(1+o(1))\log p}{\log\log p}}\right)$

and that this bound is tight. (The proof is too long to be provided here but is available in the extended version of this paper [8].)

4. Finding the Mapping

In Section 3, we determined a particular way of cutting the array so as to optimize communications: after partitioning, we get an array (of tiles) whose size is (γ_i) for which the objective is minimized. Up to this point, we have assumed that we will be able to assign tiles to processors so that the assignment posesses the *balance* and *neighbor* properties of a multipartitioning. This has not yet been shown, and we need to prove it. We point out that an assignment with the *balance* property is a generalization of the notion of **latin square** that is known as as an **F-hyper-rectangle** [10, page 392]. However, despite this reference, we have not found any paper that gives a construction for such an assignment, or even an existence proof, for our general case. Furthermore, even if such a proof exists, which we are not aware of, our constructive proof is of interest because:

- its tile-to-processor mappings have the neighbor property,
- its tile-to-processor mappings are given by a simple formula, and conversely, for each processor, the list of tiles assigned to it can be easily formulated, which is handy for use in a run-time library,
- it gives a new insight to the properties of "modular" mappings (defined below).

Therefore, we make no further reference to latin squares and F-hyper-rectangles and proceed with a presentation of our proof.

The only property we know so far is that the (γ_i) is a valid partitioning, namely, for each i, p divides $\prod_{j\neq i}\gamma_j$. Our main result is that this condition is sufficient to guarantee a mapping of processors to tiles that possesses both the balance and neighbor properties. Our proof is constructive. For any valid partitioning (γ_i), optimal or not, with or without the additional property of Lemma 1, we give an automatic way to assign a processor number to each tile so that the properties are satisfied. This assignment is done through the use of modular mappings, defined below. The proof of our construction is much too long to be given here. We refer the reader to the extended version of this paper [8] for details of the proof and interesting properties of modular mappings.

The solution we build is one particular assignment, out of a set of legal mappings. It is not unique, and more experiments might show that they are not all equivalent in terms of execution time, for example because of communication patterns. But, currently, with our objective function (Section 3.1), the network topology is not taken into account yet and all valid mappings are considered equally good.

Consider the assignment in Figure 1. Can we give a formula that describes it? There are 16 processors that can be represented as a 2-dimensional grid of size 4×4. For example the processor number $7 = 4 + 3$ can be represented as the vector $(3, 1)$, in general (r, q) where r and q are the remainder and the quotient of the Euclidean division by 4. The assignment in the figure corresponds to $(i-k \bmod 4, j-k \bmod 4)$, which is what we call a **multi-dimensional modular mapping**, i.e., a mapping $M_{\vec{m}}$ from $\mathbb{Z}^d$ to $\mathbb{Z}^{d'}$ defined by an integral $d\times d'$ matrix M and an integral positive vector $\vec{m}$ of dimension d' with $M_{\vec{m}}(\vec{i}) = (M\vec{i}) \bmod \vec{m}$. With such a mapping, each tile is assigned to a "processor number" in the form of a vector. The product of the components of $\vec{m}$ is equal to the number of processors. It then remains to define a one-to-one mapping from the hyper-rectangle $\{\vec{j} \in \mathbb{Z}^{d'} \mid \vec{0} \leq \vec{j} < \vec{m}\}$ onto the processor numbers. This can be done by viewing the processors as a virtual grid of dimension d' of size $\vec{m}$. The mapping $M_{\vec{m}}$ is then an assignment of each tile (described by its coordinates in the d-dimensional array of tiles) to a processor (described by its coordinates in the d'-dimensional virtual grid). (Actually, we need only the case $d' = d - 1$.)

The following definitions summarize the notions of modular mappings and of modular mappings that satisfy the load-balancing property. Given $\vec{b} \in \mathbb{N}^n$, the **hyper-rectangle** defined by $\vec{b}$ is the set $\mathcal{I}_{\vec{b}} = \{\vec{i} \in \mathbb{Z}^n \mid \vec{0} \leq \vec{i} < \vec{b}\}$ (component-wise). A **slice** $\mathcal{I}_{\vec{b}}(i, k_i)$ of $\mathcal{I}_{\vec{b}}$ is defined as the set of all elements of $\mathcal{I}$ whose i-th component is equal to k_i (an integer between 0 and $b_i - 1$). Given a hyper-rectangle $\mathcal{I}_{\vec{b}}$ (or any more general set), a modular mapping $M_{\vec{m}}$ is **one-to-one from $\mathcal{I}_{\vec{b}}$ onto $\mathcal{I}_{\vec{m}}$** if and only if for each $\vec{j} \in \mathcal{I}_{\vec{m}}$ there is one and only one $\vec{i} \in \mathcal{I}_{\vec{b}}$ such that $M_{\vec{m}}(\vec{i}) = \vec{j}$. $M_{\vec{m}}$ is **equally-many-to-one from $\mathcal{I}_{\vec{b}}$ onto $\mathcal{I}_{\vec{m}}$** if and only if the number of $\vec{i} \in \mathcal{I}_{\vec{b}}$ such that $M_{\vec{m}}(\vec{i}) = \vec{j}$ does not depend on $\vec{j}$. Finally, $M_{\vec{m}}$ has the **load-balancing property** for $\mathcal{I}_{\vec{b}}$ if and only if for any slice $\mathcal{I}_{\vec{b}}(i, k_i)$, the restriction of $M_{\vec{m}}$ to $\mathcal{I}_{\vec{b}}(i, k_i)$ is equally-many-to-one onto $\mathcal{I}_{\vec{m}}$.

Because a modular mapping is linear, it is easy to see that the load-balancing property needs to be checked only for the slices that contain $\vec{0}$ (the slices $\mathcal{I}_{\vec{b}}(i, 0)$). Furthermore, if $\vec{b}[i]$ denotes the vector obtained from $\vec{b}$ by removing the i-th component and $M[i]$ denotes the

matrix obtained from M by removing the i-th column, then the images of $\mathcal{I}_{\vec{b}}(i,0)$ under $M_{\vec{m}}$ are the images of $\mathcal{I}_{\vec{b}[i]}$ under the modular mapping $M[i]_{\vec{m}}$. We therefore have the following properties.

Lemma 2 *Given an hyper-rectangle $\mathcal{I}_{\vec{b}}$, a modular mapping $M_{\vec{m}}$ has the load-balancing property for $\mathcal{I}_{\vec{b}}$ if and only if each mapping $M[i]_{\vec{m}}$ is equally-many-to-one from $\mathcal{I}_{\vec{b}[i]}$ to $\mathcal{I}_{\vec{m}}$.*

Lemma 3 *If $M_{\vec{m}}$ is a one-to-one modular mapping from $\mathcal{I}_{\vec{b}'}$ onto $\mathcal{I}_{\vec{m}}$, then $M_{\vec{m}}$ is an equally-many-to-one modular mapping from any multiple $\mathcal{I}_{\vec{b}}$ of $\mathcal{I}_{\vec{b}'}$ onto $\mathcal{I}_{\vec{m}}$.*

Lemmas 2 and 3 explain why we focus on one-to-one modular mappings first, then on equally-many-to-one modular mappings, and finally on modular mappings with the load-balancing property. In the extended version of this paper [8], we explore the properties of such modular mappings, in order to define a provably adequate matrix M and shape $\vec{m}$ for the virtual grid of processors. Our results are linked to previous works on one-to-one modular mappings by Lee and Fortes [14] and Darte, Dion, and Robert [7]. As in [7], the theory we developed is linked to a famous (in covering/packing theory) theorem due to Hajós [12], which has previously been used to generate "juggling schedules" for systolic-like array designs (see [9]). These earlier papers all consider "one-to-one"-like problems; however, many questions remain open in the equally-many-to-one case because the extension of Hajós' theorem to a similar "equally-many-to-one" case is true only up through 3 dimensions. Also, while it is easy to build a one-to-one mapping (just take $\vec{m} = \vec{b}$ and the identity matrix), here we need a more constrained matrix such that any submatrix obtained by removing one column is equally-many-to-one for the corresponding $\vec{b}$ and $\vec{m}$. In other words, to use the terminology in [9], we need to juggle simultaneously in all dimensions.

Here we present our construction of a modular mapping $M_{\vec{m}}$ with the load-balancing property for an index set $\mathcal{I}_{\vec{b}}$ (which is given, $\vec{b}$ is the vector whose components are the γ_i's found in Section 3.3). The freedom we have is that we can choose the matrix M and the modulo vector $\vec{m}$, but with the constraint that the cardinality of $\mathcal{I}_{\vec{m}}$ (the product of the components of $\vec{m}$) is also given (equal to the number of processors p). The only property of $\vec{b}$ we exploit is that $\vec{b}$ is a valid partitioning: the product of any $(d-1)$ components of $\vec{b}$ is a multiple of p. We choose the matrix M with the following form:

$$M = \begin{pmatrix} N & 0 \\ \vec{\lambda} & 1 \end{pmatrix}$$

where N will be computed by induction. Therefore, finally, M will be even triangular, with 1's on the diagonal. We have the following preliminary result.

Lemma 4 *Suppose that m_d divides b_d and that the modular mapping $N_{\vec{m}[d]}$ – in dimension $(d-1)$ – has the load-balancing property for $I_{\vec{b}[d]}$. Then, the modular mapping $M_{\vec{m}}$ – in dimension d – has the load-balancing property for $\mathcal{I}_{\vec{b}}$ if it is equally-many-to-one from the last slice $\mathcal{I}_{\vec{b}}(d,0)$ onto $\mathcal{I}_{\vec{m}}$.*

Proof: In order to check that the mapping defined by M and $\vec{m}$ has the load-balancing property for the rectangular index set $\mathcal{I}_{\vec{b}}$, we have to make sure that it is equally-many-to-one for all slices $\mathcal{I}_{\vec{b}}(i,0)$, $1 \leq i \leq d$ (Lemma 2). Since we assume that this is true for $i = d$, we only have to prove it for the slices $\mathcal{I}_{\vec{b}}(i,0)$ with $i < d$.

Without loss of generality, let us consider the first dimension, i.e., the first slice $\mathcal{I}_{\vec{b}}(1,0)$. Given $\vec{j} \in \mathcal{I}_{\vec{m}}$, let us count the number of vectors $\vec{i} \in \mathcal{I}_{\vec{b}}$ such that $M\vec{i} = \vec{j} \bmod \vec{m}$ and $i_1 = 0$. By definition of M and N, $(M\vec{i} = \vec{j} \bmod \vec{m}) \Leftrightarrow (N\vec{i}[d] = \vec{j}[d] \bmod \vec{m}[d]$ and $\vec{\lambda}.\vec{i}[d] + i_d = j_d \bmod m_d)$ where $\vec{\lambda}$ is the row vector formed by the first $(d-1)$ component of the last row of M. Because $N_{\vec{m}[d]}$ has the load-balancing property for $\mathcal{I}_{\vec{b}[d]}$, there are exactly n vectors $\vec{i}' \in \mathcal{I}_{\vec{b}[d]}$ such that $i'_1 = 0$ and $N\vec{i}' = \vec{j}[d] \bmod \vec{m}[d]$, where n is a positive integer that does not depend on $\vec{j}[d]$. It remains to count the number of values i_d, between 0 and $b_d - 1$, such that $i_d = j_d - \vec{\lambda}.\vec{i}' \bmod m_d$. Since m_d divides b_d, there are exactly b_d/m_d such values, whatever the value $x = (j_d - \vec{\lambda}.\vec{i}' \bmod m_d)$. These are the values $x + km_d$, with $0 \leq k < b_d/m_d$. Therefore, $\vec{j}$ has exactly $(nb_d)/m_d$ pre-images in $\mathcal{I}_{\vec{b}}(1,0)$ and this number does not depend on $\vec{j}$. ■

We define the vector $\vec{m}$ according to the following formula:

$$\forall i,\ 1 \leq i \leq d,\ m_i = \frac{\gcd\left(p, \prod_{j=i}^{d} b_j\right)}{\gcd\left(p, \prod_{j=i+1}^{d} b_j\right)}$$

(By convention, an "empty" product is equal to 1.) Thanks to the previous lemma and the properties of the vector $\vec{m}$ defined this way, we will be able to build M in a recursive manner (see [8]). Because $m_1 = 1$, we will be able to drop, at the end, the first component of the mapping and get a mapping from $\mathbb{Z}^d$ into a subgroup of $\mathbb{Z}^{d-1}$ (or of smaller dimension if some other components of $\vec{m}$ are equal to 1). Once N is built, we write:

$$M = \begin{pmatrix} N & 0 \\ \vec{\lambda} & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ \vec{u} & T & 0 \\ \rho & \vec{z} & 1 \end{pmatrix}$$

```
// Precondition: d >= 2
void ModularMapping(int d) {
  int i,j,r,t;
  for (i=1; i<=d; i++)
    for (j=1; j<=d; j++)
      if ((j==1) || (i==j)) M[i][j] = 1;
      else M[i][j] = 0;

  for (i=2; i<=d; i++) {
    r = m[i];
    for (j=i-1; j>=2; j--) {
      t = r/gcd(r, b[j]);
      for (k=1; k<=i-1; k++) {
        M[i][k] -= t*M[j][k];
      }
      r = gcd(t*m[j],r);
    }
  }
}
```

Figure 3. Program for generating a mapping with the load-balancing property.

and we define ρ and $\vec{z}$ (a row vector) such that $\vec{z} = -\vec{t}T$ and $\rho = 1 - \vec{t}\vec{u}$, where the row vector $\vec{t}$, with $(d-2)$ components, is defined by the following (decreasing) recurrence (with the help of an intermediate vector $\vec{r}$):

- $r_{d-1} = m_d$,
- for $1 \leq i \leq d-2$, $t_i = \frac{r_{i+1}}{\gcd(b_{i+1}, r_{i+1})}$ and $r_i = \gcd(t_i m_{i+1}, r_{i+1})$.

This recurrence is linked to the *symbolic* computation of some **Hermite form** that we use to be able to apply Lemma 4 and prove the validity of the recursive construction. See details in [8].

This schema is implemented by the C program shown in Figure 3 (rows and columns are from 1 to d). In our actual implementation of this algorithm, we augment the basic kernel presented to compute the final matrix modulo the corresponding values of $\vec{m}$ as well as apply some strategies (*e.g.,* alternating signs of $\vec{t}$, or pre-permuting the components of $\vec{b}$) to make coefficients smaller.

5. Experiments

We extended the Rice dHPF compiler for High Performance Fortran to generate code based on generalized multipartitionings.

Multipartitioning within the dHPF compiler is implemented as a generalization of `BLOCK`-style HPF partitionings [5, 6]. The dHPF compiler analyzes communication and reduces loop bounds as if a multipartitioned template is a standard `BLOCK` partitioned template mapped onto an array of processors of symbolic extent. The main difference comes in the interpretation that the compiler gives to the `PROCESSORS` directive. When using multipartitioning, the number of processors cannot be specified on a per dimension basis for dimensions of the template because each hyperplane defined by a partitioning along a multipartitioned template dimension is distributed among all processors. A multipartitioned template is partitioned into tiles according to the rank and extent of the virtual processor array. These tiles are then assigned in a skewed-cyclic fashion to the processors as described in previous sections.

There are several important issues for correctly generating efficient code for multipartitioned distributions. First, the order in which a processor's tiles are enumerated has to satisfy any loop-carried dependences present in the original loop from which the multipartitioned loop has been generated. Second, communication that has been fully vectorized out of a loop nest should not be performed on a tile-by-tile basis; instead it should be performed for all of a processor's tiles at once. Communication aggregation is more tricky than for diagonal multipartitionings since generalized multipartitionings have multiple tiles per hyperrectangular slab, but it is possible because generalized multipartitionings also possess the *neighbor* property described earlier in Section 1. Third, communication caused by loop-carried dependences should not be performed on a tile-by-tile basis either. Instead, communication should be vectorized for all tiles within a hyperrectangular slab along the partitioned dimension.

By using a multipartitioned data distribution in conjunction with sophisticated data-parallel compiler optimizations, we are closing the performance gap between compiler-generated and hand-coded implementations of line-sweep computations. Earlier results and details about dHPF's compilation techniques can be found elsewhere [6, 5, 1, 2]. Here we present results from applying generalized multipartitioning in the context of a compiler-based parallelization of the NAS SP computational fluid dynamics application benchmark [3, 6] for the "class B" problem size of 102^3.

The most important analysis and code generation techniques used to obtain high-performance multipartitioned applications by the dHPF compiler are: partial replication of computation to reduce communication frequency and volume, communication vectorization, aggressive communication placement, and communication aggregation to reduce the number of mes-

sages. In addition, we use an extended on-home directive (inspired by the HPF/JA `EXT_HOME` directive[11]) to partially replicate computation into a processor's shadow regions, and the HPF/JA `LOCAL` directive to eliminate unnecessary communication for values that were previously explicitly computed in a processor's shadow region.

We performed these experiments on a SGI Origin 2000 with 128 250MHz R10000 CPUs, each CPU has 32KB of L1 instruction cache, 32KB of L1 data cache and an unified, two-way set associative L2 cache of 4MB.

Table 1 compares the performance of a hand-coded MPI version of the SP benchmark developed at NASA Ames Research Center with an MPI version generated by the dHPF compiler.[2] The hand-coded version uses 3D diagonal multipartitioning and thus can only be run on a perfect square number of processors. The dHPF-generated code MPI uses generalized multipartitioning which enables the code to be run on arbitrary numbers of processors. As Table 1 shows, the performance of the dHPF-generated code is quite close to (and sometimes exceeds) the performance of the hand-coded MPI for numbers of processors that are perfect squares. When the number of processors is a perfect square, the generalized multipartitionings used by the dHPF-generated code are exactly diagonal multipartitionings. These measurements show that our implementation of generalized multipartitionings is efficient in the case of diagonal multipartitionings, in which each processor has one tile per hyperplane of the partitioning. Both the hand-coded and dHPF-generated versions of SP deliver roughly linear speedup on numbers of processors that are perfect squares.

In the measurements taken of the dHPF-generated code for numbers of processors that are not perfect squares, we see that generalized multipartitionings deliver near linear speedup in these cases as well. The cases we have measured exploiting generalized multipartitioning are ones in which the factors of the number of processors are small primes. Performance would be less for numbers of processors that are prime or have large prime factors because computation would be divided into a large number of phases and communication volume grows in proportion to the number of phases. Currently, the code generated by dHPF cannot exploit generalized multipartitionings when the block size on any processor falls below the shift width associated with communication operations, which happens when a dimension is partitioned many times (as occurs with large primes and prime factors). This limitation prevents experiments with generalized multipartitionings using the 102^3 problem size of the SP benchmark on numbers of processors that are large primes or have large prime factors.[3]

Overall, these preliminary experiments show that generalized multipartitionings are of practical as well as theoretical interest and can be used to efficiently parallelize applications using multipartitioning in a wider range of cases.

6. Conclusions

This paper describes an algorithm for computing an optimal multipartitioning of d-dimensional arrays, $d > 2$, onto an arbitrary number of processors, p. Our algorithm minimizes cost according to an objective function that measures communication in line sweep computations. Previously, optimal multipartitionings could be computed only when $p^{\frac{1}{d-1}}$ is integral. We show that a partitioning in which the number of tiles in each hyperrectangular slab is a multiple of the num-

[2] All speedups presented are relative to the original sequential version of the code.

[3] To be perfectly clear, this limitation applies only to code generated by the dHPF compiler; the *technique* of generalized multipartitioning itself is completely general.

ber of processors — an obvious necessary condition — is also a sufficient condition for a multipartitioned mapping of tiles to processors. We present a constructive method for building the mapping of tiles to processors using new techniques based on modular mappings and demonstrate experimentally that code using generalized multipartitionings is both scalable and efficient.

Currently, when we multipartition a d-dimensional array onto p processors, we force *all* processors to participate in the computation; however, this may lead to suboptimal performance. If the partitioning is not **compact**, *i.e.*, the number of tiles per processor is large relative to a diagonal multipartitioning (more precisely, when $\prod_{i=1}^{d} \gamma_i$ is large compared to $p^{\frac{d}{d-1}}$), and the cost of communicating at tile boundaries is not small compared to the cost of the computation on tile data (the relative cost of communication to computation is proportional to the surface to volume ratio in the partitioning: $\sum_{i=1,d} \frac{\gamma_i}{\eta_i}$), it will be faster to drop back to a nearby lower number of processors for which a compact partitioning exists. For example, table 1 shows that for the 102^3 problem size, a $5 \times 10 \times 10$ decomposition on 50 processors is slower than a $7 \times 7 \times 7$ decomposition on 49 processors for NAS SP. Given a cost function (see Section 3.1) that models the cost of computation as well as communication, our algorithm could be used to search for the most efficient partitioning, which will occur on some number of processors between $\lfloor p^{\frac{1}{d-1}} \rfloor^{d-1}$ (for which a diagonal multipartitioning is possible) and p as long as the communication term is not dominant.

In this paper we consider two classes of lattice paths on the plane which use *north*, *east*, *south*, and *west* unitary steps, beginning and ending at $(0,0)$. We enumerate them according to the number of steps by means of bijective arguments; in particular, we apply the cycle lemma. Then, using these results, we provide a bijective proof for the number of directed-convex polyominoes having a fixed number of rows and columns.

Keywords: cycle lemma, directed-convex polyominoes, binomial coefficients, lattice paths.

1 Introduction

In the plane $Z \times Z$ the following four types of steps are taken into consideration: *north* steps, $(0,1)$, *east* steps, $(1,0)$, *south* steps, $(0,-1)$, and *west* steps, $(-1,0)$. Let $\mathcal{C}$ denote the set of all lattice paths which use north, east, south, and west steps, beginning and ending at $(0,0)$ (see Fig. 1 on page 2). Each path belonging to $\mathcal{C}$ has an even number of steps; for $n \geq 0$, let $\mathcal{C}_{2n}$ denote the set of paths in $\mathcal{C}$ having $2n$ steps. In this paper we will give a bijective proof that the cardinality of $\mathcal{C}_{2n}$ equals, for $n \geq 0$,

$$\binom{2n}{n}^2. \tag{1}$$

Let $\mathcal{C}^+$ ($\mathcal{C}^+_{2n}$, resp.) denote the subset of $\mathcal{C}$ ($\mathcal{C}_{2n}$, resp.) whose paths remain weakly above the x-axis (see Fig. 2 on page 2). The path set $\mathcal{C}^+$ was originally studied in [2], where the authors proved, for $n \geq 0$,

$$\left|\mathcal{C}^+_{2n}\right| = \binom{2n}{n}^2 - \binom{2n}{n+1}^2. \tag{2}$$

This result has been considered further by Guy, Krattenthaler, and Sagan in [8] and by Sulanke in [13].

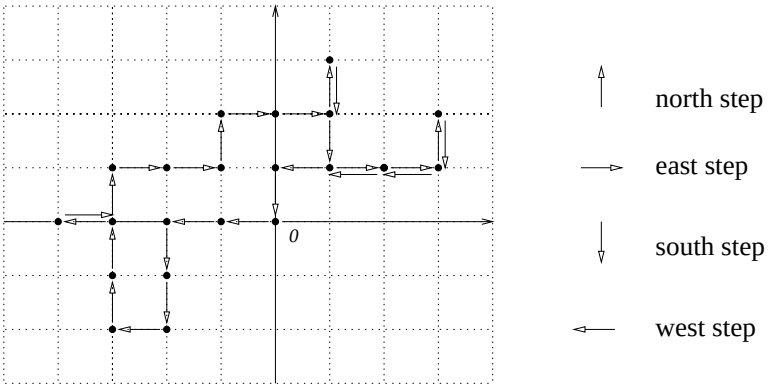

Fig. 1: A $\mathcal{C}$ path with 26 steps.

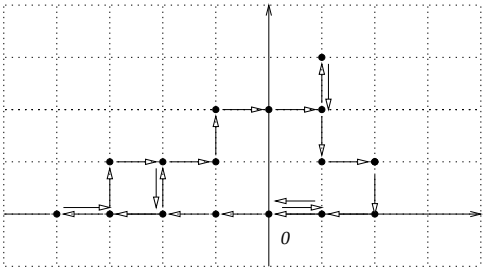

Fig. 2: A $\mathcal{C}^+$ path with 22 steps.

We prove this statement bijectively by applying the well-known cycle lemma, originally introduced in [6], and then rediscovered and applied many times as in [5] and [10]. In particular our proof first shows

$$\left|\mathcal{C}^+_{2n}\right| = \frac{2n+1}{(n+1)^2}\left|\mathcal{C}_{2n}\right| = \frac{1}{2n+1}\binom{2n+1}{n}^2, \qquad n \geq 0. \tag{3}$$

It is then straightforward to show that the formulas of (2) and (3) agree.

In the last part of the paper we consider the class of directed-convex polyominoes and the class of parallelogram polyominoes, each having $n+1$ columns and $n+1$ rows. Narayana [9] was the first to show, in essence, that the number of parallelogram polyominoes having $n+1$ columns and $n+1$ rows is equal to the number in (2). Chang and Lin [3], and later Bousquet-Mélou [1, p.111], proved that the number of directed-convex polyominoes having $n+1$ columns and $n+1$ rows is equal to the number in (1). In this paper we give a combinatorial proof of the previous statements by establishing bijections defined on the classes $\mathcal{C}^+$ and $\mathcal{C}$.

2 About cycles of 2-colored Motzkin paths

The 2-colored Grand Motzkin paths are lattice paths that begin and end on the *x*-axis and use the *rise step*, $(1,1)$, the *fall step*, $(1,-1)$, and of two types of *horizontal steps*, $(1,0)$, namely the α-*colored* and β-*colored* horizontal steps. It is easy to show that the cardinality of the set of 2-colored Grand Motzkin paths running from $(0,0)$ to $(n,0)$ is the central binomial coefficient, $\binom{2n}{n}$. The 2-colored Motzkin paths are Grand Motzkin paths that remain weakly above the *x*-axis. The number of 2-colored Motzkin paths of length *n* is well known to equal the $(n+1)$th *Catalan number*, [12, p.219].

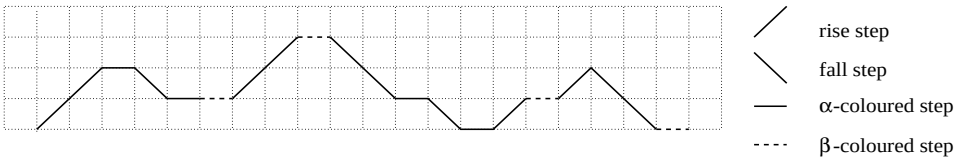

Fig. 3: A 2-colored Motzkin path with 20 steps.

We will call a 2-colored Grand Motzkin path having the same number of α and β steps, *a cycle*. This name is suggested by the simple bijection between $\mathcal{C}_{2n}$ and the set of Grand Motzkin paths having length $2n$ that is achieved by the following coding:

Fig. 4: The step transformation of paths of $\mathcal{C}_{2n}$ into cycles of length $2n$.

For example, the cycle represented in Figure 5 corresponds to the path of Fig. 1 on page 2.

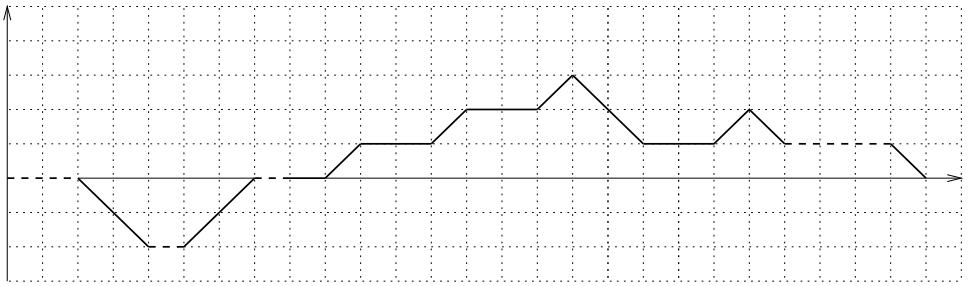

Fig. 5: A cycle having length 26.

Lemma 1 *The number of* $2n$*-length cycles is equal to the central binomial coefficients squared,*

$$\binom{2n}{n}^2. \tag{4}$$

Proof. To prove our claim, we will establish a correspondence between the cycles of length $2n$ and Grand Dyck paths of length $4n$ decomposable as pairs of Grand Dyck paths of length $2n$. Let us consider a cycle of length $2n$. We code each step of this cycle with a vector 2×1:

$$\begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad \text{for a rise step,} \qquad \begin{pmatrix} 0 \\ 1 \end{pmatrix} \quad \text{for a fall step,}$$

$$\begin{pmatrix} 1 \\ 1 \end{pmatrix} \quad \text{for an } \alpha\text{-horizontal step,} \qquad \begin{pmatrix} 0 \\ 0 \end{pmatrix} \quad \text{for a } \beta\text{-horizontal step.}$$

Therefore, we can represent the cycle by a $2 \times n$ matrix simply by concatenating the n vectors corresponding to its steps. For example, the cycle of Fig. 5 on page 3 can be represented by the matrix:

$$\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 & 1 & 0 & 1 & 0 & 0 & 0 & 1 \end{pmatrix}.$$

Moreover, if we code a rise step by 1 and a fall step by 0, then each row of the matrix is a Grand Dyck path. The concatenation of these two paths gives a Grand Dyck path of length $4n$. The previously defined transformation can be simply inverted. □

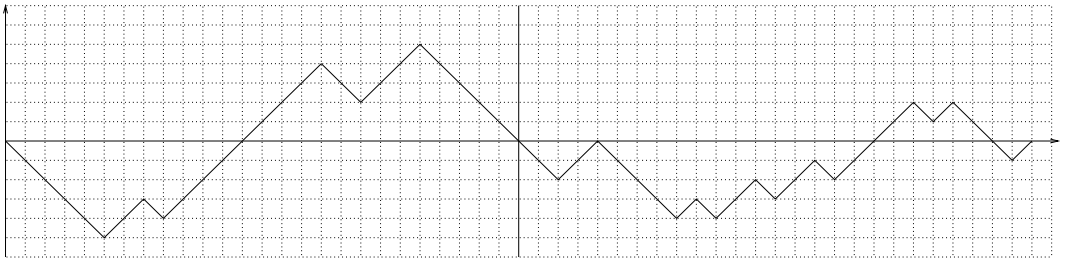

Fig. 6: The Grand Dyck path corresponding to the cycle of Fig. 5 on page 3.

Let us now examine the set of *positive cycles*, that is, the set of cycles that remain weakly above the x-axis. The coding of Fig. 4 ensures us that each path of $\mathcal{C}^+_{2n}$ corresponds to a positive cycle of length $2n$. For example the path in Fig. 2 on page 2 corresponds to that in Fig. 7.
We now combinatorially prove that the number of positive cycles with $2n$ steps is equal to

$$\left|\mathcal{C}^+_{2n}\right| = \frac{2n+1}{(n+1)^2}\left|\mathcal{C}_{2n}\right| = \frac{1}{2n+1}\binom{2n+1}{n}^2, \qquad n \geq 0. \tag{5}$$

(We leave the simple analytical proof of (5) to the reader.) Let X_{2n+1}, $n \geq 0$ denote the class of paths using the same steps as the 2-colored Motzkin paths, having the same number of α-colored and β-colored steps,

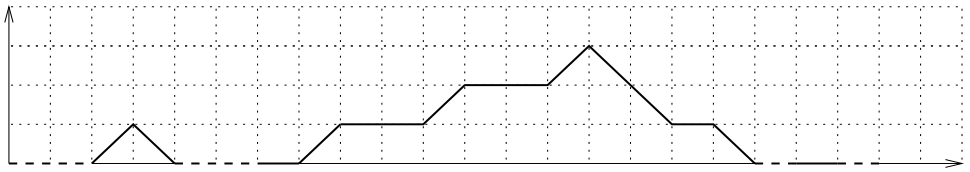

Fig. 7: The positive cycle corresponding to the path in Fig. 2 on page 2.

and running from $(0,0)$ to $(2n+1,1)$. For any path in this class, the number of rise steps exceeds the number of fall steps by one unit. The same arguments used to prove Lemma 1 will convince the reader that

$$|X_{2n+1}| = \binom{2n+1}{n}^2. \tag{6}$$

To have the desired proof of (5) it is sufficient to show

$$|X_{2n+1}| = (2n+1)\left|\mathcal{C}^{+}_{2n}\right|. \tag{7}$$

The proof of (7) will be neat application of the *cycle lemma*, as recorded in [7]:

Lemma 2 *If $< x_1, x_2 \ldots, x_m >$ is any sequence of integers whose sum is* 1*, then exactly one of the cyclic shifts $< x_1, x_2 \ldots, x_m >$, $< x_2 \ldots, x_m, x_1 >$ $\ldots$ $< x_m, x_1 \ldots, x_{m-1} >$ has all of its partial sums positive.*

In the sequel we will also represent the paths of X_{2n+1}, as $(2n+1)$-vectors, obtained by encoding each rise step with 1, each fall step by -1, each α-colored horizontal step with 2, and each β-colored horizontal step with -2. For an arbitrary path $P \in X_{2n+1}$, let $v(P)$ denote its vectorial representation.
Since there are $\binom{2n+1}{n}^2$ paths of X_{2n+1}, Lemma 2 implies that exactly $1/(2n+1)$ of these paths have a vectorial representation with all partial sums positive (see Fig. 8 on page 6). Let J_{2n+1} denote the set of those paths. We next establish a direct bijection between the positive cycles of length $2n$ and paths of J_{2n+1}, thus obtaining (7).

Let P be a positive cycle of length $2n$. Moreover, let A be the rightmost point belonging to P such that the partial sums of the vector $v(P)$ assume the lowest value, say a, $-a \leq 0$. Then P can be decomposed in two sub-paths, L and R, on the left and on the right of A, respectively (see Fig. 9 on page 7). It should be clear that the vector $v(R)$ has all partial sums positive. We consider the new path P' formed by transposing the paths L and R, and adding a rise step between them. We will prove that $P' \in J_{2n+1}$, that is, the vector $v(P')$ has all partial sums positive. Let $v(L)$ and $v(R)$ be the vectors encoding L and R respectively. Surely, the sum of the integers of $v(P')$ is equal to 1. Suppose that there is a prefix q of $v(P')$ such that q's sum is equal to 0. For the previous considerations q must contain strictly $v(R)$, thus $q = (r_1, \ldots, r_k, 1, s_1, \ldots, s_h)$, $r_i, s_i \in \{0,1\}$, $v(R) = (r_1, \ldots, r_k)$, and $h \geq 1$. Therefore, since $r_1 + \ldots + r_k = a > 0$ ($a = 0$ if and only if $v(R)$ is empty), we must have $1 + s_1 + \ldots + s_h = -a$, and then $s_1 + \ldots + s_h = -a - 1$. Finally, the vector $s = (s_1, \ldots, s_h)$ represents a prefix S of L, such that $v(S) = -a - 1$, contradicting our initial hypothesis. Then $P' \in J_{2n+1}$.

The previously defined bijection can be easily inverted as follows: given a path P' in J_{2n+1}, let B be P' rightmost point having the lowest ordinate. The point B divides P' in two sub-paths, U and V, on the left and on the right of B, respectively. Let V' be the path obtained from V by deleting the initial rise step, and

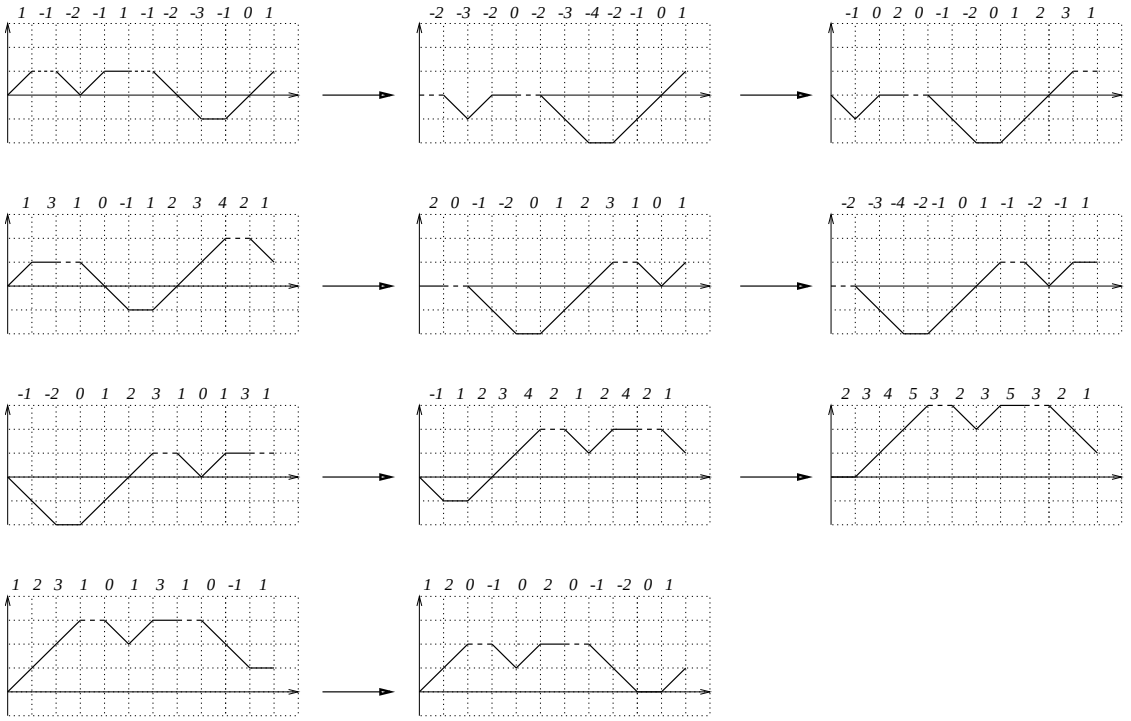

Fig. 8: The cyclic shifts of a path in X_{2n+1} and the the partial sums of the corresponding vectors.

P the path obtained by transposing the paths U and V'; namely, $P = V'U$. Clearly, P is a positive cycle. Figure 10 on page 7 shows the bijection between the 3 positive cycles of length 2 and the 3 paths of J_3.

3 Bijective results on directed-convex polyominoes

A *polyomino* is a finite union of elementary cells of the lattice $Z \times Z$, whose interior is connected. Most of them can be defined by combining two notions: *convexity* and *directed growth*. A polyomino is said to be *vertically convex* when its intersection with any vertical line is convex. We can define similarly a notion of *horizontal convexity*. A polyomino is *convex* if it is both vertically and horizontally convex. A polyomino P is said to be *directed* when every cell of P can be reached from a distinguished cell, called the root, by a path which is contained in P and uses only north and east unitary steps. A polyomino is *directed-convex* if it is both directed and convex (see Fig. 11 (a) on page 8).

A *parallelogram polyomino* is a polyomino whose boundary consists of two lattice paths that intersect only initially and finally. The boundary paths, which we call upper and lower path, use the positively directed unit steps, $(1,0)$ and $(0,1)$ (see Fig. 11, (b) on page 8). Chang and Lin [3], and later Bousquet-Mélou [1, p.111] used analytic methods to prove that the number of directed-convex polyominoes and the number of parallelogram polyominoes having q rows and p columns are equal to, respectively,

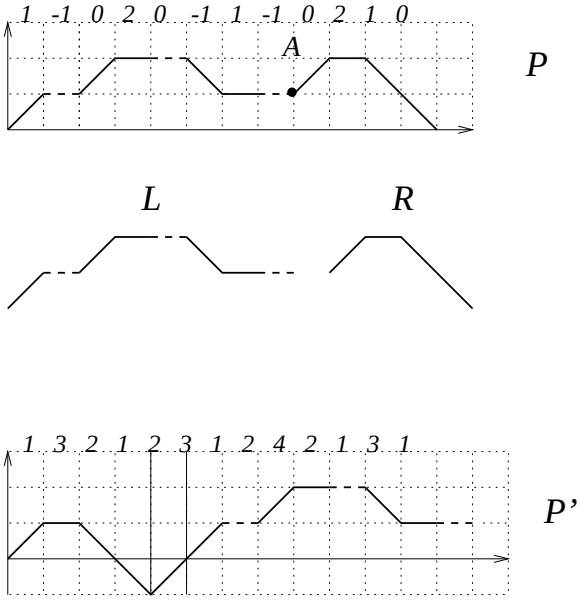

Fig. 9: A positive cycle and the corresponding path of J_{2n+1}.

$$\binom{p+q-2}{p-1}\binom{p+q-2}{q-1} \tag{8}$$

$$\frac{1}{p+q-1}\binom{p+q-1}{p-1}\binom{p+q-1}{q-1}. \tag{9}$$

(The second formula is originally due to Narayana, [9].) In particular, for polyominoes having $n+1$ rows and $n+1$ columns, these formulas reduce to

$$\binom{2n}{n}^2 \tag{10}$$

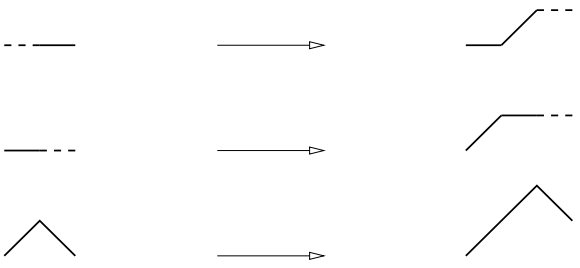

Fig. 10: The bijection between the positive cycles of length 2 and J_3.

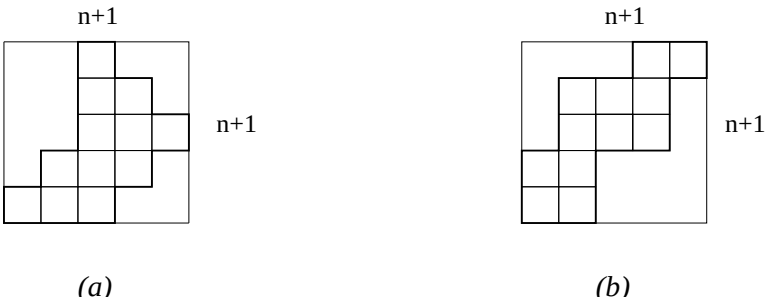

Fig. 11: (a) A directed convex polyomino; (b) a parallelogram polyomino.

$$\frac{1}{2n+1}\binom{2n+1}{n}^2, \tag{11}$$

respectively, that is the numbers in (1), and (2). Let us denote by $\mathcal{DC}_n$ the class of directed-convex polyominoes having n rows and n columns and by $\mathcal{PP}_n$ the class of parallelogram polyominoes having n rows and n columns. We will reprove (10) this time by simply establishing a bijection between the class $\mathcal{DC}_{n+1}$ and $2n$-length cycles. Similarly, we will reprove (11) by establishing a bijection from $\mathcal{PP}_{n+1}$ to the class of positive cycles of length $2n$. For this purpose, we define an auxiliary class H_n of prefixes of positive cycles, having length $2n$, having an equal number of α and β-colored horizontal steps, and having a final point with an even ordinate, say $2h$, $h \geq 0$.

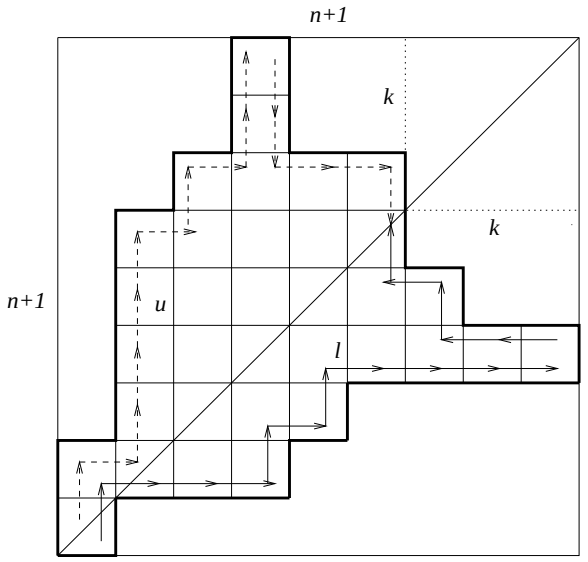

Fig. 12: A directed convex polyomino and its boundary paths.

The bijection between $\mathcal{DC}_{n+1}$ and H_n. Consider a polyomino $P \in \mathcal{DC}_{n+1}$. Let (k,k) denote the rightmost point on P on the diagonal running from $(0,0)$ to $(n+1,n+1)$. We remark that each polyomino P is uniquely determined by its boundary paths, the upper, say u, and the lower, say l, running from $(0,0)$ to (k,k) (see Fig. 12), each path consisting in $2n$ unit steps belonging to $\{(1,0),(0,1),(-1,0),(0,-1)\}$. Moreover, by considering the scheme of Fig. 12 on page 8, one can see that each boundary path can be represented by means of a binary array of $2n$-elements where 0 represents the steps $(1,0)$ and $(-1,0)$ and 1 the steps $(0,1)$ and $(0,-1)$. It follows that the polyomino P can be represented by a $2 \times n$ binary matrix, where the first row corresponds to the upper boundary path and the second corresponds to the lower one. For example, the polyomino of Fig. 12 on page 8 can be represented by the matrix:

$$\begin{pmatrix} 1 & 0 & 1 & 1 & 1 & 1 & 0 & 1 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 \end{pmatrix}.$$

We wish to point out two properties of the upper and lower paths, u and l:

1. for every prefix s of u and every prefix v of l, having the same length, we have $|s|_1 \geq |v|_1$, with $|j|_1$ defined as the number of occurrences of 1 in j;
2. $|u|_1 - |l|_1 = 2k$.

Besides, the matrix can be viewed as an array of n vectors 2×1. Then, it is possible to represent it as path P' belonging to H_n, and whose final point ordinate is equal to $2k$, by means of the coding defined for the cycles in the proof of Lemma 1. For example, Figure 13 represents the H_n path corresponding to the polyomino in Fig. 12 on page 8.

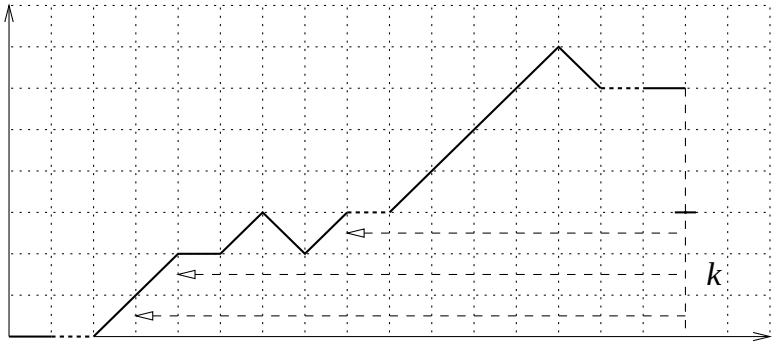

Fig. 13: The H_n path corresponding to the polyomino in Fig. 12 on page 8.

It should be clear that this mapping from directed-convex polyominoes having $n+1$ rows and $n+1$ columns to the paths of H_n can be easily inverted. In the special case that P is a parallelogram polyomino we have $|u|_1 - |l|_1 = 0$; that is, we have the desired correspondence between parallelogram polyominoes and positive cycles (see Fig. 14 on page 10). We wish to point out that the last bijection is a special case of a classical bijection between parallelogram polyominoes of perimeter $2n+4$ and 2-colored Motzkin paths of length $2n$ [4].

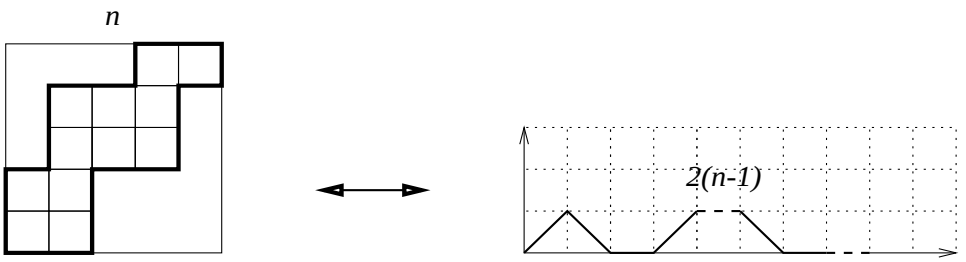

Fig. 14: A particular case of the bijection is the restriction to parallelogram polyominoes and positive cycles.

The bijection between H_n and $2n$-length cycles. Let P' be a path in H_n and let $2k$, $k \geq 0$, be its final point ordinate. If $k = 0$, then P' is a positive cycle. Otherwise, for every $i = 0, \ldots, k-1$ we consider the vertical side of unitary length $(2n, i), (2n, i+1)$. We then draw a horizontal ray to the left from the center of this side. There are k such rays. Each ray hits for the first time a rise step in P'. We modify P' by

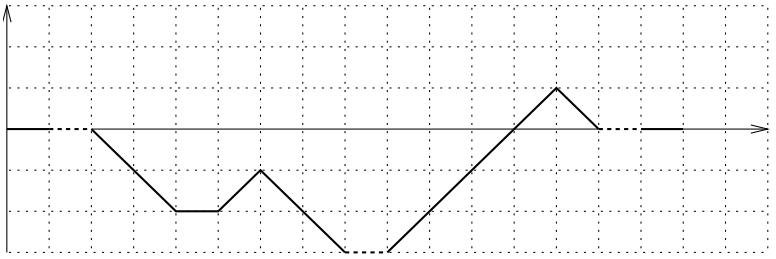

Fig. 15: The cycle corresponding to the H_n path in Figure 14.

changing the steps that are hit to fall steps. In this modified path the number of rise step is trivially equal to the number of fall steps, thus we have obtained the desired cycle (see Fig. 15 on page 10).

This mapping is inverted as follows (see Fig. 16 on page 11). Let Q be a $2n$-length cycle and let $-h$, $h > 0$ be the ordinate of the lowest point of Q. From each of the points $(0, -\frac{1}{2})$, $(0, -1-\frac{1}{2})$, …, $(0, -h+1-\frac{1}{2})$, we draw a ray to the right until it hits Q, necessarily at a fall step. Let Q' be the path obtained from Q in which each hit step is changed to a fall step. The path $Q' \in H_n$, and its final point ordinate is equal to $2h$.

4 Conclusions

In this paper we essentially described:

1. the correspondence among the class of lattice paths using north, south, east, and west steps, beginning and ending at $(0,0)$; the class of 2-colored Motzkin paths having the same number of α and β-colored steps; and the class of directed-convex polyominoes having the same number of rows and columns. That correspondence leads to a combinatorial interpretation of the numbers in (1);

2. the correspondence among the class of lattice paths using north, south, east, and west steps, beginning and ending at $(0,0)$ remaining weakly above the x-axis; the class of 2-colored Motzkin paths

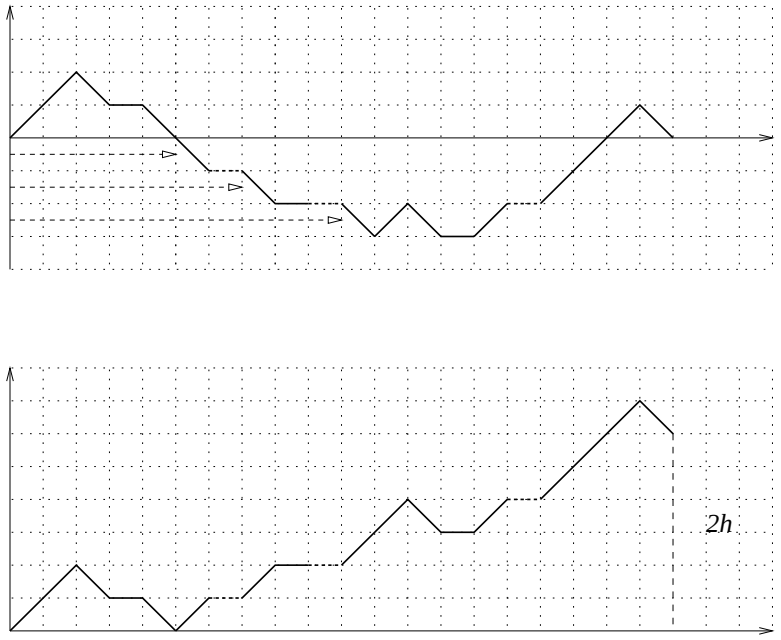

Fig. 16: From a $2n$-length cycle to a H_n path.

having the same number of α and β-colored steps, remaining weakly above the x-axis; and the class of parallelogram polyominoes having the same number of rows and columns. That correspondence leads to a combinatorial interpretation of the numbers in (3).

We observe that it is possible to generalize the correspondences 1. and 2. to

1. the class of lattice paths using north, south, east, and west steps, beginning at $(0,0)$ and ending in $(p-q,0)$, $p,q \in N$, made by $p+q-2$ steps, (resp. the paths remaining weakly above the x-axis);

2. the class of 2-colored Motzkin paths of length $p+q-2$, such that the difference between the number of α and β-colored steps is equal to $p-q$ (resp. the paths remaining weakly above the x-axis);

3. the class of directed-convex polyominoes having p rows and q columns (resp. the class of parallelogram polyominoes having p rows and q columns)

thus giving combinatorial proofs of the formulas (10) and (11).

COMBINATORICS, INFORMATION VIZUALISATION, AND ALGEBRAIC LANGUAGES

MAYLIS DELEST

Université Bordeaux 1, France
maylis@labri.u-bordeaux.fr

1. Introduction. Let Ω be a class of combinatorial objects. We suppose that they are enumerated by the integer a_n according to the value n of some parameter p. Let $f(t) = \sum_{n=0} a_n t^n$ be the corresponding generating function. One of the main problems addressed by combinatorics is finding $f(t)$ and its properties knowing a recurrence on a_n or even a sequence of the first values $a_0, a_1, a_2, \ldots$. Many books are devoted to this field [24, 32]. With computer algebra systems, new techniques have been set up for getting results [1, 2]. Internet network users may ask online information on a sequence of values [27]. This last service is an encyclopedia of integer sequences but also it gives useful references to objects that are counted by sequences. Enumerative combinatorics is focussed on getting more inside the formula using bijection with object classes. We give an old trite example due to Euler in order to enlighten what we call *getting inside formula*. Let s_n be defined by

$$s_n = \sum_{i=0}^{n} (2i+1).$$

Of course, we have $s_n = (n+1)^2$. This result can be obtained by algebra but also explained by a geometrical construction. For each i, the value $(2i+1)$ is represented by a hook of $(2i+1)$ cells in the plane $\mathbb{N}\times\mathbb{N}$. Then, the s_n value is constructed by putting the hooks upon each other. See Figure 1.1.

In this paper, we focus on methods intensively studied by the *Combinatorics Bordeaux School* and some of their applications. After some definitions and notations, we describe in Section 3 the DSV methodology and in Section 4 two extensions that are object grammars and Q-grammars. At the end, we show applications of these techniques to information visualization.

2. Definitions and notations. This section summarizes briefly the notions needed for understanding this paper. A more complete background can be acquired from [3, 4, 23]. Let X be a nonempty set called alphabet. The elements of X are called letters. A word is a finite sequence of letters from X. The empty word is usually denoted by ϵ. Let u and v be two words on X,

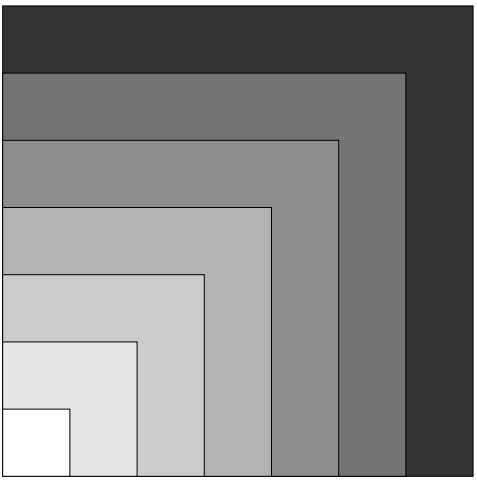

FIGURE 1.1. Euler proof for $n = 6$, $s_n = 49$.

$u = u_1 \cdots u_p$ and $v = v_1 \cdots v_q$. We define the concatenation of two words to be $uv = u_1 \cdots u_p v_1 \cdots v_q$. We denote by X^* the free monoid generated by X, that is, the set of all words on X endowed with the operation of concatenation. The number of occurrences of the letter x in the word u is denoted by $|u|_x$. The number of letters of a word w is called length of w and is denoted by $|w|$. A language is a subset of X^*. To every language $\mathcal{L}$, one can associate a noncommutative formal power series

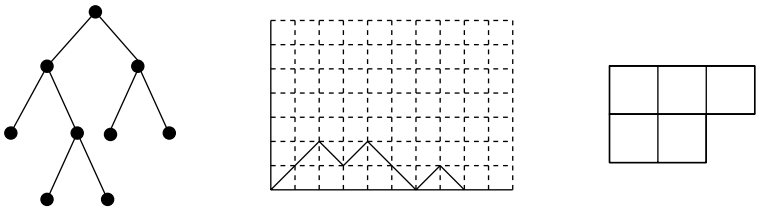
$$L = \sum_{w \in \mathcal{L}} w,$$

that is, an element of the algebra $\mathbb{Z}\langle\langle X \rangle\rangle$ of noncommutative formal power series with variables in X and coefficients in $\mathbb{Z}$.

DEFINITION 2.1. An algebraic grammar is a 4-tuple $G = \langle N, X, P, s \rangle$ such that N and X are two disjoint alphabets called, respectively, the nonterminal and the terminal alphabet, s is an element of N called axiom, and P is a set of pairs (α, β) with $\alpha \in N$ and $\beta \in (N \cup X)^*$ called production rules and is denoted by $\alpha \to \beta$.

Let α be in N and u in $(N \cup X)^*$, $u = u_1 \alpha u_2$. A derivation in G is a rewriting of u as $v = u_1 \beta u_2$ with $\alpha \to \beta$. This is denoted by $u \to v$. We say that a word w is deriving from a nonterminal symbol α in G if there exists a sequence of derivations which rewrites α as w. This will be denoted by $\alpha \xrightarrow{*} w$. The set $L(G)$ of words generated by s is called the algebraic language generated by G. In general, there may exist several grammars for a given algebraic language.

EXAMPLE 2.2. The main example in combinatorics is the Dyck language, not because of its complexity, but because of the frequency with which it occurs in



Binary tree Dyck path Skew polyomino

FIGURE 2.1. Combinatorial objects encoded by the word xxyxyyxy.

different settings. It encodes numerous and diverse structures such as trees, paths, polyominoes. See Figure 2.1. Its words are generated by the grammar G_1 given by

$$N = \{D\}, \qquad X = \{x, y\}, \qquad s = D,$$

and the production rules

$$D \longrightarrow xDyD, \quad D \longrightarrow \epsilon.$$

This example gives rise to unambiguous algebraic grammars, that is, algebraic grammars in which every word is obtained only once from the axiom using the production rules in a left-right derivation that is deriving first the leftmost terminal. In such cases, the formal power series associated to the language verifies equations which follow directly from the production rules. In our example,

$$D = xDyD + \epsilon.$$

In the following, all the grammars are considered to be unambigous.

3. DSV methodology. This methodology stems from an idea of M. P. Schützenberger from 1959 [25, 26]. This method is now known as the DSV-methodology, following M. P. Schützenberger's wish expressed to Viennot [30].

Let X be an alphabet, $X = \{x_1, \ldots, x_k\}$. The commutative image of a series produces, from a noncommutative formal power series, a commutative one, called an enumerative series of the language $\mathcal{L}$. This is defined by

$$\chi_0(\mathcal{L}) = \sum_{i_1, i_2, \ldots, i_k \in \mathbb{N}^k} n_{i_1, i_2, \ldots, i_k} x_1^{i_1} x_2^{i_2} \cdots x_k^{i_k}$$

such that $n_{i_1, i_2, \ldots, i_k}$ is the number of words w in $\mathcal{L}$ such that $|w|_{x_j} = i_j$ for each j in $[1 \cdots k]$. In this way, we obtain an application from the Boolean semi-ring $\mathbb{B}\langle\langle X \rangle\rangle$ to the semi-ring $\mathbb{N}\langle\langle X \rangle\rangle$ of commutative formal power series with variables in X. We will often denote by L the series $\chi_0(\mathcal{L})$. The application χ_0 is not a morphism but the following theorem holds.

THEOREM 3.1. *The image of an algebraic language under χ_0 is an algebraic series which is one of the components of the solution of the system of equations obtained via χ_0 from an unambiguous grammar of the language.*

EXAMPLE 3.2. The computation on the Dyck language classically leads to the equation:

$$D(x,y) = xyD(x,y) + 1.$$

An elementary computation shows that

$$D(x,y) = \frac{1-\sqrt{1-4xy}}{2x^2},$$

from which we deduce easily that the number of Dyck words of length 2n is the Catalan number

$$C_n = \frac{1}{n+1}\binom{2n}{n}.$$

Numerous results, in several areas, were obtained by this method: Polyominos [10, 12] tRNA structures [28]. Some overviews can be found in [7, 31].

REMARK 3.3. Some algebraic languages cannot be associated to unambiguous grammars. Flajolet [16] has shown that their generating series are related to transcendental series.

So, the first step in the Schützenberger methodology, namely the encoding, requires particular insight: One must find a bijection between the objects and an algebraic language. We remark that, frequently, the language which is obtained in the bijection process turns out to be closely related to the Dyck language. We will see in Section 4 an explanation of this fact. Thus, in the following, we describe bijections linked directly to Dyck words. Let us consider the set B of binary trees. If b is in B, then it admits the following recursive description: Either $b = (\text{root}(b), L(b), R(b))$ where root(b) is an internal node called root and $L(b)$ ($R(b)$, respectively) is the left (right, respectively) tree, or b is a single point called leaf. To encode a tree by a Dyck word, traverse the tree in left first depth-first order (or prefix order, that is, visiting first the root, then the left subtree, then the right subtree). During the traversal, write x at each internal node and y at each leaf, except the last one. This is the classical bijection between binary trees and Dyck words [29]. One deduces the following well-known result.

THEOREM 3.4. *The number of binary trees having $n+1$ leaves is the Catalan number C_n.*

We now consider the set of paths in $\mathbb{N}\times\mathbb{N}$ which are sequences of points $(s_0, s_1, \ldots, s_n)$. The pairs (s_i, s_{i+1}) are called elementary steps. They are North-East (South-East, respectively) if $s_i = (k,k')$ and $s_{i+1} = (k+1, k'+1)$ (respectively, $s_{i+1} = (k+1, k'-1)$). The height of the step s_i is k'. These paths are

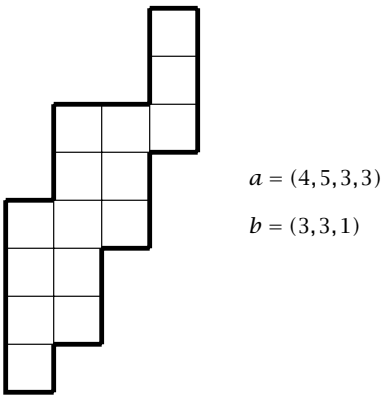


FIGURE 3.1. Euler proof for $n = 6$, $s_n = 49$.

clearly in bijective correspondence with Dyck words: Simply follow the path from s_0 to s_n, encoding each NE step by x, and each SE step by y. The word obtained in this manner is a Dyck word if and only if $s_0 = (0,0)$ and $s_n = (\lfloor n/2 \rfloor, 0)$. The corresponding path is frequently referred to a Dyck path. Another subject where the Schützenberger methodology gives good results is that of polyomino enumeration. For surveys, we refer the interested reader to [7, 18, 31]. A polyomino can be described as a finite connected union of cells (unit squares) in the plane $\mathbb{N} \times \mathbb{N}$, without cut points. A column (row, respectively) of a polyomino is the intersection of the polyomino with an infinite vertical (horizontal, respectively) strip of cells. A polyomino is column-convex (row-convex, respectively) if every column (row, respectively) is connected. A skew polyomino is both row- and column-convex and for each one of its columns there is

- no column on its right with a cell lower than its lowest cell,
- no column on its left with a cell higher than its highest cell.

An analysis of these constraints leads to an alternate definition of a skew polyomino, as a pair of integer sequences $(a_1, \ldots, a_n)$ and $(b_1, \ldots, b_{n-1})$, where a_i is the number of cells belonging to the ith column and $b_i + 1$ is the number of adjacent cells from columns i and $i + 1$. In Figure 3.1, is displayed a skew polyomino and the two sequences a and b. These two sequences can be viewed as the heights of the peaks (step North-East followed by a step South-East) and the heights of the troughs (step South-East followed by a step North-East) in a Dyck path. So encoding a skew polyomino by a Dyck word is straightforward and it is easy to deduce the next result.

THEOREM 3.5. *The number of skew polyominos whose perimeter equals* $2n + 2$ *is the Catalan number* C_n.

This result was already known a long time ago. The bijection from the Schützenberger methodology merely explains combinatorially the link between

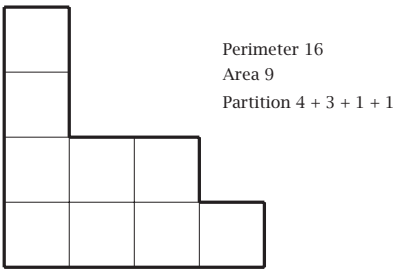

FIGURE 4.1. A Ferrer diagram.

polyominos and Catalan numbers. The first new result [12], in enumerative combinatorics obtained by this methodology, pertains to convex polyominos.

THEOREM 3.6. *The number p_{2n} of convex polyominos having a perimeter $2n+8$ is*

$$p_{2n} = (2n+11)4^n - 4(2n+1)\binom{2n}{n}.$$

This result was first proved with bijection with languages constructed from Dyck one and heavy computations. A totally bijective proof was given by Mireille Bousquet-Mélou [5].

4. Extension of DSV-methodology

4.1. *Q*-**grammars.** The study of compilers in computer science shows that the semantic attribute method described by Irons [20, 21] and then by Knuth [22] allows the translation of words from an algebraic language. Most of the resulting translations, however, are not algebraic languages. In the context of enumerative combinatorics, the same set of objects may lead to an algebraic generating function if counted according to a certain parameter, and to a nonalgebraic one if counted according to another. For example, the generating function for Ferrers diagrams (that is representation of partition of an integer, see Figure 4.1) is algebraic according to the perimeter of the diagram

$$f(x) = \frac{x^2}{1-2x}$$

and not algebraic according to the number of cells

$$f(q) = \prod_{i=1}^{\infty} \frac{1}{1-q^i}.$$

The interest presented by the attribute method lies in the fact that translation is defined locally, on each production rule of the grammar. Formally, in the combinatorics background, we have the

Definition 4.1. Let $G = (X,N,P,S)$ be a grammar. For each $U \in N$, an attribute family defined on G is given by a finite set T_U of attributes.

- Each attribute $\tau \in T_U$ has a domain D_τ; the cartesian product $\prod_{\tau \in T_U} D_\tau$ is denoted by $\mathcal{D}_U$;
- for each attribute $\tau \in T_U$ and for each derivation in P of U, $R : U \to w_0 U_1 \cdots U_k w_k$, a computation rule is defined $f_{\tau,R}$, that is a function from $\mathcal{D}_{U_1} \times \cdots \times \mathcal{D}_{U_k}$ into D_τ.

$(G,(T_U)_{U\in N})$ is called an attribute grammar.

For each word $w \in L(G)$, and each attribute τ, the function describes the recursive computation of $\tau(w)$.

It can be shown (see [9]) that if the attribute system is well defined (in a sense that we will not explain here), then a system of q-equations can be obtained directly from the q-grammarattribute grammar. Adding attributes to a grammar introduces nonalgebraic substitutions in the commutative equations. Here, we just give a trite example.

Example 4.2. The language coding Ferrers diagrams is the language encoding their profile by means of words of the form $w = aub$ written on the alphabet $\{a,b\}$. A grammar for this language is

$$G = \langle \{S,L\}, \{a,b\}, \{S \longrightarrow aLb, L \longrightarrow aL, L \longrightarrow bL, L \longrightarrow \epsilon\}, S \rangle.$$

The attribute grammar (G,τ) defined below computes the number of cells based on this encoding:

$$\begin{aligned}
S \longrightarrow aLb, &\qquad \tau(S) = q^{|\tau(L)|_a + |\tau(L)|_b + 1} ab\tau(L),\\
L \longrightarrow aL, &\qquad \tau(L) = q^{|\tau(L)|_b} a\tau(L),\\
L \longrightarrow bL, &\qquad \tau(L) = b\tau(L),\\
L \longrightarrow \epsilon, &\qquad \tau(L) = 1.
\end{aligned}$$

It is easy to show that the system of q-equations is

$$\begin{aligned}
S(a,b;q) &= qaL(aq,bq;q)b,\\
L(a,b;q) &= aL(a,bq;q) + bL(a,b;q) + 1,
\end{aligned}$$

from which one can deduce the well-known generating function

$$s(a,b;q) = \sum_{n=0}^{\infty} \frac{a^n q^{n+1}}{(1-qb)(1-q^2b)\cdots(1-q^{n+1}b)}.$$

Systems of q-equations can be obtained by this method, but solving them remains challenging even in cases when they give very nice results (see [11]). We must point out a general solution for q-equation given by M. Bousquet-Mélou in [6].

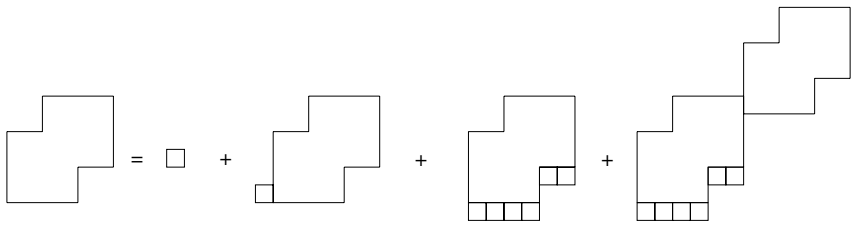

FIGURE 4.2. An object grammar for skew polyominoes.

4.2. Object grammars. Another extension of the DSV-methodology is object grammars, due to Dutour and Fédou [15]. They describe a Schützenberger method without word that is based only on the unambigous recursive decomposition of the combinatorial objects. Other methods have a similar approach see [17]. We give a definition, then we describe some applications. Let $\mathscr{E}$ a set of combinatorial objects.

DEFINITION 4.3. Let $\{E_i\}_{i=1,k}$ and E be subsets of $\mathscr{E}$. An object operation is an application from $E_1 \times E_2 \times \cdots \times E_k$ in E.

DEFINITION 4.4. An object grammar is a 4-tuple $G = \langle \mathscr{F}, \mathscr{T}, P, \int \rangle$ such that
- $\mathscr{F}$ is a set of subsets of $\mathscr{E}$,
- $\mathscr{T}$ is a finite set of terminal objects in $\mathscr{E}$,
- P is a set of object operations defined on k-tuples of $\mathscr{F}$ with value in $\mathscr{F}$,
- $\int$ is in $\mathscr{F}$ and is called axiom.

Clearly if $\mathscr{T}$ is an alphabet and $\mathscr{E} = \mathscr{T}^*$, then an algebraic language can be defined by an object grammar. As for algebraic language, one can define the derivation of an object from $\int$ in the object grammar G.

EXAMPLE 4.5. We come back to skew polyominoes. Let $\mathscr{E}$ be the set of polyominoes, and let $\mathscr{S}$ be the set of skew polyominoes. We define
- $\mathscr{F} = \{\mathscr{S}\}$,
- $\mathscr{T} = \{\square\}$, that is, the polyomino with only one cell,
- $\int = \mathscr{S}$.

Let O_1 and O_2 be skew polyominoes, then the objects operations are the following:
- ϕ_1 consists of adding to O_1 a column with one cell on its left in order to get a new skew polyomino,
- ϕ_2 consists of adding one cell to each column of O_1,
- ϕ_3 consists of gluing two polyominoes O_1 and O_2 by the rightmost upper cell of O_1 and the leftmost downer cell of O_2.

Clearly, we have the recursive equation

$$\mathscr{S} = \square + \phi_1(\mathscr{S}) + \phi_2(\mathscr{S}) + \phi_3(\phi_2(\mathscr{S}), \mathscr{S})$$

that is pictured in Figure 4.2.

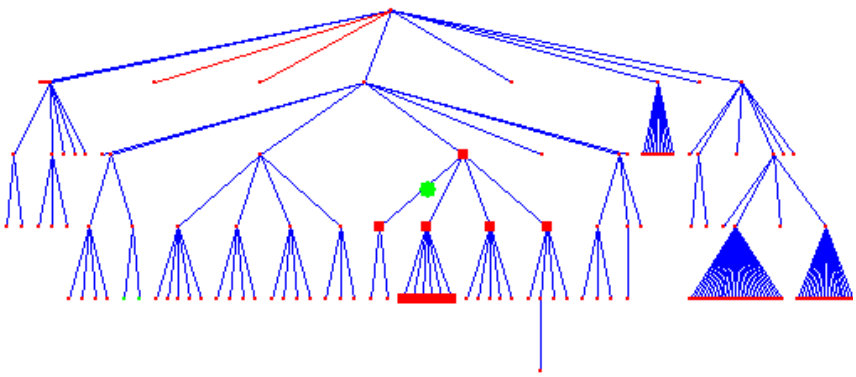

FIGURE 4.3. A view of the Latour software.

In enumerative combinatorics, Catalan numbers and Dyck words are involved in a lot of constructions. One central result in objects grammars enlightens this fact.

Let $G = \langle \mathcal{F}, \mathcal{T}, P, \int \rangle$ be an object grammar such that $\mathcal{F} = \mathcal{D}$. Dutour and Fédou associate a characteristic polynomial $g(x)$ to G. We define it for a one-dimensional system. It is obtained by substituting in the right part of the rule associated to $\mathcal{D}$ each occurence of $\mathcal{D}$ by x and each terminal object by 1, forgetting the object operations.

EXAMPLE 4.6. From the previous equation, we get $g(x) = 1 + 2x + x^2$.

Using the notion of substitution and constructing the solution, Dutour and Fédou proved the following theorem.

THEOREM 4.7. *Two one-dimensional grammars of degree almost two are isomorphic by the substitution process.*

As a consequence, for a large class of combinatorial objects, bijections can be constructed from the Dyck language. Nice examples are given in [15]. Of course, the notion of a polynomial can be extended to a system having higher degree than one. Moreover, they give an efficient tool for the random generation of objects. The Maple package is available at

http://dept-info.labri.u-bordeaux.fr/~dutour/QALGO

5. Application to information visualization. In this section, we describe the software Latour [19] developped by CWI and LaBRI. This software deals with tree visualization. The problem of displaying and interacting with large set of information can be abstracted to the same problem for graphs. Latour is devoted to the special case of tree. A lot of software try to have a very good drawing of the structure, [13]. The scale of information visualization raises

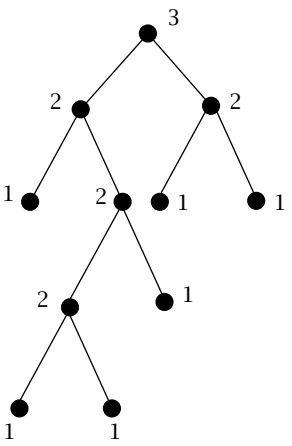

FIGURE 5.1. Strahler number computation for binary trees.

up structures having frequently several thousands of nodes. Insteed of trying to solve the complete problem, the Latour's approach is to use enumerative combinatorics in order to construct tools for exploring or folding parts of the structure.

In Figure 4.3, a tree is shown with Latour menus. The main goal in Latour is to construct measures on the tree that help the user in watching information. Here, we want to enlighten only two measures: Guiding the user in a zoom function and folding automatically subtrees that are too big or too small.

5.1. Strahler numbers as a user guide. Strahler numbers are very classical numbers in lots of fields as biology, computer science [31]. They were defined by the geographers Norton and Strahler in order to give a mathematical definition for fluvial bassin. The definition for Strahler numbers on binary trees can be done as follow.

DEFINITION 5.1. Let $b = (\text{root}(b), L(b), R(b))$ be a binary tree. To each node $v \in b$, the Strahler number $S(v)$ of v is

- if v is a leaf then $S(v) = 1$,
- if $S(\text{root}(L(b))) = S(\text{root}(R(b)))$ then $S(v) = S(\text{root}(L(b))) + 1$,
- else $S(v) = \max(S(\text{root}(L(b))), S(\text{root}(R(b))))$.

The Strahler number of the tree is $S(\text{root}(b))$.

An example is displayed on Figure 5.1. Many extensions of Strahler numbers can be set for plane trees. One of them, due to Fédou, is meaningful according to the computer science definition that is the minimum number of registers for computing an arithmetical expression [8]. In this case, the Strahler numbers are rather given by an algorithm than by a formula. Roughly, the value of the

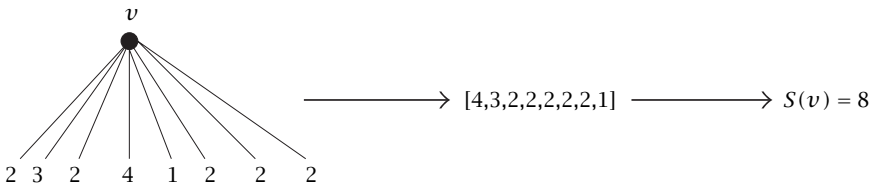

FIGURE 5.2. Strahler number computation for plane trees.

FIGURE 5.3. Views from latour.

leaves are 1. Suppose that a vertex v of the tree has sons $v_1, v_2, \ldots, v_k$ then rank the $v_{i\,i=1\ldots k}$ in decreasing order, it gives a list of values $u(i)_{i=1\ldots k}$. Then

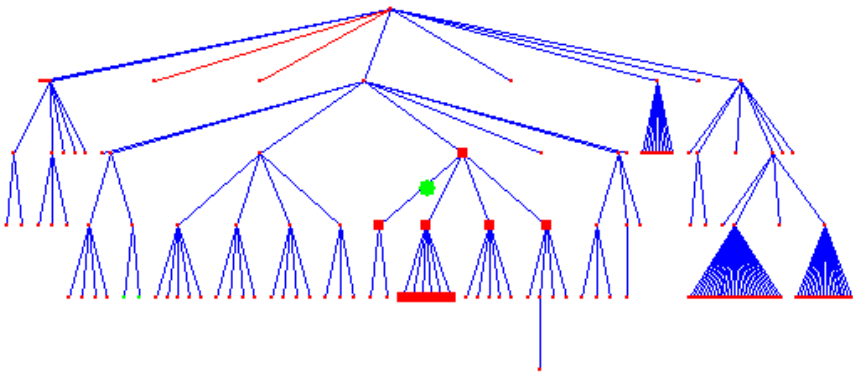
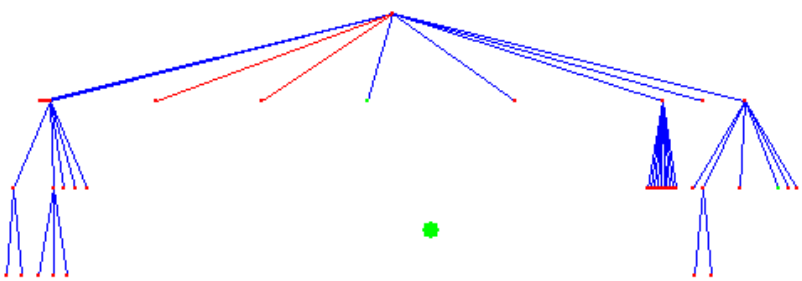
do

```
s:=u(1);
free:=u(1)-1;
for i from 2 to k do
  if free<u(i) then s:=s+1
               else free:=free-1
  fi
od;
```

Then the variable s contains the value of $S(v)$ (see Figure 5.2).



(a) Tree before folding.



(b) Tree after folding confidence level 5%.

FIGURE 5.5. Latour: a fold.

A part of the mathematical study of this parameter on trees, coloring edges according to this parameter in a tree visualization software guide the user during a zoom. It shows him which relative importance has the zoom window in the whole tree. We have experimented this technic in several fields (data structures for compilers, file hierarchical systems, …). In Figure 5.3 (respectively, Figure 5.4), we give two views of the same tree with zoom without (respectively, with) Strahler measure.

5.2. Folding trees using leaves numbers. The number of leaves of a plane tree is a very classical parameter. We have the well-known result.

THEOREM 5.2. *The number of tree B having n nodes and k leaves is*

$$C_{n,k} = \frac{1}{n-1}\binom{n-1}{k}\binom{n-1}{k-1}.$$

Let f_n be the random variable number of leaves in a tree having n nodes. Then, as soon as n is greater than 10, f_n as a normal distribution with mean $n/2$ and standard deviation $\sqrt{(n/8)}$. This approximation can be deduced based on a much more general (and highly nontrivial) theorem described in a paper of M. Dmrota [14].

In Latour, we use this distribution for folding automatically subtrees that are "unusually" large or small with respect to the number of leaves. We must point out, that, at this stage, we do not take into account the number of leaves of the full tree. This can change drastically the probability law. In the future, the fold tool will offer to the user to take into account the number of leaves in the general tree and also two others features:

- the maximum degree of the nodes,
- the maximal length of paths such that each node has only one son.

Anyway, users agree on this tool. In Figure 5.5, we show the folding effect. The Latour software is available at http://www.cwi.nl/InfoVisu.

title: On a Unimodality Conjecture in Matroid Theory

keywords: Matroid Theory, Unimodality Conjecture, Rank-2 matroids, Rank-3 matroids

abstract: A certain unimodal conjecture in matroid theory states the number of rank-*r* matroids on a set of size *n* is unimodal in *r* and attains its maximum at r=• n/2 •. We show that this conjecture holds up to *r=3* by constructing a map from a class of rank-2 matroids into the class of loopless rank-3 matroids. Similar inequalities are proven for the number of non-isomorphic loopless matroids, loopless matroids and matroids.

If your browser does not display the abstract correctly (because of the different mathematical symbols) you can look it up in the PostScript or PDF files.

Algebraic Aspects of B-regular Series

Ph. Dumas

Algorithms Project,
INRIA Rocquencourt BP 105,
78153 Le Chesnay Cedex, France

Abstract. This paper concerns power series of an arithmetic nature that arise in the analysis of divide-and-conquer algorithms. Two key notions are studied: that of B-regular sequence and that of Mahlerian sequence with their associated power series. Firstly we emphasize the link between rational series over the alphabet $\{x_0, x_1, \ldots, x_{B-1}\}$ and B-regular series. Secondly we extend the theorem of Christol, Kamae, Mendès France and Rauzy about automatic sequences and algebraic series to B-regular sequences and Mahlerian series. We develop here a constructive theory of B-regular and Mahlerian series. The examples show the ubiquitous character of B-regular series in the study of arithmetic functions related to number representation systems and divide-and-conquer algorithms.

The interest of 2-regular sequences comes from their presence in many problems which touch upon the binary representation of integers or divide-and-conquer algorithms, like sum-of-digits function, number of odd binomial coefficients, Josephus problem, mergesort, Euclidean matching or comparison networks. This explains why we study B-regular sequences that formalize the sequences which are solutions of certain difference equations of the divide-and-conquer type. In other words we want to show that B-regular series (i.e. generating functions of B-regular sequences) are as important in computer science as rational functions are common in mathematics.

Many properties of B-regular sequences like closure properties or growth properties have been established by Allouche and Shallit. In particular they showed that there is a link between B-regular sequences and rational series in the sense of formal language theory. The transition from one to another uses the B-ary representation of integers. There is already a long tradition about recognizable sets and automatic sequences.

The link provides us with the well known machinery of rational series and the first part of the paper is devoted to the illustration of its use. For example we introduce the Hankel matrix of a regular series. This is the practical way to find the rank of a regular series, to exhibit minimal recurrence relations or to build up linear representations.

In the second part we compare B-regular series and Mahlerian series. Our goal is to extend the theorem of Christol, Kamae, Mendès France and Rauzy [6], which asserts that q-automatic series with coefficients in the finite field $\mathbb{F}_q$ are exactly algebraic series. To that purpose we introduce a more general notion

[6], which asserts that q-automatic series with coefficients in the finite field $\mathbb{F}_q$ are exactly algebraic series. To that purpose we introduce a more general notion of Mahlerian series. We prove in particular that B-regular series are Mahlerian series.

The reciprocal is more intricate but most useful. Indeed the theorem of Christol *et alii* is not adequate for theoretical computer science where the sequences have elements that are integer rather than elements of a finite fields. We give a partial answer to this problem, that permits to cover numerous cases of application.

In all the examples we have aimed at making the computations effective.

It is worth noting that we concentrate here on one facet of B-regular sequences, their algebraic closure properties. A complementary point of vue is the study of asymptotic behaviour of these sequences. One will find numerous examples in [9, 10].

1 Rational Series and B-regular Series

The properties of B-regular series come mainly from the properties of rational series in non commutative indeterminates and we build up a catalog where each notion about B-regular series is a translation of the corresponding notion about rational series. In view of the richness of the subject we limit ourselves to the essentials.

Let us begin with an example which gives the flavour of 2-regular series.

Example 1. Let us assume that we want to go from 0 to an integer n by leaps whose lengths are power of 2 and directions are forward or backward. The shortest path has a length w_n which may be defined by the conditions $w_0 = 0$, $w_n = 1$ if $n = 2^q$ and $w_n = 1 + \min(w_{n-2^k}, w_{2^{k+1}-n})$ if $2^q < n < 2^{q+1}$. For example we find $w_{14} = 2$ because $14 = 16 - 2$.

Another way to obtain this sequence (w_n) is to consider the two square matrices

$$A_0 = \begin{pmatrix} 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 1 \\ 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad A_1 = \begin{pmatrix} 0 & 0 & -1 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{pmatrix}$$

and the row and column matrices

$$\lambda = \begin{pmatrix} 0 & 1 & 1 & 2 \end{pmatrix}, \quad \gamma = \begin{pmatrix} 1 & 0 & 0 & 0 \end{pmatrix}^T.$$

If the binary expansion of the integer n is $\epsilon_\ell \cdots \epsilon_1 \epsilon_0$, we have $w_n = \lambda A_{\epsilon_\ell} \cdots A_{\epsilon_1} A_{\epsilon_0} \gamma$. As an illustration

$$w_{14} = \lambda A_1 A_1 A_1 A_0 \gamma = 2.$$

This computation is akin to the definition of recognizable series and indeed B-regular series are merely a translation, as we shall see.

Let the alphabet $\mathcal{X}_B$ be formed of the digits $0, 1, \ldots, B-1$ used to write the integers in B-ary notation. To avoid confusion between figures and scalars, which lie in a ring $\mathbb{A}$, we represent figures by the indeterminates $x_0, x_1, \ldots, x_{B-1}$. We obtain B-regular series by translation of rational series [2].

Definition 1. A formal power series $f(z) \in \mathbb{A}[[z]]$ is a B-regular series if there exists a rational series $S \in \mathbb{A}^{\mathrm{rat}}\langle\langle \mathcal{X}_B \rangle\rangle$ in non-commutating indeterminates, whose support is included in the language $\mathcal{N}$ of integers B-ary expansions,

exists a rational series $S \in \mathbb{A}^{\mathrm{rat}}\langle\langle \mathcal{X}_{\mathrm{B}} \rangle\rangle$ in non-commutating indeterminates, whose support is included in the language $\mathcal{N}$ of integers B-ary expansions,

$$S = \sum_{u \in \mathcal{N}} (S,u)\, u \quad ,$$

---

such that

$$f(z) = \sum_{n \geq 0} (S, \tilde{n})\, z^n \quad ,$$

where $\tilde{n}$ is the B-ary expansion of n.

Linear Representations. In the study of recognizable series, the linear representations come from the use of the division operators that trim a word of its leftmost letter. Classically the divisions are on the left but we favour the right operations, which correspond to the least significant digits. If the alphabet is $\mathcal{X}$ and w is a word, the right division w^{-1} acts on the series S according to the formula

$$S w^{-1} = \sum_{u \in \mathcal{X}^*} (S, uw)\, u \quad .$$

The division operators give us the section operators S_r, $0 \leq r < \mathrm{B}$, acting on $f(z) = \sum_n f_n z^n$ by the formula

$$S_r f(z) = \sum_{n \geq 0} f_{\mathrm{B}n+r}\, z^n \quad .$$

Theorem 2 (Stability theorem). *A formal series is* B*-regular if and only if there exists an* $\mathbb{A}$*-module of finite type which is left stable by the section operators and contains the series.*

We obtain a linear representation of a B-regular series by expressing the section operators with respect to a generating family of that module. Moreover the linear representation permits us to exhibit a rational expression of the series S associated with the B-regular series: if $\Sigma = \sum_{0 \leq r < \mathrm{B}} x_r A_r$ and $\Sigma_+ = \sum_{0 < r < \mathrm{B}} x_r A_r$, we have $S = \lambda(I + \Sigma_+ \Sigma^*)\gamma$. This formula is only a translation of the fact that $\mathcal{N} = \epsilon + \mathcal{X}_+ \mathcal{X}^*$, where ϵ is the empty word, $\mathcal{X} = \mathcal{X}_{\mathrm{B}}$ and $\mathcal{X}_+ = \{x_1, \ldots, x_{\mathrm{B}-1}\}$.

Example 2. The complexity of mergesort in the worst case satisfies the divide-and-conquer recurrence

$$T_n = T_{\lfloor n/2 \rfloor} + T_{\lceil n/2 \rceil} + n - 1 \quad ,$$

with the initial conditions $T_0 = T_1 = 0$. The generating series $T(z)$ is 2-regular because the $\mathbb{Z}$-module generated by $T(z)$, $T(z)/z$, $2z/(1-z)^2$, $z(1+z)/(1-z)^2$ and $(1+z)/(1-z)^2$ is left stable by the two section operators S_0 and S_1. With respect to this basis, the matrices of S_0 and S_1 are

$$A_0 = \begin{pmatrix} 2 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 2 & 1 & 1 \\ 1 & 0 & 0 & 1 & 0 \end{pmatrix}, \quad A_1 = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 1 & 2 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

$$A_0 = \begin{pmatrix} 0 & 1 & 2 & 1 & 1 \\ 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}, \quad A_1 = \begin{pmatrix} 1 & 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 2 & 1 & 3 \end{pmatrix}.$$

We take

$$\lambda = \begin{pmatrix} 0 & 0 & 0 & 0 & 1 \end{pmatrix}, \quad \gamma = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \end{pmatrix}^T,$$

because the components of λ are the values at 0 of the series of the basis and γ gives the coordinates of $T(x)$.

Building a linear representation from the section operators gives the relation $\lambda A_0 = \lambda$ because the constant term of a series $g(x)$ is the constant term of $S_0 g(x)$ too. We call such a representation a standard linear representation. We have seen that every B-regular series $f(x)$ hides a rational series $S = \lambda(I + \Xi_+ \Xi^*)\gamma$, but for a standard representation it is simpler to introduce the rational series $R = \lambda \Xi^* \gamma$. Both series coincide on language $\mathcal{N} = \epsilon + \mathcal{X}_+ \mathcal{X}^*$, but the first one extends $f(x)$ by 0 whereas the second one uses the rule $(R, x_0 w) = (R, w)$. Clearly each one determines the other and they have the same rank. By definition this is the rank of the series $f(x)$.

Recurrences. The B-regular series satisfy linear recurrences and the best way to find them is to use their Hankel matrices [5]. For the sake of simplicity, we assume the ring is a field $\mathbb{K}$.

The Hankel matrix of a series $f(x)$ is an infinite matrix whose rows are indexed by the integers and columns are indexed by the words in $\mathcal{X}_B^*$. The columns of the matrix are simply the sequences (f_n), (f_{Bn}), (f_{Bn+1}), $\ldots$, (f_{Bn+B-1}), $(f_{B^2 n})$, $\ldots$, if we arrange the words according to their length and lexicographic order.

Definition 3. The Hankel matrix of $f(x) \in \mathbb{K}[[x]]$ is an infinite matrix of type $\mathbb{N} \times \mathcal{X}^*$. The coefficient $H_{n,w}$ of that matrix is $f_{B^k n + r}$ if w has length k and r is the value of w for radix B.

Clearly a series is B-regular if and only if its Hankel matrix has finite rank. Moreover searching for relations between the columns of the matrix gives us recurrence relations.

Example 3. The van der Corput's sequence associates to an integer n with binary expansion $\epsilon_\ell \ldots \epsilon_0$ the rational number $v_n = \epsilon_0/2 + \epsilon_1/4 + \cdots + \epsilon_\ell/2^{\ell+1}$. It is 2-regular with rank 2 for it satisfies the recurrence

$$v_{2n} = v_n/2, \quad v_{2n+1} = 1/2 + v_n/2 \quad (n \geq 0).$$

Its Hankel matrix begins with

$$\begin{pmatrix} 0 & 0 & 1/2 & 0 & 1/2 & 1/4 & 3/4 \\ 1/2 & 1/4 & 3/4 & 1/8 & 5/8 & 3/8 & 7/8 \\ 1/4 & 1/8 & 5/8 & 1/16 & 9/16 & 5/16 & 13/16 \\ 3/4 & 3/8 & 7/8 & 3/16 & 11/16 & 7/16 & 15/16 \\ 1/8 & 1/16 & 9/16 & 1/32 & 17/32 & 9/32 & 25/32 \\ 5/8 & 5/16 & 13/16 & 5/32 & 21/32 & 13/32 & 29/32 \\ 3/8 & 3/16 & 11/16 & 3/32 & 19/32 & 11/32 & 27/32 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \end{pmatrix}.$$

$$\begin{pmatrix} 5/8 & 5/16 & 13/16 & 5/32 & 21/32 & 13/32 & 29/32 \\ 3/8 & 3/16 & 11/16 & 3/32 & 19/32 & 11/32 & 27/32 \\ 7/8 & 7/16 & 15/16 & 7/32 & 23/32 & 15/32 & 31/32 \end{pmatrix}$$

The two columns with indices ε and x_1 (the first and the third) are independents. Expressing the columns with indices x_0, x_0x_1 and x_1x_1 according to these, we obtain the relations

$$\begin{cases} v_{2n} &= v_n/2 \ , \\ v_{4n+1} &= -v_n/4 + v_{2n+1} \ , \\ v_{4n+3} &= -v_n/2 + 3v_{2n+1}/2 \ , \end{cases}$$

which are easy to verify in this case. What we want to emphasize is the shape of these relations and a picture will be clearer than a long comment (see Figure 1).

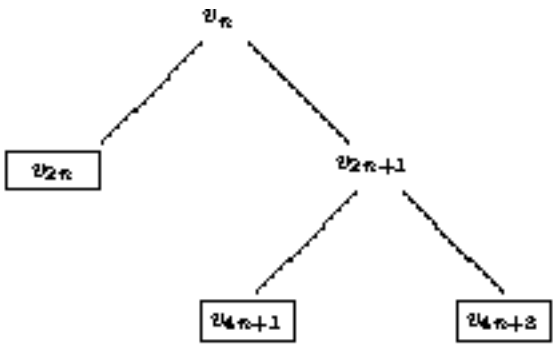

Fig. 1. The leaves of the tree give the shape of the recurrence relations.

This example epitomises the existence of a basis composed with sections $S_w f(x)$, such that the w are the addresses of the internal nodes of a B-ary tree. Furthermore to the leaves of the tree there correspond the recurrence relations; all the recurrences which express linear dependence between the sections are deduced from these [12].

Condensation. If $f(x)$ is B-regular and S is the associated rational series with support in $\mathcal{N} = \varepsilon + \mathcal{X}_+\mathcal{X}^*$, the commutative image [13, p. 147] is a rational series. We call it the condensate of $f(x)$ because it is simply

$$Kf(t) = f_0 + \sum_{l \geq 1} \left(\sum_{\mathrm{B}^{l-1} \leq n < \mathrm{B}^l} f_n \right) t^l \ .$$

The condensation is useful for regular series just as density is for a regular language.

Example 4. The Taylor series of the logarithm is not B-regular for all B. The condensate of the series

$$\frac{1}{z} \ln \frac{1}{1-z} = \sum_{n \geq 0} \frac{z^n}{n+1}$$

is

$$F(t) = 1 + \sum (H_{\mathrm{B}^l} - H_{\mathrm{B}^{l-1}}) t^l \ ,$$

$$F(t) = 1 + \sum_{i \geq 1} (H_{B^i} - H_{B^{i-1}}) t^i \quad ,$$

with H_n the n-th harmonic number. Using the equality

$$H_{B^i} - H_{B^{i-1}} \underset{i \to +\infty}{=} \ln \mathrm{B} + o(1)$$

and the transcendence of $\ln \mathrm{B}$, we see that $F(t)$ is not rational, hence the conclusion.

Closure. The closure properties of rational series show immediately that the set of B-regular series is a module left stable by Hadamard product. Besides, the Cauchy product of two B-regular series is B-regular (assuming that the ring is Noetherian) and a rational function is B-regular if and only if its poles are roots of unity (here we suppose the ring is a field). These properties have been established directly by Allouche and Shallit [2], using computation on sequences.

For the sake of simplicity we assume that we use a field in the next theorem.

Theorem 4 (Closure theorem). *A rational function is* B*-regular if and only if its poles are roots of unity. The set of* B*-regular series is closed under*
— *linear combination,*
— *Hadamard product (term by term product),*
— *Cauchy product (function product),*
— *derivation.*

Example 5. Greene and Knuth [11, pp. 25–28] consider the sequence $f(n)$ defined by

$$f(n) = 1 + \min_i \left\{ \frac{i-1}{n} f(i-1) + \frac{n-i}{n} f(n-i) \right\} ,$$

which is relative to the search of an integer between 1 and n. The sequence $g(n) = nf(n)$ has second order difference given by

$$\Delta^2 g(n) = \begin{cases} 2 & \text{if } n \text{ is a power of } 2 \\ 1 & \text{if } n \text{ is even but not a power of } 2 \\ -1 & \text{if } n \text{ odd.} \end{cases}$$

Hence the generating series $g(z)$ is given by

$$g(z) = \frac{1}{(1-z)^2} \left(\frac{1}{1+z} + \sum_{s \geq 0} z^{2^s} \right)$$

and $g(z)$ is 2-regular as sum and product of 2-regular series.

Clearly the subject is not exhausted (we did not speak of Fatou lemma, of properties of coefficients, of decidability questions, *etc*).

2 Mahlerian Series and B-regular Series

As we want to extend the theorem of Christol *et alii* about automatic sequences, we recall at first the subject. Next we establish a general criterion and finally we apply the criterion to four cases:

1. a common case which is very useful because almost all divide-and-conquer recurrences are concerned,
2. the finite field case where we get back the theorem of Christol *et alii*,
3. the modular case, which provides examples where the ring is not an integral domain,
4. the algebraically closed field case, which completes the first case because it permits us to treat more complicated examples.

Let us recall the definition of a B-automatic sequence with values in a set $\mathcal{A}$. First a B-machine is a finite set of states, $\mathcal{S}$, with a distinguished initial state, i, and equipped with transitions $s \mapsto \epsilon s$ $(0 \leq \epsilon < \mathrm{B})$ from $\mathcal{S}$ into itself. Next we adjoin to this B-machine an application π from $\mathcal{S}$ into $\mathcal{A}$ and so we have a B-automaton. Finally for each integer n, we write its B-ary expansion $\epsilon_\ell \cdots \epsilon_0$ and we compute the state $s = \epsilon_\ell \cdots \epsilon_1 \epsilon_0 . i$ by going through the automaton from the state i according to the digits of n. The value of the sequence for n is $\pi(s)$.

Clearly the B-automatic sequences with values in a ring are B-regular sequences. The matrices of the transitions, the initial state and the output application provide a linear representation. Conversely a B-regular sequence which takes only a finite number of values is B-automatic.

The theorem under consideration is the next one and has given rise to an extended literature [1, 7].

Theorem 5 (Christol, Kamae, Mendès France, Rauzy). *The generating series of q-automatic sequences with values in the finite field $\mathbb{F}_q$ are exactly the series algebraic over the field $\mathbb{F}_q(x)$ of rational functions.*

This theorem is based on the equality $f(x^q) = f(x)^q$ for a formal series with coefficients in $\mathbb{F}_q$ and this is the reason why algebraic series are in question. In fact the equations which come naturally in light in this situation are Mahlerian equations.

Definition 6. A Mahlerian equation is a functional equation of the form

$$c_0(x)\,f(x) + c_1(x)\,f(x^B) + \cdots + c_N(x)\,f(x^{B^N}) = b(x)\ ,$$

where $c_0(x)$, ..., $c_N(x)$ are polynomials. A Mahlerian series is a power series which satisfies a non trivial homogeneous Mahlerian equation.

Our purpose is to extend the theorem to regular series and to separate the radix B and the characteristic m of the ring we use. We show first that every B-regular series is B-mahlerian, at least when the ring is a field. Next we give some criteria which focus on the coefficient $c_0(x)$ and ensure that a solution of the equation is B-regular.

Minimal Equation. Let us assume that the ring is a field $\mathbb{K}$. In this case one can develop an arithmetic for the ring of operators $\mathbb{K}[x, M]$, where M refer to the Mahler operator $f(x) \mapsto f(x^B)$. Precisely there is a Euclidean left division, which causes the left ideals to be principal and every Mahlerian series posesses a minimal homogeneous equation [8].

The proof given by Allouche [1] to etablish that a q-automatic series over $\mathbb{F}_q$ is algebraic remains adequate to show that a B-regular series is B-mahlerian. Moreover it often gives a minimal equation for the series if one uses carefully a linear representation of the series. The idea is just to express $f(x)$, $f(x^B)$, *etc* in the basis corresponding to the representation and it leads to an effective method of computation.

Example 6. The series $o(z) = \prod_{s\geq 0} \left(1 + 2z^{2^s}\right)$ gives the number of odd coefficients in a row of Pascal's triangle [2, ex. 14] [14, seq. 109] [15]. Consequently the complementary series $e(z) = \dfrac{1}{(1-z)^2} - o(z)$ gives the number of even coefficients in a row. This series is 2-regular with rank 3 and a representation is

$$A_0 = \begin{pmatrix} 0 & -2 & -4 \\ 1 & 3 & 4 \\ 0 & 0 & 1 \end{pmatrix}, \quad A_1 = \begin{pmatrix} 2 & 0 & 0 \\ 0 & 0 & -2 \\ 0 & 1 & 3 \end{pmatrix}, \quad \lambda = \begin{pmatrix} 0 & 0 & 1 \end{pmatrix}, \quad \gamma = \begin{pmatrix} 1 & 0 & 0 \end{pmatrix}^T.$$

$$\begin{pmatrix} 0 & 0 & 1 \end{pmatrix} \qquad \begin{pmatrix} 0 & 1 & 3 \end{pmatrix} \qquad \gamma = \begin{pmatrix} 1 & 0 & 0 \end{pmatrix}^{\top}.$$

The algorithm gives the equation

$$z^2 e(z) - \left(3z^2 - z + 1\right)\left(z^2 + z + 1\right) e(z^2)$$
$$+ \left(3 + 4z^2 + 11z^4 + 2z^5 + 6z^8\right) e(z^4) - 2\left(2z^4 + 1\right)\left(1 + z^4\right)^2 e(z^8) = 0 \ .$$

In fact the minimal equation, which is the lcm of the minimal equations for $1/(1-z)^2$ and $o(z)$, is

$$z^2 e(z) - [(1+z^2)^2 + z^2(1+2z)]e(z^2) + (1+z^2)^2(1+2z^2)e(z^4) = 0 \ .$$

Another proof, most in the spirit of this paper, consists in introducing the B-rational operators

$$F = \sum_{k \geq 0} c_k(z)\, M^k \in \mathbb{K}[[z, M]] \ ,$$

which are the images of the rational series S with support in $\mathcal{N} = \varepsilon + \mathcal{X}_+\mathcal{X}^*$ by the anti-morphism which associates to the letter x_r the operator $z^r M$. They are the natural intermediate between the rational series and the B-regular series, since every B-regular series is the value of a rational operator at the series 1. Using the closure properties of rational series and the arithmetic of operators, it is not difficult to prove that every B-rational operator satisfies an equality $QF = P$ where Q and P are two members of $\mathbb{K}[z, M]$ with the constraint $Q \neq 0$ and $\omega_M(Q) = 0$ (Q is a polynomial with respect to z and M and $\omega_M(Q)$ is the valuation of Q according to M). Now if $f(z)$ is a B-regular series it is written $f(z) = F.1$ where F is a rational operator; taking for Q a denominator of F, we have $Qf(z) = P.1$ hence a Mahlerian equation where the second member is a polynomial; it is not difficult to render it homogeneous.

General Criterion. For the rest of the paper we study the converse of the preceding property and we give first a general criterion to ensure that the solutions of a Mahlerian equation are B-regular.

Let us consider a Mahlerian equation

$$c_0(z) f(z) + c_1(z) f(z^{\mathrm{B}}) + \cdots + c_N(z) f(z^{\mathrm{B}^N}) = b(z)$$

where $b(z)$ is a B-regular series. We assume that the ring $\mathbb{A}$ is Noetherian and the coefficient of lowest degree in $c_0(z)$ is inversible in $\mathbb{A}$: we have $c_0(z) = Cz^\gamma g(z)$ with C inversible, γ a non negative integer and $g(0) = 1$. These constraints are normally fulfilled but we need to add the main condition: the set of the sections

$$S_{r_K} \cdots S_{r_1}\left(\frac{1}{g(z^{\mathrm{B}^{K-1}}) \cdots g(z^{\mathrm{B}}) g(z)}\right) = S_{r_K} \frac{1}{g}\left(S_{r_{K-1}} \frac{1}{g}\left(\cdots S_{r_1}\left(\frac{1}{g}\right)\right)\right),$$

where $K \geq 0$, $0 \leq r_k < \mathrm{B}$ for $k = 1, \cdots, K$, is contained in a module of finite type. With these hypotheses a solution $f(z)$ of the equation is B-regular.

As we impose a condition only on coefficient c_0 and nothing on $c_1, \ldots, c_N$, there is no hope to find a necessary and sufficient condition. Nevertheless the hypothesis about the set of sections which appears in the criterion is exactly the condition which ensures that the Mahlerian infinite product

$$f(z) = \prod \frac{1}{g(z^{\mathrm{B}^k})}$$

$$f(z) = \prod_{k \geq 0} \frac{1}{g(z^{\mathrm{B}^k})}$$

is B-regular.

Common Case. If $g(z) = 1$, the main condition vanishes and we have an easy criterion to recognize a B-regular series. The case contains almost all the divide-and-conquer recurrences and in view of its importance, we extend the result to study vector of series instead of series. This permits us to treat sequences which admits a definition by case according to the residue modulo a power of B, say B^{k+1}, which expresses $\mathrm{B}^{k+1}n + r$ according to the $\mathrm{B}^l n + s$ with $0 \leq l \leq k$. The next assertion uses a natural extension of B-regularity to vector of series.

Theorem 7 (Common case). *We consider a vector of series*

$$F(z) = \left(\begin{array}{ccc} f_1(z) & \cdots & f_d(z) \end{array} \right)^T$$

and we assume the following hypothesis:
— *the ring is Noetherian,*
— *the vector of series satisfies an equation*

$$z^\gamma F(z) + \sum_{k=1}^{N} C_k(z) F(z^{\mathrm{B}^k}) = B(z)$$

where $\gamma \geq 0$, $C_1(z)$, ..., $C_N(z)$ are some square matrices of polynomials and $B(z)$ is a column matrix whose components are B*-regular series.*

With these conditions, the components of $F(z)$ are B*-regular series.*

Example 7. Supowit and Reingold [16] encountered the sequence (C_n) defined by the recurrence

$$\left\{ \begin{array}{lcl} C_{4n} & = & a(C_{2n+1} + C_{2n-1}) + b \\ C_{4n+1} & = & a(C_{2n+1} + C_{2n}) \\ C_{4n+2} & = & a(C_{2n+1} + C_{2n+1}) + b \\ C_{4n+3} & = & a(C_{2n+2} + C_{2n+1}) \end{array} \right.$$

for $n \geq 1$ and the initial conditions $C_0 = C_1 = 0$, $C_2 = b$, $C_3 = ab$, with $a = 1/\sqrt{2}$ and $b = \sqrt{3}$. The number b is only a scale factor and with a division by b we may suppose $b = 1$.

We call $f(z)$ the generating series of (C_n) and we refer to the section $S_\omega f(z)$ as $f_\omega(z)$. The recurrence gives us the system

$$\left\{ \begin{array}{lcl} f_{00}(z) & = & a(1+z) f_1(z) + 1/(1-z) \\ f_{01}(z) & = & a f_1(z) + a f_0(z) \\ f_{10}(z) & = & 2a f_1(z) + 1/(1-z) \\ f_{11}(z) & = & a f_0(z)/z + a f_1(z) \ . \end{array} \right.$$

If we express $f_0(z)$ and $f_1(z)$ with respect to $f_{00}(z)$, $f_{01}(z)$, $f_{10}(z)$ and $f_{11}(z)$ as $f_c(z) = f_{0c}(z^2) + z f_{1c}(z^2)$, we obtain an equation

$$F(z) = a\, C_1(z) F(z^2) + B(z)$$

in which the unknown is the vector $F(z) = \left(\begin{array}{cccc} f_{00}(z) & f_{01}(z) & f_{10}(z) & f_{11}(z) \end{array} \right)^T$ and the coefficients are given by

in which the unknown is the vector $F(z) = (\, f_{00}(z) \;\; f_{01}(z) \;\; f_{10}(z) \;\; f_{11}(z) \,)^{\top}$ and the coefficients are given by

$$C_1(z) = \begin{pmatrix} 0 & 1+z & 0 & z(1+z) \\ 1 & 1 & z & z \\ 0 & 2 & 0 & 2z \\ 1/z & 1 & 1 & z \end{pmatrix}, \quad B(z) = \begin{pmatrix} 1/(1-z) \\ 0 \\ 1/(1-z) \\ 0 \end{pmatrix}.$$

In accordance with our result, we may assert that $F(z)$ and hence $f(z)$ is 2-regular.

Finite Fields and Rings. Let $p(x) \in \mathbb{A}[x]$ be a polynomial such that $p(0) = 1$. We say that T is the period of $p(x)$ if the sequence of coefficients of the formal power series $1/p(x)$ is periodic with period T. The study of the period [4] of

$$g(x^{\mathrm{B}^{K-1}}) \cdots g(x^{\mathrm{B}}) g(x)$$

provide us with cases in which we can guarantee that the main condition is satisfied.

Theorem 8 (Finite field). *Let a formal series $f(x)$ have coefficients in the field $\mathbb{F}_q$ with characteristic p and satisfy a Mahlerian equation whose right-hand side is* B*-automatic*

$$c_0(x) f(x) + c_1(x) f(x^{\mathrm{B}}) + \cdots + c_N(x) f(x^{\mathrm{B}^N}) = b(x) \;.$$

We assume that $c_0(x) = C x^{\gamma} g(x)$ with $\gamma \geq 0$, $g(0) = 1$. If p divides B *or if the period T of $g(x)$ and the radix* B *have a common prime divisor, other than the characteristic p, then $f(x)$ is* B*-automatic.*

It is worth noting that $g(x)$ does not matter in the first condition about B. This case extends directly the theorem of Christol, Kamae, Mendès France and Rauzy.

Example 8. The polynomial $g(z) = 1 + z^2 + z^3$, which lies in $\mathbb{F}_2[z]$, is 7-periodic. Hence a formal series $f(z) \in \mathbb{F}_4[[z]]$ which satisfies a Mahlerian equation of the shape

$$z^{1993}(1 + z^2 + z^3) f(z) + c_1(z) f(z^{21}) + c_2(z) f(z^{441}) = 0$$

is 21-regular. (Here $p = 2$, $q = 4$, $T = 7$ and $\mathrm{B} = 21$.)

Starting from these results for the fields $\mathbb{F}_p$, it is not difficult to attain the quotient rings $\mathbb{Z}/(p^a)$. In fact if $g(x)$ has period t modulo p^a, it has period pt modulo p^{a+1}. Next the chinese remainder theorem permits us to consider rings $\mathbb{Z}/(m)$.

Theorem 9 (Modular case). *Let $f(x) \in \mathbb{Z}/(m)[[x]]$ be a formal series which satisfies*

$$c_0(x) f(x) + c_1(x) f(x^{\mathrm{B}}) + \cdots + c_N(x) f(x^{\mathrm{B}^N}) = b(x)$$

with right-hand side $b(x)$ B*-automatic, $c_0(x) = C x^{\gamma} g(x)$, C invertible, $\gamma \geq 0$ and $g(0) = 1$. We assume that for every prime divisor p of m, one of the next two conditions is satisfied: i) p divides* B*, or ii) there exists a prime number p' which is different from p and divides both the radix* B *and the period $T(q,p)$ of*

two conditions is satisfied: i) p divides B*,or ii) there exists a prime number p' which is different from p and divides both the radix* B *and the period $T(g,p)$ of $g(x)$ reduced modulo p. Then $f(x)$ is* B*-automatic.*

Example 9. Let us consider the integer sequence (u_n) defined by the initial conditions $u_0 = 0$, $u_1 = 1$ and the recurrence relation

$$u_n = u_{n-1} + u_{n-2} + u_{\lfloor n/2 \rfloor} \ .$$

Clearly u_n is greater than the Fibonacci number F_{n-1} and the generating series

$$u(z) = z + 2z^2 + 4z^3 + 8z^4 + 14z^5 + 26z^6 + 44z^7 + 78z^8 + \cdots$$

---

is not 2-regular because its coefficients grow too rapidly. Nevertheless it is 2-regular when we reduce it modulo every integer. It suffices to look at the primary numbers p^a. If $p = 2$ the result is immediatly obtained for p equals B. Otherwise it suffices to remark that the period of $1 - z - z^2$ modulo an odd prime is even, because the Mahlerian equation which is to be considered is

$$(1 - z - z^2)u(z) - (1 + z)u(z^2) = z \ .$$

Example 10. A B-ary partition is an integer partition in which the parts are power of B. As an illustration there are nine 3-partitions of 16, namely 1^{16}, $1^{13}3$, $1^{10}3^2$, $1^7 3^3$, $1^4 3^4$, 13^5, $1^7 9$, $1^4 3\,9$, $13^2 9$ (we use the classical notation: $13^2 9$ refers to $1+3+3+9$). The generating function of the number of B-ary partition is [3, p. 161]

$$p(z) = \prod_{k=0}^{+\infty} \frac{1}{1 - z^{B^k}}$$

and it satisfies the Mahlerian equation

$$(1 - z)p(z) = p(z^B) \ .$$

Because the period of $g(z) = 1 - z$ is 1 modulo every integer, we cannot use the second condition of our theorem, but the first one shows that $p(z)$ is B-regular if we reduce it modulo m and every prime divisor of m divides B. As an example the number of binary partition reduced modulo 8 may be defined by the 2-automaton

$$A_0 = \begin{pmatrix} 0&0&0&0&0&0&0 \\ 1&0&0&0&0&0&0 \\ 0&1&0&0&0&1&0 \\ 0&0&0&1&0&0&0 \\ 0&0&0&0&1&0&0 \\ 0&0&1&0&0&0&0 \\ 0&0&0&0&0&0&1 \end{pmatrix}, \quad A_1 = \begin{pmatrix} 0&0&0&0&0&0&0 \\ 1&0&0&0&0&0&0 \\ 0&0&0&0&0&0&0 \\ 0&0&1&1&0&0&0 \\ 0&1&0&0&0&1&1 \\ 0&0&0&0&0&0&0 \\ 0&0&0&0&1&0&0 \end{pmatrix},$$

$$\lambda = \begin{pmatrix} 1&1&0&4&2&0&6 \end{pmatrix}, \quad \gamma = \begin{pmatrix} 1&0&0&0&0&0&0 \end{pmatrix}^T.$$

Algebraically Closed Field. Finally we apply our criterion to algebraically closed fields. Here the trick to obtain the main condition is to impose that

$$S_{r_K} \cdots S_{r_1} \left(\frac{1}{g(z^{B^{K-1}}) \cdots g(z^B) g(z)} \right)$$

$$\Delta_{r_K}\cdots\Delta_{r_1}\left(\frac{1}{g(z^{\mathrm{B}^{K-1}})\cdots g(z^{\mathrm{B}})g(z)}\right)$$

have poles in a finite set with bounded multiplicities. This guarantees that they lie in a vector space of finite dimension. We obtain the following theorem.

Theorem 10 (Algebraically closed field). *Let $f(z)$ be a formal series with coefficients in an algebraically closed field. We assume that $f(z)$ satisfies a Mahlerian equation*

$$c_0(z)f(z)+c_1(z)f(z^{\mathrm{B}})+\cdots+c_N(z)f(z^{\mathrm{B}^N})=b(z)$$

in which $b(z)$ is B*-regular, $c_0(z)=Cz^\gamma g(z)$ with $C\neq 0$, $\gamma\geq 0$ and $g(0)=1$. If all the roots of $g(z)$ are roots of unity with an order (in the sense of group theory) which is not prime relative to* B*, then $f(z)$ is* B*-regular.*

Example 11. Let us consider the integer sequence (u_n) defined by $u_0=0$, $u_1=1$ and the recurrence

$$u_n=u_{n-1}-u_{n-2}+u_{\lfloor n/2\rfloor}\quad(n\geq 2)\ .$$

Its generating function $u(z)$ is the solution of

$$(1-z+z^2)u(z)-u(z^2)=z\ .$$

The roots of $1-z+z^2$ are the primitive 6-th roots of unity, hence $u(z)$ is 3-regular. Besides its rank is 3. Moreover it is 3-automatic according to the equality

$$u(z)=(1+z)\sum_{k,l\geq 0}(-1)^l z^{2^k(2l+1)}\ .$$

Algebraic Aspects of B-regular Series

(1993) (Make Corrections) (1 citation)
Ph. Dumas
Automata, Languages and Programming

Abstract: . This paper concerns power series of an arithmetic nature that arise in the analysis of divide-and-conquer algorithms. Two key notions are studied: that of B-regular sequence and that of Mahlerian sequence with their associated power series. Firstly we emphasize the link between rational series over the alphabet fx0 ; x1 ; : : : ; xB\Gamma1 g and B-regular series. Secondly we extend the theorem of Christol, Kamae, Mend`es France and Rauzy about automatic sequences and algebraic series to... (Update)

Using Monte Carlo Methods in the Analysis of Spatial Patterns

The formal statistical material--that which supports part II in the outline below--comes form Ebdon, 1985. *Statistics in Geography*. 2nd ed. Blackwell. Everything else, including all program code, is my own and is distributed to students for use on ICARUS.

I. Introduction
- A. Why do we do this? ...in an attempt to understand spatial processes.
- B. What are spatial processes?
  1. conscious and unconscious "decisions" or documentable sequences of events that give rise to arrangements of things on landscapes
  2. examples: arrangements of points: cities and towns, eagles' nests, partiular tree species, lunar craters; of zones: census-tract data, crime incidences by police district, voting tallies by precinct
  3. arrangements we see are "artifacts" of the processes that gave rise to them
- C. Are there conceptual models of spatial processes?
  1. geography: central place theory
  2. notions of bird-nesting behavior, seed distribution, etc.

II. A quick review of "standard" pattern analytic methods, which involves
- A. having students fabricate two sets of hypothetical datasets
  1. use random number generaters to create point and quadrat data
  2. objectives: get people up and running on ICARUS, thinking in terms of what "random" MIGHT mean, and able to do some editting
- B. develop a real world dataset
  1. use immediately available means to come up with point and quadrat data for an assigned study area
  2. objective: learn some of the methods (and drudgery?) of developing real world data and preparing it for analysis
- C. and process fabricated and real data using a variety of analyses
  1. fixed quadrat methods (with multiple variations for each)
     - a. quadrat counts, single-process models
     - b. mixed-process models
     - c. join count methods
  2. floating quadrat methods
  3. neareast neighbor methods
     - a first and higher order neighbors

c. effects and implications of "biases" and "disturbances"

4. contiguity analysis for (fixed) quadrats
   a. Moran's "I" statistic
   b. Geary's "C" statistic
5. contiguity analysis for points
6. objectives: assess test capabilities, assumptions, formulation of working and null hypotheses, interpretatons, and data requirements

III. Shooting for more than "one-number ouotcomes," as in...

A. tease more information out of nearest neighbor analysis
   1. "standardizing" nearest neighbor distances
   2. size-spacing analysis of central places

B. and out of Geary's "C" statistic.
   1. computations resemble those for Chi-square
   2. contributing terms may lend themselves to K-S testing
   3. develop criteria for contextual evaluations of quadrat values

C. objectives: learn to identify "anomalous" observations and patterns

III. Extentions to "nonstandard" applications, as in...

A. locate potentially viable market centers in rural areas
B. support archeological "prospecting"
C. recognize possible "dispersed cities"
D. devise "geographic taxonomies"
E. objectives: add to existing knowledge and/or guide future research

An unusual metallic phase in a chain of strongly interacting particles (Make Corrections)

J. Phys.: Condens. Matter (1997) L561-L567. Printed in the Uk Pii:...

Abstract: . We consider a one-dimensional lattice model with the nearest-neighbour interaction V 1 and the next-nearest-neighbour interaction V 2 with filling factor 1/2 at zero temperature. The particles are assumed to be spinless fermions or hard-core bosons. Using very simple assumptions we are able to predict the basic structure of the insulator--metal phase diagram for this model. Computations of the flux sensitivity support the main features of the proposed diagram and show that the system... (Update)

``Proof of Conway's Lost Cosmological Theorem'' By S. B. Ekhad and D. Zeilberger

(Appeared in Electronic Research Announcement of the Amer. Math. Soc. 3(1997) 78-82.)

Written: May 1, 1997.

Last Update: July 9, 1997.

At this time of writing, we still need human creative geniuses, like John Horton Conway, to DEFINE such marvelous things as surreal numbers and the audioactive sequence 1, 11, 21, 1211, 111221, 312211, ... But given the definition, all the rest can be done by computerkind (with, at present, routine programming still done by humans.) In ref. [C] of the present paper, Conway begs: `Can you find a proof in just a few pages? Please!' (p. 186) If you count pages modulo routine verification and programming, then the present proof is about .1-page-long.

(Plain) .tex version (4 pages)

.dvi version (for previewing)

.ps version

.pdf version

Most importantly, download the Maple package HORTON , without which the present paper makes little sense.

To understand the present paper, you are advised to read first Steve Finch's fascinating essay on Conway's constant..

If you are skeptical, your computer can reproduce the proof by downloading the input file for Cosmo , and after about two weeks (on nice) you should get the output file for Cosmo .

If you want to construct the periodic table ab initio, and at the same time find how each atom splits after it is acted on by Conway's audioactive operator, the relative abundance of each element, the minimal polynomial for Conway's constant lambda, and its value (to 50 digits), all you have to do (assuming that you have maple and HORTON) is run input file for PTlam , and after less than half an hour, you should

get the output file for PTlam .

The Mathematical Knight

Noam D. Elkies
Richard P. Stanley

Introduction

Much has been said of the affinity between mathematics and chess: two domains of human thought where very limited sets of rules yield inexhaustible depths, challenges, frustrations and beauty. Both fields support a venerable and burgeoning technical literature and attract much more than their share of child prodigies. For all that, the intersection of the two domains is not large. While chess and mathematics may favor similar mindsets, there are few places where a chess player or analyst can benefit from a specific mathematical idea, such as the symmetry of the board and of most pieces' moves (see for instance [24]) or the combinatorial game theory of Berlekamp, Conway, and Guy (as in [4]). Still, when mathematics does find applications in chess, striking and instructive results often arise.

This two-part article shows several such applications that feature the knight and its characteristic $(2,1)$ leap. It is based on portions of a book tentatively entitled *Chess and Mathematics*, currently in preparation by the two authors of this article, that will cover all aspects of the interactions between chess and mathematics. Mathematically, the choice of $(2,1)$ and of the 8×8 board may seem to be a special case of no particular interest, and indeed we shall on occasion indicate variations and generalizations involving other leap parameters and board sizes. But long experience points to the standard knight's move and chessboard size as felicitous choices not only for the game of chess but also for puzzles and problems involving the board and pieces, including several of our examples.

This first part concentrates on puzzles such as the knight's tour. Many of these are clearly mathematical problems in a very thin disguise (for instance, a closed knight's tour is a Hamiltonian circuit on a certain graph $\mathcal{G}$), and can be solved or at least better understood using the terminology and techniques of combinatorics. We also relate a few of these ideas with practical endgame technique (see Diagrams 1ff., 10, 11). The second part shows some remarkable chess problems featuring the knight or knights. Most "practical" chess players have little patience for the art of chess problems, which has evolved a long way from its origins in instructive exercises. But the same formal concerns that may deter the over-the-board player give some problems a particular appeal to mathematicians. For instance, we will exhibit a position, constructed by P. O'Shea and published in 1989, where White, with only king and knight, has just one way to force mate in 48 (the current record). We also show the longest known legal game of chess that is determined completely by its last move (discovered by Rösler in 1994) — which happens to be checkmate by promotion to a knight.

Algebraic notation.
We assume that the reader is familiar with the rules of chess, but require very little knowledge of chess strategy. (The reader who knows, or is willing to accept as intuitively obvious, that king and queen win against king or even king and knight if there is no immediate draw, will have no difficulty following the analysis.) The reader will, however, have to follow the notation for chess moves, either by visualizing the moves on the diagram or by setting up the position on the board. Several notation systems have been used; the most common one nowadays, and the one we use here, is "algebraic notation", so called because of the coordinate system used to name the squares of the board. In the remaining paragraphs of this introductory section we outline this notation system. Readers already fluent in algebraic notation may safely skip ahead to Section 1.

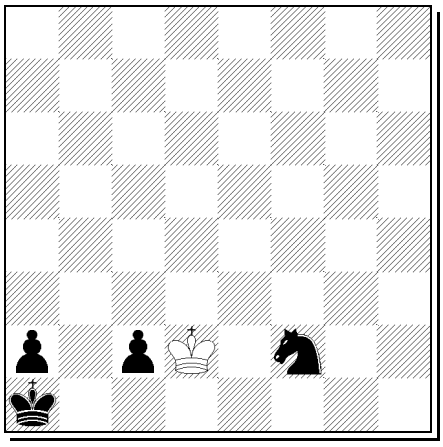
Each square on the 8×8 board is uniquely determined by its row and column, called "rank" and "file" respectively. The ranks are numbered from 1 to 8, the files named by letters a through h. In the initial array, ranks 1 and 2 are occupied by White's pieces and pawns, ranks 8 and 7 by Black's, both queens are on the d-file, and both kings on the e-file. Thus, viewed from White's side of the board (as are all the diagrams in this article), the ranks are numbered from bottom to top, the files from left to right. We name a square by its column followed by the row; for instance, the White king in Diagram 1 below is at d2. Each of the six kinds of chessmen is referred to by a single letter, usually its initial: K, Q, R, B, P are king, queen, rook, bishop, and pawn (often lower-case p is seen for pawn). We cannot use the initial letter for the knight because K is already the king, so we use its phonetic initial, N for kNight. For instance, Diagram 1 can be described as: White Kd2, Black Ka1, Nf2, Pa2, Pc2. To notate a chess move we name the piece and its destination square, interpolating "×" if the move is a capture. For pawn moves the P is usually suppressed; for pawn captures, it is replaced by the pawn's file. Thus in Diagram 11, Black's pawn moves are notated a2 and a×b2 rather than Pa2 and P×b2. We follow a move by "+" if it gives check, and by "!" or "?" if we regard it as particularly strong or weak. In some cases "!" is used to indicate a thematic move, i.e., a move that is essential to the "theme" or main point of the problem. As an aid to following the analysis, moves are numbered consecutively, from the start of the game or from the diagram. For instance, we shall begin the discussion of Diagram 1 by considering the possibility "1.K×c2 Nd3!". Here "1" indicates that these are White's and Black's first moves from the diagram; "K×c2" means that the White king captures the unit on c2; and "Nd3!" means that the Black knight moves to the unoccupied square d3, and that this is regarded as a strong move (the point here being that Black prevents 2.Kc1 even at the cost of letting White capture the knight). When analysis begins with a Black move, we use "..." to represent the previous White move; thus "1 ... Nd3!" is the same first Black move.

A few further refinements are needed to subsume promotion and castling, and to ensure that every move is uniquely specified by its notation. For instance, if Black were to move first in Diagram 1 and promoted his c2-pawn to a queen (giving check), we would write this as 1 ... c1Q+, or more likely 1 ... c1Q+?, because we shall see that after 2.K×c1 White can draw. Short and long castling are notated 0-0 and 0-0-0 respectively. If the piece and destination square do not specify the move uniquely, we also give the departure square's file, rank, or both. An extreme example: Starting from Diagram 9, "Nb1" uniquely specifies a move of the c3 knight. But to move it to d5 we would write "Ncd5" (because other knights on the b- and f-files could also reach d5); to a4, "N3a4" (not "Nca4" because of the knight on c5); and to e4, "Nc3e4" (why?).

1 A chess endgame

We begin by analyzing a relatively simple chess position (Diagram 1 below). This may look like an endgame from actual play, but is a composed position — an "endgame study" — created (by NDE) to bring the key point into sharper focus.

Diagram 1



White to move

White, reduced to bare king, can do no better than draw, and even that with difficulty: Black will surely win if either pawn safely promotes to a queen. A natural try is 1.K×c2, eliminating one pawn and imprisoning two of Black's remaining three men in the corner. But 1 ... Nd3! breaks the blockade (Diagram 2a). Black threatens nothing but controls the key square c1. The rules of chess do not allow White to pass the move; unable to go to c1, the king must move elsewhere and release Black's men. After 2.K×d3 (or any other move) Kb1 followed by 3 ... a1Q, Black wins easily.

Diagram 2a

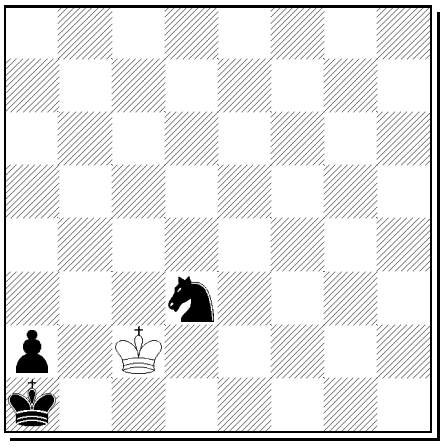


Diagram 2b

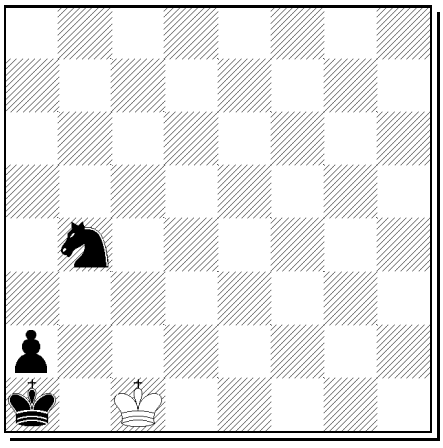

Returning to Diagram 1, let us try instead 1.Kc1! This still locks in the Black Ka1 and Pa2, and prepares to capture the Pc2 next move, for instance 1 ... Nd3+ 2.K×c2, arriving at Diagram 2a with Black to move. White has in effect succeeded in passing the move to Black by taking a detour from d2 to c2. Now it is Black who cannot pass, and any move restores the White king's access to c1. For instance, play may continue 2 ... Nb4+ 3.Kc1, reaching Diagram 2b. Black is still bottled up. If it were White to move in Diagram 2b, White would have to release Black with Kd1 or Kd2 and lose; but again Black must move and allow White back to c2, for instance 3 ... Nd3+ 4.Kc2 and we are back at Diagram 2a.

So White does draw — at least if Black obligingly shuttles the knight between d3 and b4 to match the White king's oscillations between c1 and c2. But what if Black tries to improve on this? While the king is limited to those two squares, the knight can roam over almost the entire board. For instance, from Diagram 2a Black might bring the knight to the far corner in m moves, reaching a position such as Diagram 3a, and then back to d3 in n moves. If $m + n$ is odd, then Black will win since it will be White's turn to move. Instead of d3, Black can aim for b3 or e2, which also control c1; but each of these is two knight moves away from d3, so we get an equivalent parity condition. Alternatively, Black might try to reach b4 from d3 in an *even* number of moves, to reach Diagram 2b with White to move; and again Black could aim for another square that controls c2. But each of these squares is one or three knight moves away from d3, so again would yield a closed path of odd length through d3.

Can Black thus pass the move back to White? For that matter, what should White do in Diagram 3b? Does either Kc1 or K×c2 draw, or is White lost regardless of this choice?

Diagram 3a

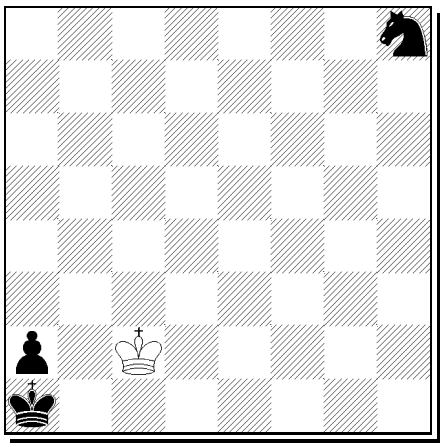

Diagram 3b

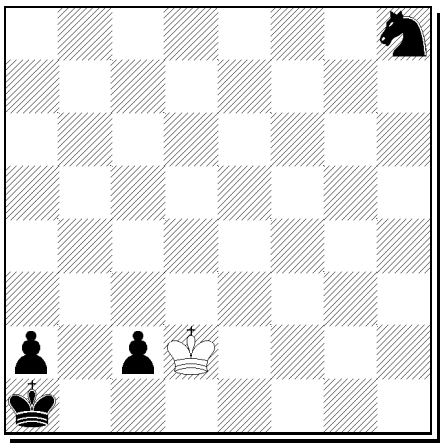


White to move

The outcome of Diagram 2a thus hinges on the answer to the following problem in graph theory:

Let $\mathcal{G} = \mathcal{G}_{8,8}$ be the graph whose vertices are the 64 *squares of the* 8×8 *chessboard and whose edges are the pairs of squares joined by a knight's move. Does $\mathcal{G}$ have a cycle of odd length through d3?*

Likewise White's initial move in Diagram 3b and the outcome of this endgame comes down to the related question concerning the same graph $\mathcal{G}$:

What are the possible parities of lengths of paths on $\mathcal{G}$ from h8 to c1 or c2?

The answers result from the following basic properties of $\mathcal{G}$:

Lemma. *(i) The graph $\mathcal{G}$ is connected. (ii) The graph is bipartite, the two parts comprising the* 32 *light squares and* 32 *dark squares of the chessboard.*

Proof: Part (i) is just the familiar fact that a knight can get from any square on the chessboard to any other square. Part (ii) amounts to the observation that every knight move connects a light and a dark square.

Corollaries. 1) There are no knight cycles of odd length on the chessboard. 2) Two squares

of the same color are connected by knight-move paths of even length but not of odd length; two square of opposite color are connected by knight-move paths of odd length but not of even length.

We thus answer our chess questions: White draws both Diagram 1 and Diagram 3b by starting with Kc1. More generally, for any initial position of the Black knight, White chooses between c1 and c2 by moving to the square of the same color as the one occupied by the knight.

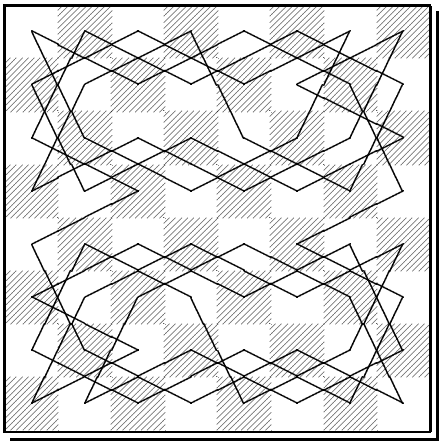
REMARK. Our analysis would reach the same conclusions if the Black pawn on c2 were removed from Diagrams 1 and 3b; we included this superfluous pawn only as bait to make the wrong choice of c2 more tempting.

Puzzle 1. For which rectangular boards (if any) does part (i) or (ii) of the Lemma fail? That is, which $\mathcal{G}_{m,n}$ are not connected, or not bipartite? (All puzzles and all diagrams not explicated in the text have solutions at the end of this article.)

Knight's tours and the Thirty-Two Knights

The graph $\mathcal{G}$ arises often in problems and puzzles involving knights. For instance, the perennial knight's tour puzzle asks in effect for a Hamiltonian path on $\mathcal{G}$; a "re-entrant" or "closed" knight's tour is just a Hamiltonian circuit. The existence of such tours is classical — even Euler spent some time constructing them, finding among others the following elegant centrally symmetric tour (from [9, p. 191]):

Diagram 4



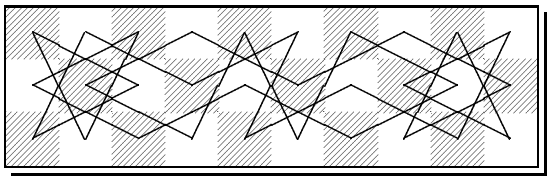
a closed knight's tour constructed by Euler

The extensive literature on knight's tours includes many examples, which, when numbered along the path from 1 to 64, yield semi-magic squares (all row and column sums equal 260), sometimes with further "magic" properties, but it is not yet known whether a fully magic knight's tour (one with major diagonals as well as rows and columns summing to 260), either open or closed, can exist.

More generally, we may ask for Hamiltonian circuits on $\mathcal{G}_{m,n}$ for other m, n; that is, for closed knight's tours on other rectangular chessboards. A necessary condition is that $\mathcal{G}_{m,n}$ be a connected graph with an even number of vertices. Hence we must have $2|mn$ and both m, n at least 3 (cf. Puzzle 1). But not all $\mathcal{G}_{m,n}$ satisfying this condition admit Hamiltonian circuits. For instance, one easily checks that $\mathcal{G}_{3,4}$ is not Hamiltonian. Nor are $\mathcal{G}_{3,6}$ and $\mathcal{G}_{3,8}$,

but $\mathcal{G}_{3,10}$ has a Hamiltonian circuit, as does $G_{3,n}$ for each even $n > 10$. For instance, the next diagram shows a closed knight's tour on the 3×10 board:

Diagram 5



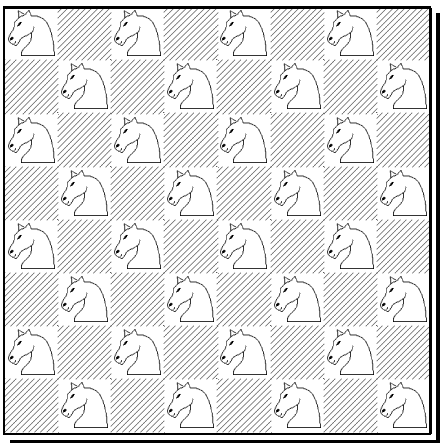
a closed knight's tour on the 3×10 board

There are sixteen such tours (ignoring the board symmetries). More generally, enumerating the closed knight's tours on a $3 \times (8 + 2n)$ board yields a sequence 16, 176, 1536, 15424, ... satisfying a constant linear recursion of degree 21 that was obtained independently by Knuth and NDE in April, 1994. See [23, Sequence A070030]. In 1997, Brendan McKay first computed that there are 13267364410532 (more than 1.3×10^{13}) closed knight's tours on the 8×8 board ([19]; see also [23, Sequence A001230],[26]).

We return now from enumeration to existence. After $\mathcal{G}_{3,n}$ the next case is $\mathcal{G}_{4,n}$. This is trickier: the reader might try to construct a closed knight's tour on a 4×11 board, or to prove that none exists. We answer this question later.

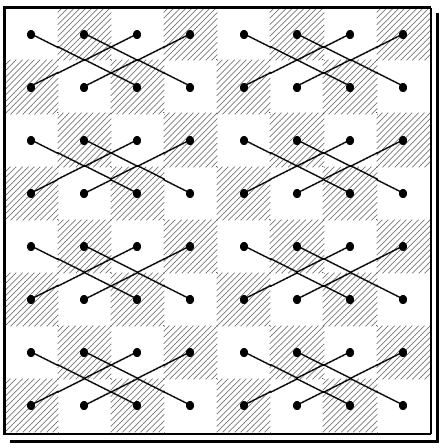
What of maximal cliques and cocliques on $\mathcal{G}$? A clique is just a collection of pairwise defending (or attacking) knights. Clearly there can be no more than two knights, again because $\mathcal{G}$ is bipartite: two squares of the same color cannot be a knight's move apart, and any set of more at least three squares must include two of the same color. Cocliques are more interesting: how many pairwise *non*attacking knights can the chessboard accommodate?[1] We follow Golomb ([21], via M. Gardner [9, p. 193]). Again the fact that $\mathcal{G}$ is bipartite suggests the answer (Diagram 6):

Diagram 6



32 mutually nonattacking knights

Diagram 7



A one-factor in $\mathcal{G}$

It is not hard to see that we cannot do better: the 64 squares may be partitioned into 32 pairs each related by a knight move, and then at most one square from each pair can be

[1] Burt Hochberg jokes (in [11, p. 5], concerning the analogous problem for queens) that the answer is 64, all White pieces or all Black: pieces of the same color cannot attack each other! Of course this joke, and similar jokes such as crowding several pieces on a single square, are extraneous to our analysis.

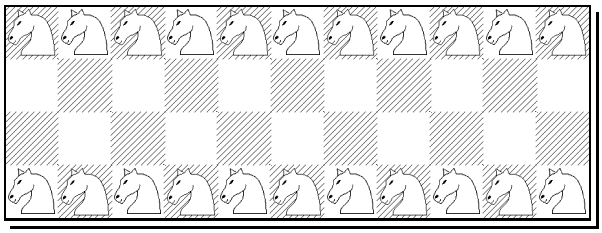
used. See Diagram 7. This is Patenaude's solution in [21]. Such a pairing of $\mathcal{G}$ is called a "one-factor" in graph theory. Similar one-factors exist on all $\mathcal{G}_{m,n}$ when $2|mn$ and m, n both exceed 2; they can be used to show that in general a knight coclique on an $m \times n$ board has size at most $mn/2$ for such m, n.

Puzzle 2. What happens if m, n are both odd, or if $m \leq 2$ or $n \leq 2$?

Are Diagram 6 and its complement the only maximal cocliques? Yes, but this is harder to show. One elegant proof, given by Greenberg in [21], invokes the existence of a closed knight's tour, such as Euler's Diagram 4. In general, on a circuit of length $2M$ the only sets of M pairwise nonadjacent vertices are the set of even-numbered vertices and the set of odd-numbered ones on the circuit. Here $M = 32$, and the knight's tour in effect embeds that circuit into $\mathcal{G}$, so *a fortiori* there can be at most two cocliques of size M on $\mathcal{G}$ — and we have already found them both!

Of course this proof applies equally to any board with a closed knight's tour: on any such board the light- and dark-squared subsets are the only maximal cocliques. Conversely, a board for which there are further maximal cocliques cannot support a closed knight's tour. For example, any $4 \times n$ board has a mixed-color maximal coclique, as illustrated for $n = 11$ in the next diagram:

Diagram 8



a third maximal knight coclique on the 4×11 board

This yields possibly the cleanest proof that *there is no closed knight's tour on a $4 \times n$ board for any n.* (According to Jelliss [14], this fact was known to Euler and first proved by C. Flye Sainte-Marie in 1877; Jelliss attributes the above clean proof to Louis Posa.)

Warning: the existence of a closed knight's tour is a sufficient but not necessary condition for the existence of only two maximal knight cocliques. It is known that an $m \times n$ board supports a closed tour if and only if its area mn is an even integer > 24 and neither m nor n is 1, 2, or 4. In particular, as noted above there are no closed knight's tours on the 3×6 and 3×8 boards, though as it happens on each of these boards the only maximal knight cocliques are the two obvious monochromatic ones.

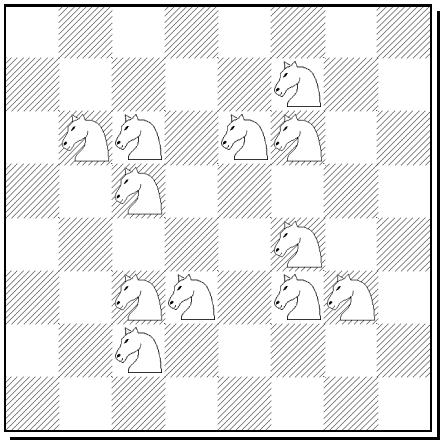
More about $\mathcal{G}$: Domination number, girth, and the knight metric

Another classic puzzle asks: how many knights does it take to either occupy or defend every square on the board? In graph theory parlance this asks for the "domination number" of $\mathcal{G}$.[2]

[2]This terminology is not entirely foreign to the chess literature: A piece is said to be "dominated" when it can move to many squares but will be lost on any of them. (The meaning of "many" in this definition is not precise because domination is an artistic concept, not a mathematical one.) The introduction of this term into the chess lexicon is attributed to Henri Rinck ([12, p. 93], [16, p. 151]). The task of constructing economical domination positions, where a few chessmen cover many squares, has a pronounced combinatorial flavor; the great composer of endgame studies G.M. Kasparyan devoted an entire book to the subject, *Domination in 2545 Endgame Studies*, Progress Publishers, Moscow, 1980.

For the standard 8×8 board, the following symmetrical solution with 12 knights has long been known:

Diagram 9



All unoccupied squares controlled

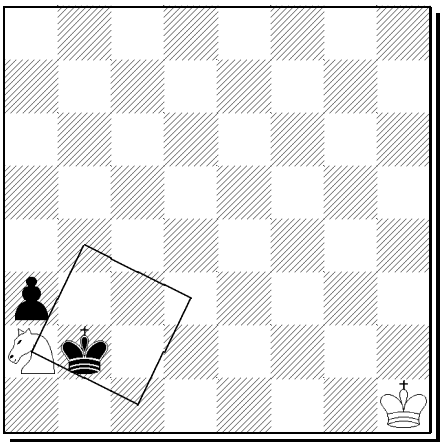
Puzzle 3. Prove that this solution is unique up to reflection.

The knight domination number for chessboards of arbitrary size is not known, not even asymptotically. See [9, Ch.14] for results known at the time for square boards of order up to 15, most dating back to 1918 [1, Vol.2, p. 359]. If we ask instead that every square, occupied or not, be defended, then the 8×8 chessboard requires 14 knights. On an $m \times n$ board, at least $mn/8$ knights are needed since a knight defends at most 8 squares.

Puzzle 4. Prove that $mn/8 + O(m + n)$ knights suffice. HINT: treat the light and dark squares separately.

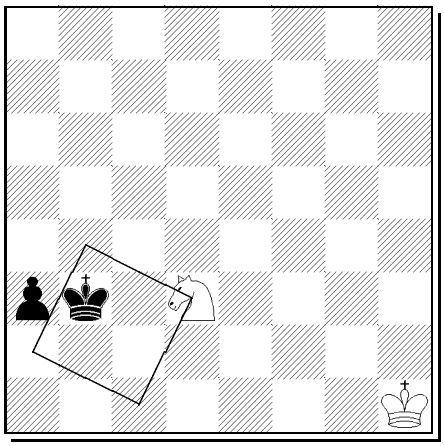
We already noted that $\mathcal{G}$, being bipartite, has no cycles of odd length. (We also encountered the non-existence of 3-cycles as "$\mathcal{G}$ has no cliques of size 3".) Thus the girth (minimal cycle length) of $\mathcal{G}$ is at least 4. In fact the girth is exactly 4, as shown for instance in Diagram 10.

Diagram 10



White to move draws

Diagram 10a



After 2 Nd3!

This square cycle is important to endgame theory: a White knight traveling on the cycle can

prevent the promotion of the Black pawn on a3 supported by its king. To draw this position White must either block the pawn or capture it, even at the cost of the knight. The point is seen after 1.Nb4 Kb3 2.Nd3! (reaching Diagram 10a) a2 3.Nc1+!, "forking" king and pawn and giving White time for 4.N×a2 and a draw. On other Black moves from Diagram 10a White resumes control of a2 with 3.Nc1 or 3.Nb4; for instance 2 ... Kc2 3.Nb4+ or 2 ... Kc3 3.Nc1 Kb2 (else Na2+) 4.Nd3+! etc. Note that the White king was not needed. [3]

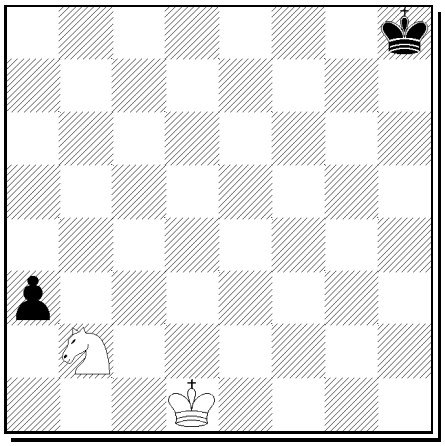
Puzzle 5. Construct a position where this Nd5 resource is White's only way to draw.

Warning: this puzzle is hard, and requires considerably more chess background than anything else in this article. The construction requires some delicacy: is not enough to simply stalemate the White king, since then White can play 2.Na2 with impunity; on the other hand if the White king is put in Zugzwang (so that it has some legal moves, but all of them lose), then the direct 1 ... a2 2.N×a2 K×a2 wins for Black.

Even more important for the practical chessplayer is the distance function on $\mathcal{G}$, which encodes the number of moves a knight needs to get from any square to any other. The diameter (maximal distance) on $\mathcal{G}$ is 6, which is attained only by diagonally opposite corners. This is to be expected, but shorter distances bring some surprises. The following table shows the distance from each vertex of $\mathcal{G}$ to a corner square:

5	4	5	4	5	4	5	6
4	3	4	3	4	5	4	5
3	4	3	4	3	4	5	4
2	3	2	3	4	3	4	5
3	2	3	2	3	4	3	4
2	1	4	3	2	3	4	5
3	4*	1	2	3	4	3	4
♘	3	2	3	2	3	4	5

Diagram 11



White loses

The starred entry is due to the board edges: a knight can travel from any square to any diagonally adjacent square in two moves except when one of them is a corner square. But the other irregularities of the table at short distances do not depend on edge effects. Anywhere on the board, it takes the otherwise agile knight three moves to reach an orthogonally adjacent square, and four moves to travel two squares diagonally. This peculiarity must be absorbed by any chessplayer who would learn to play with or against knights. One consequence, known to endgame theory, is Diagram 11, which exploits both the generic irregularity and the special corner case. Even with White to move, this position is a win for Black, who will play ... a2 and ... a1Q. One might expect that the knight is close enough to stop this, but in fact it would take it three moves to reach a2 and four to reach a1, in each case one too many. In

[3] Note to more advanced chessplayers: it might seem that the knight does need a bit of help after 1.Nb4 Kb1!?, when either 2.Na2? or 2.Nd3? loses (in the latter case to 2 ... a2) but Black has no threat so White can simply make a random ("waiting") king move. But this is not necessary, as White could also draw by thinking (and playing) out of the a2-b4-d3-c1-a2 box: 1.Nb4 Kb1 2.Nd5! If now 2 ... a2 then 3.Nc3+ is a new drawing fork, and otherwise White plays 3.Nb4 and resumes the square dance.

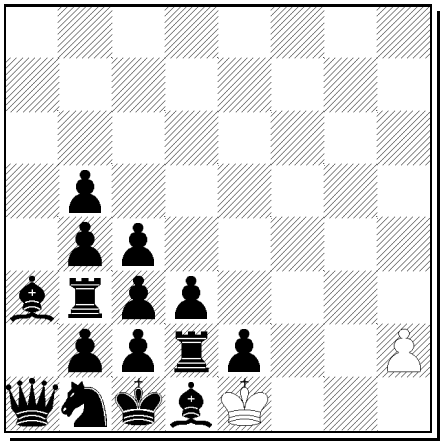
fact this knight helps Black by blocking the White king's approach to a1!

Puzzle 6. Determine the knight distance from $(0,0)$ to (m,n) on an infinite board as a function of the integers m,n.

Further puzzles

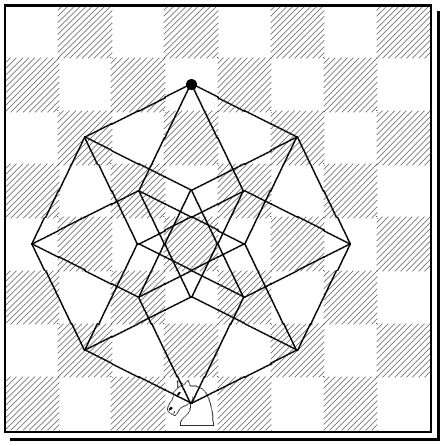
We conclude the first part with several more puzzles that exploit or extend our discussion:

Diagram 12



White to play and mate as quickly as possible

Diagram 13



the 4! shortest knight paths from d1 to d7

Puzzle 7. How does White play in Diagram 12 to force checkmate as quickly as possible against any Black defense?

Yes, it's White who wins, despite having only king and pawn against 15 Black men. But these men are almost paralyzed, with only the queen able to move in its corner prison. White must keep it that way: if he ever moves his king, Black will sacrifice his e2-pawn by promoting it, bring the Black army to life and soon overwhelm White. So White must move only the pawn, and the piece that it will promote to. That's good enough for a draw, but how to actually win?

Puzzle 8. (See Diagram 13.) There are exactly $24 = 4!$ paths that a knight on d1 can take to reach d7 in four moves; plotting these paths on the chessboard yields a beautiful projection of (the 1-skeleton of) the 4-dimensional hypercube! Explain.

Puzzle 9. We saw that there is an essentially unique maximal configuration of 32 mutually non-defending knights on the 8×8 board.
i) Suppose we allow each knight to be defended at most once. How many more knights can the board then accommodate?
ii) Now suppose we require each knight to be defended *exactly* once. What is the largest number of knights on the 8×8 board satisfying this constraint, and what are all the maximal configurations?

Puzzle 10. A "camel" is a $(3,1)$ leaper, that is, an unorthodox chess piece that moves from (x,y) to one of the squares $(x \pm 3, y \pm 1)$ or $(x \pm 1, y \pm 3)$. (A knight is a $(2,1)$ leaper.) Since there are eight such squares, it takes at least $mn/8$ camels to defend every square, occupied or not, on an $m \times n$ board. Are $mn/8 + O(m+n)$ sufficient, as in Puzzle 4?

Synthetic games

The remainder of this article will be devoted to composed chess problems featuring knights. A *synthetic game* [13] is a chess game composed (rather than played) in order to achieve some objective, usually in a minimal number of moves. Ideally the solution should be unique, but this is very rare. Failing this, we can hope for an "almost unique" solution, e.g., one where the final position is unique though not the move order. For instance, the shortest game ending in checkmate by a knight is 3.0 moves: 1.e3 Nc6 2.Ne2 Nd4 3.g3 Nf3 mate. White can vary the order of his moves and can play e4 and/or g4 instead of e3 and g3. The Black knight has two paths to f3. The biggest flaw, however, is that White could play c3/c4 instead of g3/g4, and Black could mate at d3. At least all 72 solutions share the central feature that White incarcerates his king at its home square. A better synthetic game involving a knight is the following.

Puzzle 11. Construct a game of chess in which Black checkmates White on Black's fifth move by promoting a pawn to a knight.

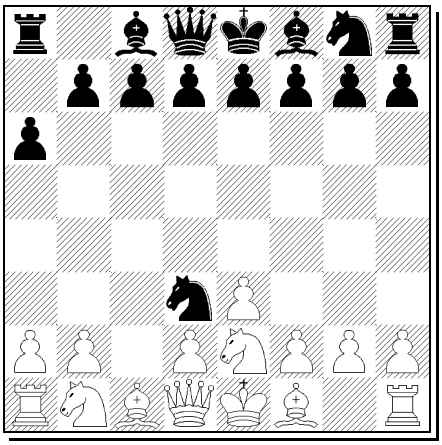
Proof games

A very successful variation of synthetic games that allows unique solutions are *proof games*, for which the length n of the game and the final position P are specified. In order for the condition (P, n) to be considered a sound problem, there should be a *unique* game in n moves ending in P. (Sometimes there will be more than one solution, but they should be related in some thematic way. Here we will only consider conditions (P, n) that are uniquely realizable, with the exception of Diagram 17.)

The earliest proof games were composed by the famous "Puzzle King" Sam Loyd in the 1890's but did not have unique solutions; the earliest sound (by today's standards) proof game seems to have been composed by T. R. Dawson in 1913. Although some interesting proof games were composed in subsequent years, the vast potential of the subject was not suspected until the fantastic pioneering efforts of Michel Caillaud in the early 1980's. A close to complete collection of all proof games published up to 1991 (around 160 problems) appears in [28].

Let us consider some proof games related to knights. We mentioned above that the shortest game ending in mate by knight has length 3.0 moves. None of the 72 solutions yield proof games with unique solutions, i.e., every terminal position has more than one way of reaching it in 3.0 moves. It is therefore natural to ask for the least number n (either an integer or half-integer) for which there exists a *uniquely realizable* game of chess in n moves ending with checkmate by knight, i.e., given the final position, there is a unique game that reaches it in n moves. Such a game was found independently by the two authors of this article in 1996 for $n = 4.0$, which is surely the minimum. The final position is shown in Diagram 14.

Diagram 14



Position after Black's 4th move. How did the game go?

Five other proof game problems involving knights are the following. The minimum known number of moves for achieving the game is given in parentheses. (We repeat that the game must be uniquely realizable from the number of moves and final position.)

Puzzle 12. Construct a proof game without any captures that ends with mate by a knight (4.5).

Puzzle 13. Construct a proof game ending with mate by a knight making a capture (5.5)

Puzzle 14. Construct a proof game ending with mate by a pawn promoting to a knight (5.5).

Puzzle 15. Construct a proof game ending with mate by a pawn promoting to a knight without a capture on the mating move (6.0).

Puzzle 16. Construct a proof game ending with mate by a pawn promoting to a knight with no captures by the mating side throughout the game (7.0).

There is a remarkable variant of Puzzle 14. Rather than having the game determined by its final position and number of moves, it is instead completely determined by its last move (including the move number)! This is the longest known game with this property.

Puzzle 14′. Construct a game of chess with last move 6.g×f8N mate.

The above proof games focused on achieving some objective in the minimum number of moves. Many other proof games in which knights play a key role have been composed, of which we give a sample of five problems. Diagrams 15, 16, and 17 feature "impostors"—some piece(s) are not what they seem. The first of these (Diagram 15) is a classic problem that is one of the earliest of all proof games, while Diagram 16 is considerably more challenging. Diagram 17 features a different kind of impostor. Note that it has two solutions; it is remarkable how each solution has a different impostor. The complex and difficult Diagram 18 illustrates the *Frolkin theme*: the multiple capture of promoted pieces. Diagram 19 shows, in the words of Wilts and Frolkin [28, p. 53], that "the seemingly indisputable fact that a knight cannot lose a tempo is not quite unambiguous."

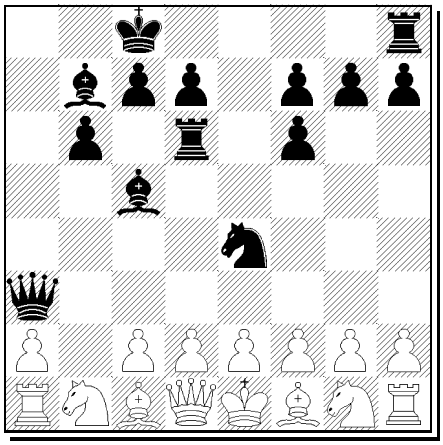
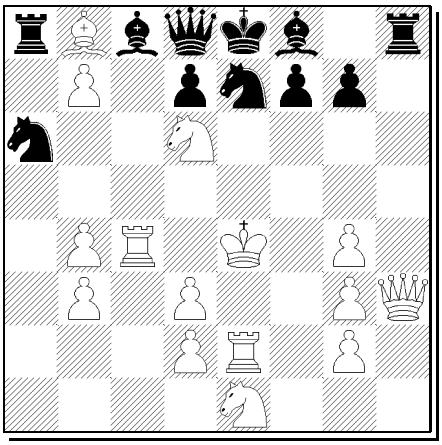
Diagram 17



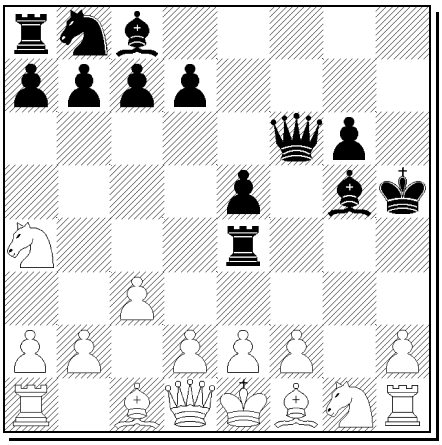
After White's 13th. How did the game go? Two solutions!

Diagram 18



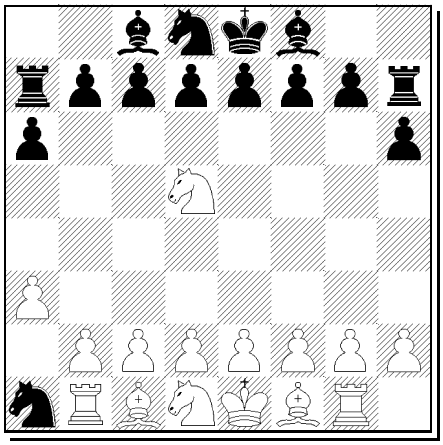
After White's 27th. How did the game go?

Diagram 19



After Black's 10th move. How did the game go?

Diagram 20



Mate in one

Retrograde analysis

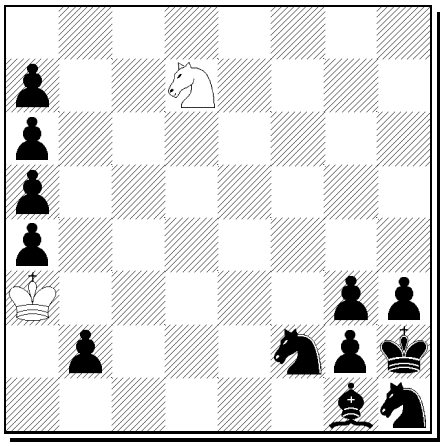
In retrograde analysis problems (called retro problems for short), it is necessary to deduce information from the current position concerning the prior history of the game. It is only assumed that the prior play is legal; no assumption is made that the play is "sensible." Proof games are a special class of retro problems. We will give only one illustration here of a retro problem that is not a proof game. It is based on considerations of parity, a common theme whenever knights are involved. Diagram 20 is a *mate in one*. A chess problem with this stipulation almost invariably involves an element of retrograde analysis, such as determining who has the move.[4]

Length records

[4] In a problem with the stipulation "Mate in n," it is assumed that White moves first unless it can be proved that Black has the move in order for the position to be legal.

Here one tries to construct a position that maximizes the number of moves which must elapse before a certain objective is satisfied. The most obvious and most-studied objective is checkmate. In other words, how large can n be in a problem with the objective "mate in n" (i.e., White to play and checkmate Black in n moves)? Chess problem standards demand that the solution should be unique if at all possible. It is too much to expect, especially for long-range problems, that White has a unique response to *every* Black move in order for White to achieve his objective. In other words, it is possible for Black to defend poorly and allow White to achieve his objective in more than one way, or even achieve it earlier than specified. The correct uniqueness condition is that the problem should be *dual-free*, which means that Black has at least one method of defending which forces each White move uniquely if White is to achieve his objective. The objective of checkmate can be combined with other conditions, such as White having only one unit besides his king. The ingenious Diagram 21 shows the current record for a "knight minimal," i.e., White's only unit besides his king is a knight. For other length records, as well as many other tasks and records, see [20].

Diagram 21



Mate in 48

Paradox

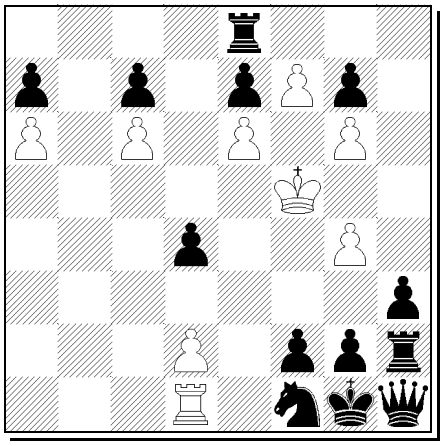
The term "paradox" has several meanings in both mathematics and ordinary discourse. We will regard a feature of a chess problem (or chess game) as paradoxical if it is seemingly opposed to common sense. For instance, common sense tells us that a material advantage is beneficial in winning a chess game or mating quickly. Thus *sacrifice* in an orthodox chess problem (i.e., a direct mate or study) is paradoxical. Of course it is just this paradoxical element that explains the appeal of a sacrifice. Another common paradoxical theme is underpromotion. Why not promote to the strongest possible piece, namely, the queen? This theme is related to that of sacrifice, since in each case the player is forgoing material. To be sure, underpromotion to knight in order to win, draw, or checkmate quickly is not so surprising (and has even occurred a fair number of times in games) since a knight can make moves forbidden to a queen. Tim Krabbé thus remarks in [15] that knighting hardly counts as a true "underpromotion."[5] Nevertheless, knight promotions can be used for surprising purposes that heighten the paradoxical effect.

Diagram 22 shows four knight sacrifices, all promoted pawns, with a total of five promotions

[5] More paradoxical are underpromotions to rooks and bishops, but we will not be concerned with them here.

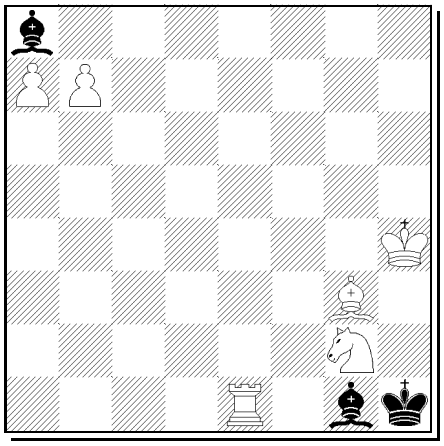
to knight. Diagram 23 shows a celebrated problem composed by Sam Loyd where a pawn promotes to a knight that threatens no pieces or checks and is hopelessly out of play. For some interesting comments by Loyd on this problem, see [27, p. 403].

Diagram 22



White to play and win

Diagram 23



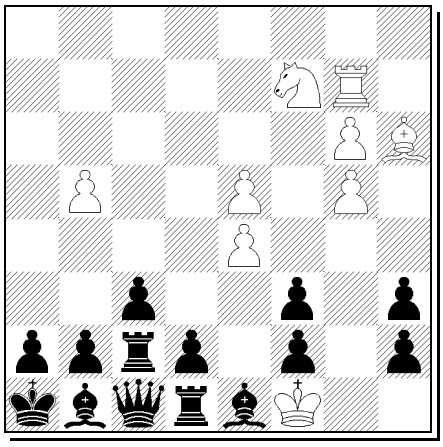
Mate in 3

Note that the impostors of Figures 15–17 may also be regarded as paradoxical, since we're trying to reach the position as quickly as possible, and it seems a waste of time to move knights into the original square(s) of other knights. Similarly the time-wasting 5.h×g8N 6.Nh6 7.N×f7 of Diagram 19 seems paradoxical—why not save a move by 5.h×g8B and 6.B×f7+?

Helpmate

In a *helpmate in n moves*, Black moves first and *cooperates* with White so that White mates Black on White's nth move. If the number of solutions of a helpmate is not specified, then there should be a unique solution. For a long time it was thought impossible to construct a sound helpmate with the theme of Diagram 24, featuring knight promotions. Note that the first obstacle to overcome is the avoidance of checkmating White or stalemating Black. The composer of this brilliant problem, Gabor Cseh, was tragically killed in an accident in 2001 at the age of 26.

Diagram 24

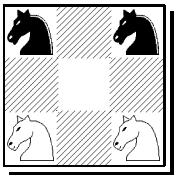


Helpmate in 10

Piece shuffle

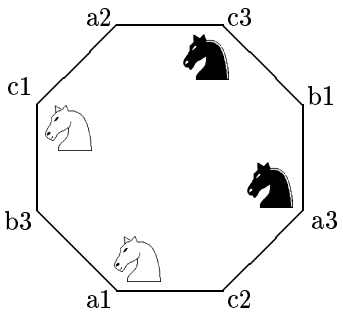
In *piece shuffles* or *permutation tasks*, a rearrangement of pieces is to be achieved in a minimum number of moves, sometimes subject to special conditions. They may be regarded as special cases of "moving counter problems" such as given in [2, pp. 769–777] or [3, pp. 58–68]. A classic example involving knights, going back to Guarini in 1512, is shown in Diagram 25. The knights are to exchange places in the minimum number of moves. (Each White knight ends up where a Black knight begins, and *vice versa*.) The systematic method for doing such problems, first enunciated by Dudeney [3, solution to #341] and called the method of "buttons and strings," is to form a graph whose vertices are the squares of the board, with an edge between two vertices if the problem piece (here a knight) can move from one vertex to the other. For Diagram 25 the graph is just an eight-cycle (with an irrelevant isolated vertex corresponding to the center square of the board). See Diagram 26. This representation of the problem makes it quite easy to see that the minimum number of moves is sixteen (eight by each color), achieved for instance by cyclically moving each knight four steps clockwise around the eight-cycle. If a White knight is added at b1 and a Black knight at b3, then somewhat paradoxically the minimum number of moves is reduced to eight! A variation of the stipulation of Diagram 25 is the following problem, whose solution is a bit tricky and essentially unique.

Diagram 25



Exchange the knights
in a minimum number of moves

Diagram 26



The graph corresponding
to Diagram 25

Puzzle 17 In Diagram 25 exchange the knights in a minimum number of move sequences, where a "move sequence" is an unlimited number of consecutive moves by the same knight.

For some more sophisticated problems similar to Diagram 25, see [10, pp. 114–124]. The most interesting piece shuffle problems connected with the game of chess (though not focusing on knights) are due to G. Foster [5, 6, 7, 8], created with the help of his computer program WOMBAT (Work Out Matrix By Algorithmic Techniques).

Puzzle answers, hints, and solutions

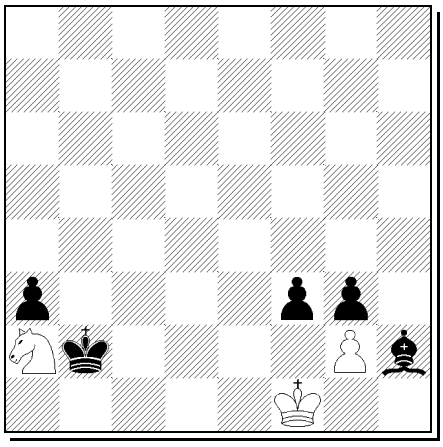
1 The graph $\mathcal{G}_{m,n}$ is connected for $m = n = 1$ (only one vertex) and not connected for $m = n = 3$ (the central square is an isolated vertex). With those two exceptions, $\mathcal{G}_{m,n}$ is connected if and only if $m > 2$ and $n > 2$. Every $G_{m,n}$ is bipartite, except $G_{1,1}$ (empty parts not allowed); each non-connected graph $G_{m,n}$ is bipartite in several ways except for $\mathcal{G}_{1,2} = \mathcal{G}_{2,1}$.

2 If $m = 1$ or $n = 1$ then $\mathcal{G}_{m,n}$ is disconnected, so the maximal coclique is the set of all mn vertices. The graph $\mathcal{G}_{2,n}$ (or $\mathcal{G}_{n,2}$) decomposes into two paths of length $\lfloor n/2 \rfloor$ and two of length $\lceil n/2 \rceil$. It thus has a one-factor if an only if $4|n$, and otherwise has cocliques of size $> n$; the maximal coclique size is $n + \delta$ where $\delta \in \{0, 1, 2\}$ and $n \equiv \pm\delta \bmod 4$. If m and n are odd integers greater than 1 then the maximal coclique size of $\mathcal{G}_{m,n}$ is $(mn+1)/2$, attained by placing a knight on each square of the same parity as a corner square of an $m \times n$ board. One can prove that this is maximal by deleting one of these squares and constructing a one-factor on the remaining $mn - 1$ vertices of $\mathcal{G}_{m,n}$.

3 Each of the four 2×2 corner subboards requires at least three knights, and no single knight may occupy or defend squares in two different subboards. Hence at least $4 \cdot 3 = 12$ knights are needed. For three knights to cover the $\{\mathrm{a1}, \mathrm{b1}, \mathrm{a2}, \mathrm{b2}\}$ subboard, one of them must be on c3; likewise f3, f6, c6 must be occupied if 12 knights are to suffice. It is now easy to verify that Diagram 9 and its reflection are the only ways to place the remaining 8 knights so as to cover the entire chessboard.

4 ([3, #319, p. 127]) On an infinite chessboard, each square of odd parity is a knight-move away from exactly one of the squares with coordinates $(2x, 2y)$ with $x \equiv y \bmod 4$. Intersecting this lattice with an $m \times n$ chessboard yields $mn/16 + O(m + n)$ knights that cover all odd squares at distance at least 3 from the nearest edge. Thus an extra $O(m + n)$ knights defend all the odd squares on the board. The same construction for the even squares yields a total of $mn/8 + O(m + n)$.

Diagram 27



White to move draws

5 One such position is Diagram 27 above. Once the a-pawn is gone, the position is a theoretical draw whether Black plays f×g2+ (Black can do no better than stalemate against K×g2, Kh1, Kg2 etc.) or f2 (ditto after Ke2, Kf1, etc.), or lets White play g×f3 and Kg2 and then jettison the f-pawn to reach the same draw that follows f×g2+. But as long as Black's a-pawn is on the board, White can move only the knight since g×f3 would liberate Black's bishop which could then force White's knight away (for instance 1.Nb4 Kb1 2.g×f3? g2+! 3.K×g2 Bd6 4.Nd5 Kb2) and safely promote the a-pawn. Black's pawn on f3 could also be on h3 with the same effect.

6 The distance is an integer, congruent to $m+n$ mod 2, that equals or exceeds each of $|m|/2$, $|n|/2$, and $(|m|+|n|)/3$. It is the smallest such integer except when in the cases already noted of $(m,n) = (0,\pm1)$, $(\pm1,0)$, or $(\pm2,\pm2)$, when the distance exceeds the above lower bound by 2.

7 (adapted from Gorgiev) To win, White must promote the pawn to a knight, capture the pawns on b5 and c4, and then mate with N×b3 when the Black queen is on a1. Thus N×b3 must be an odd-numbered move. Therefore 1.h4, 2.h5, 3.h6, 4.h7, 5.h8N does not work because all knight paths from h8 to b3 have odd length. Since the knight cannot "lose the move", the pawn must do so on its initial move: 1.h3!, followed by 6.h8N!, 7.Nf7, 8.Nd6, 9.N×b5, 10.Nd6, 11.N×c4, 12.Na5. At this point the Black queen is on a2, having made 11 moves from the initial position; whence the conclusion: 12 ... Qa1 13.N×b3 mate. (We omitted from Gorgiev's original problem the initial move 1.Kf2×Ne1 Qa2-a1, which only served to give Black his entire army in the initial position and thus maximize the material disparity; and moved a Black pawn from c5 to b5 to make the solution unique, at some cost in strategic interest.)

8 Recall that a knight's move joins squares differing by one of the eight vectors $(\pm1,\pm2)$ or $(\pm2,\pm1)$, and check that to get some four of those to add to $(0,6)$ we must use the four vectors with a positive ordinate in some order. Thus, to reach d7 from d1 (or, more generally, to travel six squares north with no obstruction from the edges of the board) in four moves, the knight must move once in each of its four north-going directions. Therefore a path corresponds to a permutation of the four vectors $(\pm1,2)$ and $(\pm2,1)$. The number of paths is thus $4! = 24$, and drawing them all yields the image of the 4-cube under a projection taking the unit vectors to $(\pm1,2)$ and $(\pm2,1)$. Instead of d1 and d7 we could also draw the

24 paths from a4 to g4 in four moves to get the same picture. Not b2 and f6, though: besides the 24 paths of Diagram 13 there are other four-move journeys, for instance b2-d3-f4-h5-f6.

9 (i) The maximum is still 32 (though there are many more configurations that attain this maximum). To show this, it is enough to prove that at most 8 knights can fit on a 4×4 board if each is to be defended at most once. This in turn can be seen by decomposing $\mathcal{G}_{4,4}$ as a union of four 4-cycles (Diagram 28), and noting that only two knights can fit on each 4-cycle.

(ii) Once again, the maximum is 32, this time with a new configuration (Diagram 29) unique up to reflection! (But note that this configuration has a cyclic group of 4 symmetries, unlike the elementary abelian 2-group of symmetries of the maximal coclique (Diagram 6).) That this is maximal follows from the first part of this puzzle. For uniqueness, our proof is too long to reproduce here in full; it proceeds as follows. In any 32-knight configuration, each of the four 4×4 corner subboards must contain 8 knights, two on each of its four 4-cycles. We analyze cases to show that it is impossible for two knights in different subboards to defend each other. We then show that Diagram 29 and its reflection are the only ways to fit four 8-knight configurations into an 8×8 board under this constraint.

10 Yes, $mn/8+O(m+n)$ camels suffice. The camel always stays on squares of the same color. The squares of one color may be regarded on a chessboard in its own right, tilted 45° and magnified by a factor of $\sqrt{2}$ — in other words, multiplied by the complex number $1+i$. On this board, the camel's move amounts to the ordinary knight's move since $3+i = (2-i)(1+i)$. We can thus adapt our solution of Puzzle 4. Explicitly, on an infinite chessboard each square with both coordinates odd is a camel's move away from exactly one square of the form $(4x, 8y)$. Thus camels at $(4x + a, 8x + b)$ $(a, b \in \{0, 1\})$ cover the entire board without duplication, and the intersection of this configuration with an $m \times n$ board covers all but $O(m + n)$ of its squares.

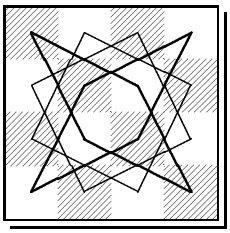

Diagram 29

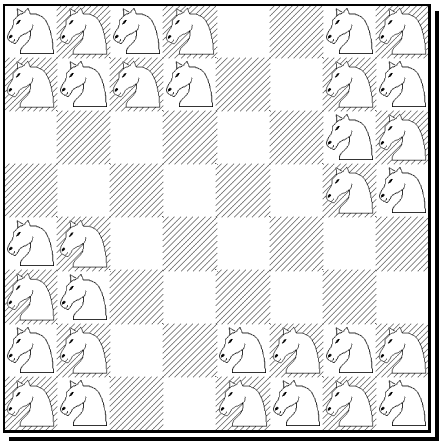

Solution of Puzzle 8(ii)

11 1.d3 e5 2.Kd2 e4 3.Kc3 e×d3 4.b3 d×e2 5.Kb2 e×d1N mate. White can play d4 instead of d3 (so Black plays e×d4) and can vary his move order, but the final position is believed to be unique. This game first appeared in [17].

12 (G. Forslund, Retros Mailing List, June 1996) 1.e3 f5 2.Qf3 Kf7 3.Bc4+ Kf6 4.Qc6+ Ke5 5.Nf3 mate.

13 (G. Wicklund, Retros Mailing List, October 1996) 1.Nf3 e6 2.Ne5 Ne7 3.N×d7 e5 4.N×f8 Bd7 5.Ne6 Rf8 6.N×g7 mate.

14 (P. Rössler, *Problemkiste*, August 1994 (version)) 1.h4 d5 2.h5 Nd7 3.h6 Ndf6 4.h×g7 Kd7 5.Rh6 Ne8 6.g×f8N mate.

15 (G. Donati, Retros Mailing List, June 1996) 1.h4 g6 2.Rh3 g5 3.Re3 g×h4 4.f3 h3 5.Kf2 h2 6.Qe1 h1N mate.

16 (O. Heimo, Retros Mailing List, June 1996) 1.d4 e5 2.d×e5 d5 3.Qd4 Be6 4.Qb6 d4 5.Kd2 d3 6.Kc3 d2 7.a3 d1N mate.

14′ See solution to Puzzle 14.

17 a1-c2, c1-b3-a1, c3-a2-c1-b3, a3-b1-c3-a2-c1, c2-a3-b1-c3, a1-c2-a3, b3-c1. Seven move sequences.

Diagram solutions

Diagram 14. (N. Elkies, R. Stanley, 1996) 1.c4 Na6 2.c5 N×c5 3.e3 a6 4.Ne2 Nd3 mate.

Diagram 15. (G. Schweig, *Tukon*, 1938) 1.Nc3 d6 2.Nd5 Nd7 3.N×e7 Ndf6 4.N×g8 N×g8. The impostor is the knight at g8, which actually started out at b8.

Diagram 16. (U. Heinonen, *The Problemist* 1991) 1.c4 Nf6 2.Qa4 Ne4 3.Qc6 N×d2 4.e4 Nb3 5.Bh6 Na6! 6.Nd2 Nb4 7.Rc1 Nd5 8.Rc3 Nf6 9.Rf3 Ng8 10.Rf6 Nc5 11.f4 Na6 12.Ngf3 Nb8. Here both Black knights are impostors, as they have exchanged places! For a detailed analysis of this problem, see [16, pp. 207–209].

Diagram 17 (D. Pronkin, *Die Schwalbe*, 1985, 1st prize) 1.b4 Nf6 2.Bb2 Ne4 3.Bf6 e×f6 4.b5 Qe7 5.b6 Qa3 6.b×a7 Bc5 7.a×b8B Ra6 8.Ba7 Rd6 9.Bb6 Kd8 10.Ba5 b6 11.Bc3 Bb7 12.Bb2 Kc8 13.Bc1.

1.Nc3 Nf6 2.Nd5 Ne4 3.Nf6+ e×f6 4.b4 Qe7 5.b5 Qa3 6.b6 Bc5 7.b×a7 b6 8.a×b8N Bb7 9.Na6 0-0-0 10.Nb4 Rde8 11.Nd5 Re6 12.Nc3 Rd6 13.Nb1. This problem illustrates the *Phoenix theme*: a piece leaves its original square to be sacrificed somewhere else, then a pawn promotes to exactly the same piece which returns to the original square to replace the sacrificed piece. In the first solution the bishop at c1 is phoenix, while in the second it is the knight at b1! As if this weren't spectacular enough, Black castles in the second solution but not the first.

Diagram 18. (M. Caillaud, *Thèmes-64*, 1982, 1st prize) 1.a4 c5 2.a5 c4 3.a6 c3 4.a×b7 a5 5.Ra4 Na6 6.Rc4 a4 7.b4 a3 8.Bb2 a2 9.Na3 a1N! 10.Nb5 Nb3 11.c×b3 c2 12.Be5 c1N! 13.Bb8 Nd3+ 14.e×d3 e5 15.Qg4 e4 16.Ke2 e3 17.Kf3 e2 18.Ke4 e×f1N! 19.Nf3 Ng3+ 20.h×g3 h5 21.Re1 h4 22.Re2 h3 23.Ne1 h2 24.Qh3 h1N! 25.g4 Ng3+ 26.f×g3 Ne7 27.Nd6 mate. An amazing four promotions by Black to knight, all captured!

Diagram 19. (A. Frolkin, *Shortest Proof Games*, 1991) 1.g4 e5 2.g5 Be7 3.g6 Bg5 4.g×h7 Qf6 5.h×g8N! Rh4 6.Nh6 Re4 7.N×f7 K×f7 8.Nc3 Kg6 9.Na4 Kh5 10.c3 g6. If 5.h×g8B? Rh4 6.B×f7+ K×f7 7.Nc3 Re4 8.Na4 Kg6 9.c3 Kh5, then White must disturb his position before 10... g6. A knight is able to "lose a tempo" by taking two moves to get from g8 to f7, while a bishop must take one or at least three moves.

Diagram 20. (V. A. Korolikov, *Schach*, 1957) White's knights are on squares of the same color and hence have made an odd number of moves in all. Each White rook and the White king have made an even number of moves, and White has made one pawn move. No other

White unit (i.e., the queen and bishops) have moved. Hence White has made an even number of moves in all. Similarly Black has made an odd number of moves. Since White moved first it is currently Black's move, so Black mates in one with 1...N×c2 mate.

Diagram 21. (P. O'Shea, *The Problemist*, 1989, 1st prize) 1.Ne5 b1N+ (the only defense to 2.Nf3 mate) 2.Ka2 Nd2 3.Ka1 Nb3+ 4.Kb1 Nd2+ 5.Ka2. If Black moves either knight then checkmate is immediate, so 5... a3 is forced. Now White and Black repeat the maneuver Ka1, Nb3+, Kb1, Nd2+, Ka2 (any pawn moves by Black would just hasten the end): 8.Ka2 a4 11.Ka2 a5 14.Ka2 a6. Then 15.Ka1 Nb3+ 16.Kb1 a2+ 17.K×a2 Nd2. This manuever gets repeated until all Black's a-pawns are captured: 44.K×a2 Nd2 45.Ka1 Nb3+ 46.Kb1 Nd2+ 47.Ka2. Finally Black must allow 48.Nf3 mate or 48.Ng4 mate!

Diagram 22. (H. M. Lommer, *Szachy*, 1965) White cannot allow Black's rook at e8 to stay on the board, but how does White prevent Black from being stalemated without releasing the sleeping units in the h1 corner? 1.f×e8N d3 2.Nf6 (not 2.Nd6? e×d6, and stalemate cannot be prevented without releasing the h1 corner) g×f6 (capturing with the other pawn merely hastens the end) 3.g5 f×g5 4.g7 g4 5.g8N g3 6.Nf6 e×f6 7.Kg6 f5 8.e7 f4 9.e8N f3 10.Nd6 c×d6 11.c7 d5 12.c8N d4 13.Nb6 a×b6 14.a7 b5 15.a8N and wins, as White can play 19 N×f3 mate just after 18... b1Q. For the history of this problem, see [25, pp. xxi–xxii].

Diagram 23. (S. Loyd, *Holyoke Transcript*, 1876) 1.b×a8N! K×g2 2.Nb6, followed by 3.a8Q (or B) mate. Note that a knight is needed to prevent 2... B×a7. A queen or bishop promotion at move one would be stalemate, and a rook promotion leads nowhere. Normally a key move of capturing a piece is considered a serious flaw since it reduces Black's strength. Here, however, the capture seems to accomplish nothing so it is acceptable. Loyd himself says "[i]f the capture seems a hopeless move ...then it is obviously well concealed, and the most difficult key-move that could be selected" [18, p. 156]. For further problems by Loyd featuring distant knight promotion, see [27, pp. 402–403].

Diagram 24. (G. Cseh, *StrateGems*, 2000, 1st prize) 1.h1N! Nd6 2.h2 Nf5 3.Ng3+ N×g3 4.h1N! Ne2 5.f×e2+ Kg2! (not 5... K×e2?, since Black's tenth move would then check White) 6.f1N! Rc7 7.Bg3 R×c3 8.B×e5 R×c2 9.Bg7 R×c1 10.b×c1N! B×g7 mate. Four promotions to knight by Black.

Exploiting the Induced Order on Type-Labeled Graphs for Fast Knowledge Retrieval (1994) (Make Corrections) (6 citations)

Gerard Ellis, Fritz Lehmann

International Conference on Conceptual Structures

Abstract: . The graph structure of a conceptual graph can be used for efficient retrieval in complex (graphical) object databases. The aim is to replace most graph matching with efficient operations on precompiled codes for graphs. The unlabeled graph or "skeleton" of a type-labeled conceptual graph (without negated contexts) can be used as a filter for matching, subsumption testing, and unification. For two type-labeled graphs to match, their skeletons must first match. One type-labeled graph can... (Update)

EXPECTED NUMBER OF INVERSIONS AFTER A SEQUENCE OF RANDOM ADJACENT TRANSPOSITIONS — AN EXACT EXPRESSION

NIKLAS ERIKSEN

Abstract. A formula for calculating the expected number of inversions after t random adjacent transpositions has been presented by Eriksson et al. We have improved their result by determining a formula for the unknown integer sequence d_r that was used in their formula and also made the formula valid for large t.

Résumé. Une formule pour calculer le nombre attendu d'inversions après t transpositions adjacentes aléatoires a été présentée par Eriksson et al. Nous avons amélioré ce résultat en déterminant une formule pour la séquence inconnue d'entiers d_r, qui était utilisée dans leur formule et qui rendait la formule valide lorsque t prend une grande valeur.

1. Introduction

In a recent article [1], the Eriksson-Sjöstrand family calculated the expected number of inversions in a permutation, given the number of adjacent transpositions applied to it. Problems of this type have applications in computational biology, where the genome may be regarded as a permutation of genes. Consider two such genomes π and ρ, in which we have named the genes such that $\rho = id$. The evolutionary distance between π and ρ is assumed to be proportional to the number of evolutionary operations that have changed the gene order since the two genomes diverged. To calculate this number of operations, we can either calculate the least number of operations needed to transform π into $\rho = id$ (this corresponds to sorting π), which gives a lower bound of the true number of operations, or we can calculate the expected number of operations, given some measure on the difference between the two genomes. One such common measure is the number of breakpoints, that is the number of adjacencent pairs in π that are not consecutive.

In the paper by Eriksson et al., they calculated the inverse of the second alternative: they found the expected measure of difference given a certain number of operations. With this information, we may determine this measure of difference between two given genomes and then extract the number of operations that is expected to produce this difference. The same approach has been taken by Wang [2], for breakpoints and the long range inversions and transpostions usually considered in computational biology.

As mentioned, Eriksson et al. considered inversions and adjacent transpositions. Their result is the following

Theorem 1.1. *The expected number of inversions in a permutation in S_{n+1} after t random adjacent transpositions is, for $n \geq t$,*

$$E_{nt} = \sum_{r=0}^{t} \frac{(-1)^r}{n^r} \left[\binom{t}{r+1} 2^r C_r + 4 d_r \binom{t}{r} \right],$$

where d_r is an integer sequence that begins with $0, 0, 0, 1, 9, 69, 510$ and C_r are the Catalan numbers.

There are a couple of things that can be improved in the result of Eriksson et al. First, their formula includes some numbers d_r that they have no expression formula for. Second, the formula is only valid for $n \geq t$.

In this paper, we will present an improved formula, where both these flaws have been eliminated. The theorem is given directly below, and the proof will appear in the following sections.

Supported by a grant from the Swedish Research Council.

Theorem 1.2. *The expected number of inversions in a permutation in S_{n+1} after t random adjacent transpositions is*

$$E_{nt} = \sum_{r=1}^{t} \frac{1}{n^r} \binom{t}{r} \sum_{s=1}^{r} \binom{r-1}{s-1} (-1)^{r-s} 4^{r-s} g_{s,n}.$$

The integer sequence $g_{s,n}$ is given by

$$g_{s,n} = \sum_{l=0}^{n} \sum_{k \in \mathbb{N}} (-1)^k (n-2l) \binom{2\lceil \frac{s}{2} \rceil - 1}{\lceil \frac{s}{2} \rceil + l + k(n+1)} \sum_{j \in \mathbb{Z}} (-1)^j \binom{2\lfloor \frac{s}{2} \rfloor}{\lfloor \frac{s}{2} \rfloor + j(n+1)}$$

For $n \geq t$, we get

$$E_{nt} = \sum_{r=0}^{t} \frac{(-1)^r}{n^r} \left[2^r C_r \binom{t}{r+1} + 2 \binom{t}{r} \sum_{s=3}^{r} \binom{r-1}{s-1} (-1)^{s-1} 4^{r-s} \binom{2\lfloor \frac{s}{2} \rfloor}{\lfloor \frac{s}{2} \rfloor} \sum_{l=0}^{\lfloor \frac{s-1}{2} \rfloor} l \binom{2\lceil \frac{s}{2} \rceil - 1}{\lceil \frac{s}{2} \rceil + l} \right]$$

where C_r are the Catalan numbers. Thus, the sequence d_r is given by

$$d_r = \frac{1}{2} \sum_{s=3}^{r} \binom{r-1}{s-1} (-1)^{s-1} 4^{r-s} \binom{2\lfloor \frac{s}{2} \rfloor}{\lfloor \frac{s}{2} \rfloor} \sum_{l=0}^{\lfloor \frac{s-1}{2} \rfloor} l \binom{2\lceil \frac{s}{2} \rceil - 1}{\lceil \frac{s}{2} \rceil + l}.$$

2. The heat flow model

To prove Theorem 1.2, we have used the heat flow model proposed by Eriksson et al. Before we state this model, we need a few definitions.

We look at the symmetric group S_{n+1}. The transposition that changes the elements π_i and π_{i+1} is denoted s_i. We let

$$\mathcal{P}_{nt} = \{s_{i_1} s_{i_2} \dots s_{i_t} : 1 \leq i_1, i_2, \dots, i_t \leq n\},$$

that is the set of sequences of exactly t adjacent transpositions.

Fix n. We define the matrix $(p_{ij})(t)$, where

$$p_{ij}(t) = \text{Prob}(\pi_i < \pi_j)$$

for a permutation $\pi \in \mathcal{P}_{nt}$, where the adjacent transpositions $s_k, 1 \leq k \leq t$ have been chosen randomly from a uniform distribution. From this, it follows that

$$E_{nt} = \sum_{i>j} p_{ij}(t).$$

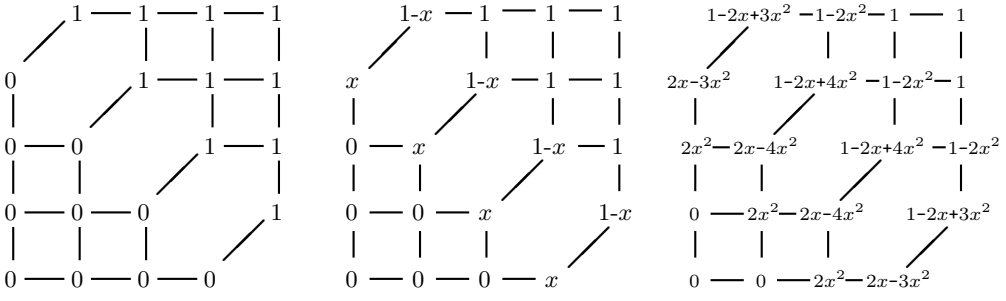

FIGURE 1. The matrices $(p_{ij})(0)$, $(p_{ij})(1)$ and $(p_{ij})(2)$ for $n = 4$.

We now define a discrete heat flow process as follows. On a (finite or infinite) graph, every vertex has at time zero some heat associated to itself. In each time step, all vertices sends a fraction x of its heat to each of its neighbours. At the same time, it will receive the same fraction of each neighbours' heat. The following proposition is proven in [1].

Proposition 2.1. *(Eriksson et al. [1]) The sequence of (p_{ij})-matrices for $t = 0, 1, 2, \dots$ describes a discrete heat flow process with conductivity $x = 1/n$ on the grid graph depicted in Figure 1 (left).*

In the same paper, they also show that we can replace the graph in Figure 1 by the grid in Figure 2. The sequence of (p_{ij})-matrices for $t = 0, 1, 2, \ldots$ describes a heat flow process on this grid graph. In this process, the heat on the diagonal will never change. Furthermore, we are only interested in the part below the diagonal. We thus get a model with two insulated boundaries (below and to the left) and one hot boundary (the diagonal). This is depicted in Figure 3.

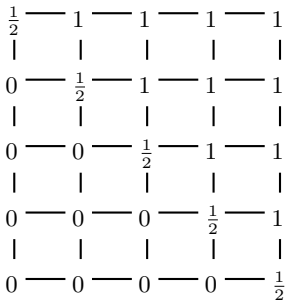

FIGURE 2. Grid graph with initial values

By reflection, we can extend this graph to a graph with no insulated boundaries (as in Figure 3). We will now calculate the amount of heat that flows from one of the borders (say the northeast one) onto this grid. This will equal the amount of heat in the upper right quarter of the grid, which is what we are trying to calculate. Remember that this heat equals E_{nt}.

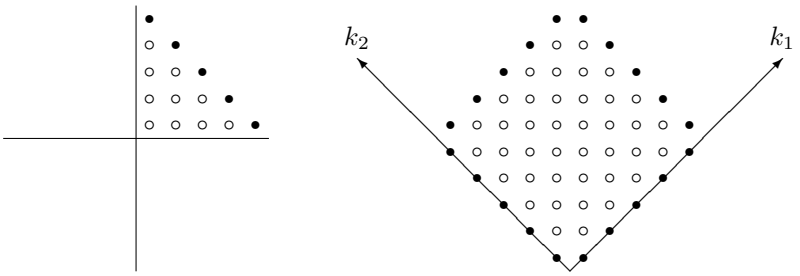

FIGURE 3. By reflection, the graph with one hot and two insulated boundaries is extended to a diamond shaped graph with no insulated boundaries. The new set of coordinates (k_1, k_2) is introduced.

The amazing thing about the heat flow model is that we can calculate the contribution from every heat packet separately, and then add them all together. In the model proposed by Eriksson et al., the vertices at the hot boundary send out heat packets with value $\frac{1}{2n}$ to their neighbours at each time step. These packets are then sent back and forth between the inner vertices. There are three possible travel steps for a packet [1]:

- It stays on the vertex unchanged.
- It travels to a neighbouring vertex, getting multiplied by $\frac{1}{n}$.
- It travels halfway to a neighbouring vertex, gets multiplied by $\frac{-1}{n}$ and returns to the vertex it came from.

Now, in order to calculate the total heat at a vertex, we sum, over all travel routes from the boundary, the heat packets that have traveled these routes. We define new coordinates k_1 and k_2 on this grid as in Figure 3 (the origin is at the bottom of the graph). If a packet has traveled from the northeast border to (i, j) in t days, we know the following.

- Out of the t days, there are r travel days. They can be chosen in $\binom{t}{r}$ ways.

- From these travel days, we must choose s true travel days, in which the packet changes vertex. This can be done in $\binom{r-1}{s-1}$ ways, since the packet must change vertex the first travel day.
- If the packet does not change vertex on a travel day, it has four direction to choose from. This gives the factor 4^{r-s}.
- The heat that reaches the destination is $\frac{(-1)^{r-s}}{2}\frac{1}{n^r}$.
- For each of the true travel days, both coordinates k_1 and k_2 change. Only paths that do not touch the boundary are valid. We will enumerate these walks, which we call **two-sided Catalan walks**.

It should be noted that Eriksson et al. used a similar approach, but only on a semi-infinite model, which gave a lower bound for E_{nt}.

We are now able to prove the first part of Theorem 1.2. We will sum over all vertices in the diamond graph, and for each vertex over all paths from the northeast border. These paths will display two-sided Catalan walks from $(0,a)$ to (s,b) (with a odd), where the y-coordinate corresponds to k_2, and two-sided Catalan walks from $(0,1)$ to $(s-1,b)$ where the y-coordinate corresponds to $2n+2-k_1$. Let $b_{s,n}$ and $c_{s-1,n}$ be the number of such two-sided Catalan walks, respectively. This yields, with $x=1/n$,

$$E_{nt} = \frac{1}{2}\sum_{r=1}^{t}\frac{1}{n^r}\binom{t}{r}\sum_{s=1}^{r}\binom{r-1}{s-1}(-1)^{r-s}4^{r-s}b_{s,n}c_{s-1,n}.$$

Thus, the first part of the theorem is proven (we have, of course, $g_{s,n} = \frac{b_{s,n}c_{s-1,n}}{2}$).

3. Two-sided Catalan walks

We start by formally defining two-sided Catalan walks and then proceed to enumerate them.

Definition 3.1. *A* **two-sided Catalan walk of height** n *is a walk on the integer grid from* $(0,a)$ *to* (s,b)*, where* $a,b\in\{1,2,\dots n-1\}$ *and* $s>0$*, allowing only the steps* $(1,1)$ *and* $(1,-1)$*, such that* $0<y<n$ *at all positions along the way.*

We see that the number of two-sided Catalan walks from $(0,1)$ to $(2k,1)$ is C_k (ordinary Catalan numbers) if the height is larger than $k+1$ (we can never hit the ceiling then).

Proposition 3.2. *The number of two-sided Catalan walks of height* n *from* $(0,a)$ *to* (s,b) *is given by*

$$\sum_{k\in\mathbb{Z}}\left(\binom{s}{\frac{s+b-a+2kn}{2}}-\binom{s}{\frac{s-b-a+2kn}{2}}\right)$$

or 0, if $s+b-a$ *is an odd number.*

This proposition can be proven using the standard reflection argument, in combination with the principle of inclusion-exclusion.

With this proposition, we are able to determine $b_{s,n}$ and $c_{s,n}$. We start with the latter.

Lemma 3.3. *The number of two-sided Catalan walks of height* $2n+2$ *from* $(0,1)$ *to* (s,b) *for all* $0<b<2n+2$ *is given by*

$$c_{s,n} = \sum_{k\in\mathbb{Z}}(-1)^k\binom{s}{\frac{s+2k(n+1)}{2}}$$

if s *is an even number, and*

$$c_{s,n} = \frac{1}{2}c_{s+1,n}$$

if s *is an odd number.*

Proof. We get, for even s,

$$\begin{aligned} c_{s,n} &= \sum_{m=0}^{n} \sum_{k\in\mathbb{Z}} \left(\binom{s}{\frac{s}{2}+m+2k(n+1)} - \binom{s}{\frac{s}{2}-m-1+2k(n+1)} \right) \\ &= \sum_{k\in\mathbb{Z}} (-1)^k \binom{s}{\frac{s+2k(n+1)}{2}}. \end{aligned}$$

Most terms cancel by symmetry of the binomial coefficients. For odd s, we see that for each two-sided Catalan walk to $x = s$ we get two such walks to $x = s + 1$. □

Lemma 3.4. *The number of two-sided Catalan walks of height $2n + 2$ from $(0, a)$ to (s, b) for all $0 < a, b < 2n + 2$, a odd, is given by*

$$\begin{aligned} b_{s,n} &= 2 \sum_{l=0}^{n} \sum_{k\in\mathbb{N}} (-1)^k (n-2l) \binom{s}{\frac{s+1}{2}+l+k(n+1)} \\ &= n2^s - 2 \sum_{l=0}^{n} 2l \sum_{k\in\mathbb{N}} (-1)^k \binom{s}{\frac{s+1}{2}+l+k(n+1)} \\ &= n2^s - 4\ \beta_{s,n} \end{aligned}$$

if s is an odd number, and

$$b_{s,n} = 2b_{s-1,n} = n2^s - 8\ \beta_{s-1,n}$$

if s is an even number.

Proof. Assume s is an odd number. For all odd a but $n + 1$, we get a term $\binom{s}{\frac{s+1}{2}}$. Hence, there are n such terms. Similarily, we get $n - 2$ ($n - 1$ positive and 1 negative) $\binom{s}{\frac{s+1}{2}+1}$ and $(n-4)\binom{s}{\frac{s+1}{2}+2}$, etc. to $(n-2n)\binom{s}{\frac{s+1}{2}+n}$. We then get $(n-2n)\binom{s}{\frac{s+1}{2}+n+1}$, $(n-2(n-1))\binom{s}{\frac{s+1}{2}+n+2}$, etc. Continuing in this fashion gives the first equality in the lemma. The leading 2 comes from symmetry, adding all paths going down.

For the second equality, we use that the row sums in Pascal's triangle are 2^n.

For even s, there are b_{s-1} paths to $x = s-1$. For each of these paths, there are two valid options (up or down) for the last step. □

We have now proved the second part of our main theorem. What remains is the simplifications for $n \geq t$. Assuming this, we can simplify our formula using the following lemma.

Lemma 3.5.

$$\sum_{s=0}^{r} (-1)^s 2^{r-s} \binom{r}{s} \binom{s}{\lceil \frac{s}{2} \rceil} = C_r,$$

where C_r is the r:th Catalan number.

Proof. Consider vectors v of length $2r+1$, containing $r+1$ zeroes and r ones. The number $T(r, s)$ of such vectors that contain exactly $2s+1$ palindrome positions, i.e. positions i such that $v_i = v_{2r+2-i}$, can be found as follows. We concentrate on the first r positions. First choose which of these should be palindrome positions. Fill in the others arbitrarily. We then fill in the palindrome positions using $\lceil \frac{s}{2} \rceil$ zeroes and $\lfloor \frac{s}{2} \rfloor$ ones. All other positions can then be filled in so that the chosen palindrome positions really are palindrome positions and the other positions are not. It is easy to check that we get a valid palindrome vector, and that we do not miss any valid vectors. From this analysis, we find that

$$T(r, s) = 2^{r-s} \binom{r}{s} \binom{s}{\lceil \frac{s}{2} \rceil}.$$

It turns out that the element at position $r + 1$ is 0 if s is even and 1 otherwise. If we remove this position, we get vectors of length $2r$ with r zeroes and r ones, for even s, and $r + 1$ zeroes and $r - 1$

ones for odd s. The number of such vectors are $\binom{2r}{r}$ and $\binom{2r}{r+1}$, respectively. We thus get

$$\sum_{s=0}^{r}(-1)^s T(r,s) = \binom{2r}{r} - \binom{2r}{r+1} = C_r.$$

□

Now, for $n \geq t \geq r \geq s$, we get

$$g_{s,n} = b_{s,n}c_{s-1,n} = n2^{s-1}\binom{s-1}{\lceil \frac{s-1}{2} \rceil} - 2\binom{2\lfloor \frac{s}{2} \rfloor}{\lfloor \frac{s}{2} \rfloor}\sum_{l=0}^{\lfloor \frac{s-1}{2} \rfloor} l \binom{2\lceil \frac{s}{2} \rceil - 1}{\lceil \frac{s}{2} \rceil + l}.$$

This yields

$$E_{nt} = \sum_{r=0}^{t}\frac{(-1)^r}{n^r}\left[2^r C_r\binom{t}{r+1} + 2\binom{t}{r}\sum_{s=3}^{r}\binom{r-1}{s-1}(-1)^{s-1}4^{r-s}\binom{2\lfloor \frac{s}{2} \rfloor}{\lfloor \frac{s}{2} \rfloor}\sum_{l=0}^{\lfloor \frac{s-1}{2} \rfloor} l \binom{2\lceil \frac{s}{2} \rceil - 1}{\lceil \frac{s}{2} \rceil + l}\right].$$

4. An alternative formula

There is another way of writing E_{nt} that can be obtained using a similar model. We start with the same heat flow model, but instead of the three possible travel steps previously described, we merge two of them, giving these options:

- The packet changes vertex. It will then get multiplied with $x = \frac{1}{n}$.
- The packet does not change vertex. If it has not changed vertex before, nothing happens. Otherwise, it gets multiplied with $(1 - 4x)$.

We need no longer keep track of the true travel days (there will be no other travel days). We must, however, keep track of the first day (q) of travel. With this in mind, we easily find this expression valid:

$$E_{nt} = \frac{1}{2}\sum_{q=1}^{t}\sum_{r=0}^{t-q}\binom{t-q}{r}\left(1-\frac{4}{n}\right)^{t-q-r}\frac{1}{n^{r+1}}b_{r+1,n}c_{r,n}.$$

This gives the following theorem.

Theorem 4.1. *The expected number of inversions in a permutation in S_{n+1} after t random permutations is given by*

$$E_{nt} = \sum_{u=0}^{t-1}\left(\frac{n-4}{n}\right)^u\sum_{r=0}^{u}\binom{u}{r}\frac{1}{(n-4)^r}(2^r + \frac{2\beta_{r+1,n}}{n})c_{r,n}.$$

Proof. Trivial calculations give

$$\begin{aligned}
E_{nt} &= \frac{1}{2}\sum_{q=1}^{t}\sum_{r=0}^{t-q}\binom{t-q}{r}\left(1-\frac{4}{n}\right)^{t-q-r}\frac{1}{n^{r+1}}b_{r+1,n}c_{r,n} \\
&= \frac{1}{2}\sum_{u=0}^{t-1}\sum_{r=0}^{u}\binom{u}{r}\left(1-\frac{4}{n}\right)^{u-r}\frac{1}{n^{r+1}}b_{r+1,n}c_{r,n} \\
&= \sum_{u=0}^{t-1}\left(\frac{n-4}{n}\right)^u\sum_{r=0}^{u}\binom{u}{r}\frac{1}{(n-4)^r}(2^r + \frac{2\beta_{r+1,n}}{n})c_{r,n}.
\end{aligned}$$

□

This expression seems particularly useful for fixed n (try for instance $n = 4$). Also, it is easy to find out how much E_{nt} increases when we increase t one step. This is given by

$$\Delta_t E_{nt} = E_{n,t+1} - E_{nt} = \sum_{r=0}^{t}\binom{t}{r}\left(1-\frac{4}{n}\right)^{t-r}\frac{1}{n^{r+1}}b_{r+1,n}c_{r,n}.$$

It is easy to see that $\Delta_t E_{nt}$ is always positive for $n \geq 4$. This means that E_{nt} is monotonically increasing for almost all n. It should be pointed out that although this may seem trivial, for $n = 1$ (permutations of length 2), $E_{1,t}$ takes the values $0, 1, 0, 1, 0, 1 \ldots$, which is not a monotone sequence.

To be able to apply this in the biological context, where we wish to estimate the number of transpositions given the inversion number of a permutation, we need this monotonicity property. The reason is that when we have found an expectation value E_{nt} which is close to our number of inversions, we must be sure that we will not find a better expectation value for a much larger t. If the sequence if monotone, this can never happen.

Acknowlegdments

For help with the proof of Lemma 3.5, the author is indebted to Axel Hultman and Sloane's On-Line Encyclopedia of Integer Sequences. The translation of the abstract has been generously provided by Delphine Rousseau.

Abstract

A uniform analogue of Zsigmondy's Theorem for Elliptic Divisibility and Denominator Sequences is discussed. The conjectured result is obtained for 1-parameter families of elliptic curves using bounds for elliptic logarithms.

1 Introduction

Consider the Lucas sequence $l(n) = a^n - b^n$, where $a > b$ are positive coprime integers. The famous Zsigmondy Theorem [18] says that $l(n)$ always has a primitive divisor unless (i) $a = 2, b = 1$ and $n = 6$ or (ii) $a + b = 2^k$ and $n = 2$. The term *primitive divisor* of $l(n)$ means a prime divisor which does not divide $l(m)$ for $m < n$. This theorem has recently been generalized to give a very strong uniformity statement. Bilu, Hanrot and Voutier proved in [1] that for any $n > 30$, the n-th term of any Lucas or Lehmer sequence has a primitive divisor.

Let $\mathcal{E}$ denote an elliptic curve defined over $\mathbb{Q}$, the field of rational numbers. For background on definitions and all properties of elliptic curves used in this paper, consult [11] and [13]. Assume $\mathcal{E}$ is given by a generalized Weierstrass equation in global minimal form

$$y^2 + a_1xy + a_3y = x^3 + a_2x^2 + a_4x + a_6 \tag{1}$$

with $a_1, \ldots, a_6 \in \mathbb{Z}$. Let Q denote any rational point on $\mathcal{E}$. There are two sequences associated to the pair $(\mathcal{E}, Q)$ which I study in this paper. Form the sequence nQ of multiples of Q and write (where possible)

$$x(nQ) = a(n)/b(n)^2,$$

for coprime integers $a(n)$ and $b(n)$. If Q is torsion then $b(n)$ is a periodic sequence which is not defined on multiples of the order of Q. Call the sequence b an *Elliptic Denominator Sequence*. The analogue of Zsigmondy's Theorem was proved for Elliptic Denominator Sequences in [12] then generalized in [3].

Theorem 1. *Given a non-torsion rational point on an elliptic curve in global minimal form, let b denote the corresponding Elliptic Denominator Sequence. For all sufficiently large n, every term $b(n)$ has a primitve divisor.*

Example The point [0,0] on the elliptic curve

$$y^2 + y = x^3 - x$$

is non-torsion. Its Elliptic Denominator Sequence begins

$$0, 1, 1, 1, 1, 2, 1, 3, 5, 7, 4, 23, 29 \ldots$$

This sequence appears in the Online Encyclopedia as A006769, see [14]. Calculations suggest all terms beyond $u(10)$ have primitive divisors.

In this paper, I am going to discuss my reasons for believing that a uniform version of this theorem holds for all elliptic curves in minimal form. The proofs in [12] and [3] use Siegel's Theorem together with some local arithmetic of elliptic curves. I will re-prove the result using some elliptic transcendence theory. This hints at the kind of result which would give the uniformity statement - namely Lang's Conjecture. Although Lang's conjecture seems to

be some way from a proof, this approach does allow two positive outcomes. The first is to prove a uniformity statement for a 1-parameter family of curves and the second is to highlight the potential for a uniformity result over function fields.

Say the elliptic curve $\mathcal{E}$ forms a 1-parameter family if the coefficients $a_1, \ldots, a_6$ are polynomials in one variable T. Assuming the discriminant is not a constant polynomial, there are only finitely many values of T for which the curves in the family fail to be elliptic curves.

Example The family

$$y^2 = x^3 - T^2 x \tag{2}$$

with $T \geq 1$. An explicit form of the theorem that follows will be presented at the end of the paper.

Theorem 2. *Given a non-torsion rational point $Q(T)$ on an elliptic curve $\mathcal{E}(T)$ belonging to a 1-parameter family, let b denote the corresponding Elliptic Divisibility Sequence. For all n, greater than some uniform bound, every term $b(n)$ has a primitve divisor, provided $\mathcal{E}(T)$ is in global minimal form.*

Let $\omega(k)$ denote the number of distinct primes divisors of an integer $k \neq 0$. Let $W(N)$ the number of distinct prime divisors

$$W(N) = \omega\left(\prod_{n=1}^{N} b(n)\right)$$

which occur among the first N terms of the sequence b. How large might is $W(N)$ expected to be? It follows from Theorem 2 that

$$N - C < W(N), \tag{3}$$

for some constant C. Using the trivial bound $w(k) \ll \log k / \log\log(k+1)$ together with Lemma 5 below gives

$$W(N) \ll N^3 / \log N.$$

The results of numerical experiments suggest that the true order of $W(N)$ is approximately N^2.

2 Elliptic Divisibility Sequences

Given the pair $(\mathcal{E}, Q)$ as before, let ψ_n denote the sequence of division polynomials associated to $\mathcal{E}$. Extend this to $\mathbb{Z}$ by defining $\psi_{-n} = \psi_n$ and note that $\psi_0 = 0$ and $\psi_1 = 1$ by definition. Evaluating at Q gives the *Elliptic Divisibility Sequence* associated to the pair $(\mathcal{E}, Q)$; see [7], [10] or [17]. This sequence satsifies the recurrence relation: for all $m, n \in \mathbb{Z}$,

$$u(m+n)u(m-n) = u(m+1)u(m-1)u(n)^2 - u(n+1)u(n-1)u(m)^2. \tag{4}$$

If the point Q was integral then this is a divisibility sequence of integers, that is, $u_m | u_n$ whenever $m|n$. Otherwise, the denominators can be removed by a transformation of the form $\psi_n \mapsto c^{n^2-1}\psi_n$ for some integral c to obatin an integral sequence.

Lucas claimed to have worked with elliptic divisibility sequences although he published nothing apart from a few hints. The modern theory goes back to Morgan Ward's beautiful paper [17]. There has been interest in the divisibility properties of Elliptic Divisibility Sequences for some time. Ward himself considered this in [16] and [17]. In [4], Chudnovsky and Chudnovsky suggested these sequences might be a good source of large primes. More recently, experimental evidence in [7], together with proofs in special cases in [6], suggest that any fixed Elliptic Divisibility Sequence contains only finitely many prime terms. Shipsey [10] provides interesting links between these questions and some cryptographic applications. Technically, the sequences we study are *non-degenerate* in Morgan Ward's terminology. In his paper [17], he actually studies all sequences which satisfy (4) and not all of these come from elliptic curves; the integers for example. Any non-degenerate Elliptic Divisibility Sequence is the division sequence for some point Q on a rational elliptic curve using Morgan Ward's formulae in [17].

Although the sequence b above is a divisibility sequence associated to an elliptic curve, it is not always an Elliptic Divisibility Sequence. An important relation between the two follows: for all n

$$b(n) | u(n). \tag{5}$$

Shipsey discusses the relationship bewteen these two classes of sequence in her thesis [10]. For Elliptic Divisibility Sequences, it is possible for terms

$u(n)$ to be 0 if the underlying point is torsion. In the sequel, we will assume that the underlying point is non-torsion for both types of sequence.

Theorem 3. *Given a non-torsion rational point on an elliptic curve, let u denote the corresponding Elliptic Divisibility Sequence. For all n greater than some bound, every term $u(n)$ has a primitve divisor. Inside a fixed 1-parameter family, this bound is uniform.*

There are only finitely many primes p for which $\mathcal{E}$ fails to reduce to an elliptic curve modulo p. These are called primes of *singular reduction* (see [11]). The next Lemma was proved by Morgan Ward. He does not use the language of singular reduction, instead he makes much use of the equivalent condition; p is a prime of singular reduction if and only if it divides $\gcd(u(3), u(4))$.

Lemma 4. *Let p denote any prime of non-singular reduction. If $p|u(n)$ then $p|b(n)$.*

Proof. The proof of this Lemma is not that easy; it occupies sections 15 and 16 in [17]. The case when p does not divide n is easy however so we give that. It uses the fact that the roots of the division polynomial ψ_n are precisely the x-coordinates of the n-torsion points. Also, that ψ_n^2 is a polynomial in x whose leading coefficient is n^2. Let K denote the field generated by the x-coordinates of the n-torsion points. Let $\wp$ denote any prime ideal of K lying above p. The condition that $p|u(n)$ implies that $x(Q) \equiv x(T) \bmod \wp$ for some n-torsion point T. Since $\wp$ is a prime of non-singular reduction, we may reduce the curve modulo $\wp$. We deduce that $\wp|b(n)$. Since this is true for all $\wp|p$ it follows that p itself is a divisor of $b(n)$. See [17], section 16, for the proof in the case when $p|n$. □

The immediate consequence of Lemma 4 is that Theorem 3 follows from Theorem 2.

3 Proof of Theorem 2

In [6], [7] and more generally in [8] growth rates of u and b were considered in all valuations. The proof of the Theorem 2 relies on the following Lemma.

Lemma 5. *Suppose $\mathcal{E}$ belongs to a 1-paramter family of elliptic curves in the variable T. Suppose Q denotes a non-torsion rational point of $\mathcal{E}$. Let b denote the corresponding Elliptic Denominator Sequence. For all sufficiently large n*

$$\log |b(n)| = hn^2 + O(\log T \log n \log\log n).$$

The constant h is the global canonical height of the underlying point Q.

Proof. This follows from elliptic transcendence theory (see [5]) using an explicit version of David's Theorem first stated in [15]. Firstly, it is known that

$$\log \max\{|a(n)|, |b(n)|\} = hn^2 + O(\log \Delta),$$

where Δ denotes the discriminant of the curve. If $|b(n)| > |a(n)|$ then we are done. To obtain a bound for $\log |b(n)|$ alone requires an upper bound for $\log |a(n)/b(n)|$. Ann upper bound for this quantity is tantamount to the lower bound for the corresponding elliptic logarithms. Such a bound is provided by elliptic transcendence theory. From the Appendix in [15] (taking $r = 1$),

$$\log |a(n)/b(n)| < \exp(ch_E \log n \log\log n),$$

where c is an explicit positive constant and where h_E denotes the height of the curve. We may take $h_E = O(\log T)$ since the coefficients are polynomials in T. □

Proof of Theorem 2. Suppose n satisfies the following property: for all primes $p|b(n)$, there is $m < n$ with $p|b(m)$. We will show n is bounded. It is well-known that

$$\gcd(b(n), b(m)) = b(\gcd(n, m)). \tag{6}$$

This follows using the formal group and the standard local analysis of elliptic curves and can be found in Chapter VII of [11]. Using (6) we deduce that $p|b(m_p)$ for some m_p where m_p is a proper divisor of n. Again, using the local properties of elliptic curves, for any m with $p|b(m)$ and any integer $k \geq 1$,

$$\mathrm{ord}_p(b(mk)) = \mathrm{ord}_p(k) + \mathrm{ord}_p(b(m)). \tag{7}$$

We claim that for every prime $p|u(n)$, there is a divisor $1 < d_p|n$ such that

$$\mathrm{ord}_p(u(n)) \leq 1 + \mathrm{ord}_p(u(n/d_p)). \tag{8}$$

If $\mathrm{ord}_p(u(n)) > \mathrm{ord}_p(u(m_p))$ then, by (7), $p|n$ so take $d_p = p$. Otherwise take $d_p = n/m_p$ with strict inequality in (8). Thus, for some set W of divisors $1 < d$ of n, $u(n)$ divides

$$n \prod_{d \in W} u(n/d). \tag{9}$$

We may assume the divisors d are distinct - otherwise, simply omit any repetitions. Taking logarithms in (9) gives

$$\log u(n) \leq \log n + \sum_{d \in W} \log u(n/d). \tag{10}$$

Applying Lemma 5 gives

$$hn^2 \leq \log n + hn^2 \sum_{d \in W} 1/d^2 + O(d(n) \log T \log n \log\log n), \tag{11}$$

where $d(n)$ denotes the number of divisors of n. Now $d(n) = O(\log n)$, also since each $d > 1$,

$$\sum_{d \in W} 1/d^2 < \sum_{k=2}^{\infty} 1/k^2 = \pi^2/6 - 1 = 0.644934 \cdots < 1.$$

Therefore, for any fixed T, (11) shows n is bounded. The uniformity result follows because

$$c \log T < h,$$

where $c > 0$ is some uniform constant, depending only on the family. □

Note If it is possible to replace the bound in the Lemma by one of the form

$$\log |b(n)| = hn^2 + O(\log \Delta)$$

then a bound for n of the form $O(\sqrt{\log \Delta / h})$ would follow. Under Lang's Conjecture (see [9]), this quantity is uniformly bounded above. Lang's Conjecture seems to be far away from being proved.

Example For Example (2), a lower bound for h is given in [2]. For any non-torsion rational point Q on $y^2 = x^3 - T^2 x$,

$$\frac{1}{16} \log(2T^2) \leq \hat{h}(Q).$$

Replacing the left hand side by $\frac{1}{8}\log T$, inserting the explicit bounds from [15] and cancelling $\log T$ gives an explicit form of (11):

$$\frac{1}{8}n^2 < 0.644935n^2 + 2^{29}3^{36}5^{22}(\log n)^2 \log\log n.$$

From this follows the uniform bound for n.

On the diameter of the rotation graph of binary coupling trees

V. Fack, S. Lievens and J. Van der Jeugt[1]
Department of Applied Mathematics and Computer Science,
University of Ghent, Krijgslaan 281-S9, B-9000 Gent, Belgium

Abstract

A binary coupling tree on $n+1$ leaves is a binary tree in which the leaves have distinct labels. The rotation graph G_n is defined as the graph of all binary coupling trees on $n+1$ leaves, with edges connecting trees that can be transformed into each other by a single rotation. In this paper we study distance properties of the graph G_n. Exact results for the diameter of G_n for values up to $n = 10$ are obtained. For larger values of n we prove upper and lower bounds for the diameter, which yield the result that the diameter of G_n grows like $n \lg(n)$.

1 Introduction

In computer science and discrete mathematics, one often faces the problem of transforming one configuration into another by specified rules. The question arises of how many steps might be needed, in the worst case. This is modeled graph-theoretically by letting the configurations be the vertices of a graph whose edges correspond to the allowed steps. The question is then to determine the diameter of this graph. In this paper, we consider a family of these problems where the configurations are binary trees with the same number of leaves.

Binary trees are of fundamental importance in graph theory and in various branches of applied mathematics and computer science. The trees that occur most often are the binary plane trees, being associated with binary search trees. (In a binary tree, every node has zero or two children; in a plane tree, the children of a node have a fixed left-to-right order.) The number of binary rooted plane trees with $n+1$ leaves is the nth Catalan number. On the set of binary rooted plane trees with a fixed number of leaves, one can define a "rotation" that transforms one tree into another. A fundamental question is to find the number of rotations needed to transform one such tree into a second one. Often this problem is formulated as a graph distance problem: the graph is defined on the set of binary rooted plane trees with $n+1$ leaves, and adjacency is determined by the rotation operation. It has been shown that the diameter of this graph is bounded by $2n-6$; computing the actual distance between two given trees remains a difficult problem [18, 13, 12, 16].

Inspired by this problem, and motivated by two applications, we consider in this paper a similar problem. The trees appearing here are ordinary (i.e. not plane) binary rooted trees with $n+1$ labeled leaves. The number of such trees is given by $(2n-1)!! = 1 \cdot 3 \cdot \ldots \cdot (2n-1)$. We consider a graph G_n defined on the set of such trees, and also define adjacency by a "rotation" operation that transforms one tree into another. This operation models transformations between objects modeled by the trees. In various applications (e.g. generalized recoupling coefficients in quantum theory of angular momentum [5], computation of a similarity measure between dendrograms [20]) the question of how many operations are needed to turn one object into another is of interest. Thus we study the diameter of this

graph.

The structure of the paper is as follows. Section 2 defines the trees we are dealing with (referred to as binary coupling trees) and the rotation graph G_n, and describes some basic properties of the graph G_n. In Section 3 exact results for some distance properties (such as distance degree sequence and diameter) are given for small values of n ($n \leq 10$). The size of G_n is growing exponentially in n, so for large values of n we look for theoretical bounds for the diameter of G_n. In Section 4 we obtain an explicit upper bound by constructing a path between two arbitrary binary coupling trees and by showing that its length is necessarily bounded by $n \lg(n) + O(n)$. Section 5 shows how an $\Omega(n \lg(n))$ lower bound for the diameter can be obtained from an upper bound for the number of trees within a certain distance of any given tree, for which the technique of short encodings introduced by Sleator *et al* in [17] can be used. We conclude that the diameter of G_n is $\Theta(n \lg(n))$. In particular, we will prove the following theorem:

Theorem 1 *For $n \geq 1$, the diameter* $\mathrm{diam}(G_n)$ *of G_n satisfies*

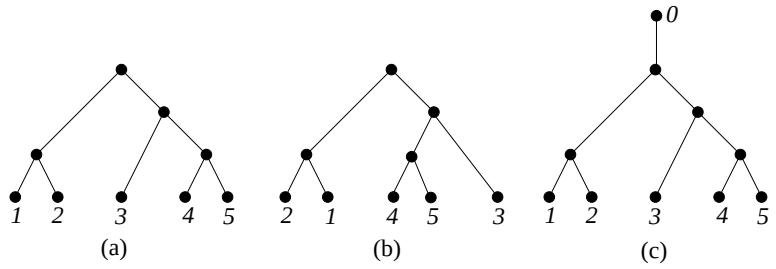
$$\frac{1}{4} n \lg(\frac{n}{e}) < \mathrm{diam}(G_n) < n \lceil \lg n \rceil + n - 2 \lceil \lg n \rceil + 1.$$

2 Binary coupling trees and the graph G_n

We define a *binary coupling tree* as a binary tree in which the leaves (i.e. nodes with no children) are given distinct labels. Without loss of generality, we can assume that these labels are the integer numbers between 1 and $n+1$ if the binary coupling tree has $n+1$ leaves. For fixed $n \geq 1$, we denote the set of all binary coupling trees with $n+1$ leaves, or equivalently with n non-leaf nodes, as $\mathcal{T}_n$. Figure 1(a) and (b) give two drawings of the same binary coupling tree. Note that one can place the children of a node in a binary coupling tree in any order; i.e. binary coupling trees are *not* plane trees. Sometimes, it will be convenient to attach an extra leaf with label 0 to the root and regard the binary coupling tree as an unrooted tree in which every node has degree 1 or 3; this is shown in Figure 1(c). We call these *extended binary coupling trees* and use $\tilde{\mathcal{T}}_n$ to denote the set of extended binary coupling trees with $n+2$ leaves.

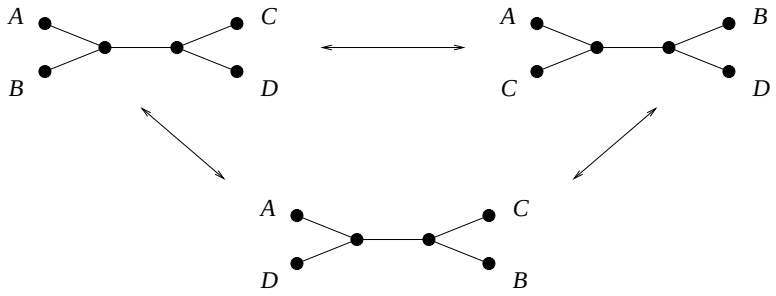
An edge joining non-leaf nodes is an *internal edge*. In an extended binary coupling

Figure 1: Binary coupling trees



tree, the two nodes of an internal edge are adjacent to four other nodes. There are three pairings of four elements. A *rotation* allows these four nodes to be paired in one of the two other ways. There are thus two rotations around an internal edge. Figure 2 gives an illustration; here each of A, B, C, D stands for a leaf or an arbitrary subtree. Note that a rotation is invertible; if T_2 is obtained by performing a rotation on T_1, then T_1 can be obtained by performing a rotation on T_2. This is also indicated in Figure 2. In the literature, other names for rotations appear: *flops* [6], *nearest neighbour interchanges* [4] and *crossovers* [15]. Note that when *plane* binary trees are studied there is only one rotation available at each internal edge.

Figure 2: Rotations on binary coupling trees



For fixed $n \geq 1$, we build the *rotation graph* G_n as follows: each vertex of G_n represents an element from $\mathcal{T}_n$. Two vertices are adjacent if and only if the two binary coupling trees they represent are related through a single rotation. Some simple properties of G_n were proved in [15]; see also [5]. We summarize them here:

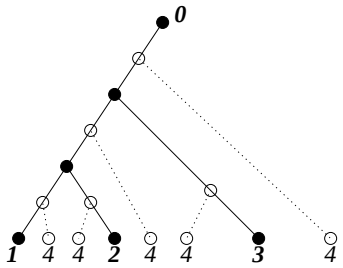
- $|V(G_n)| = |\mathcal{T}_n| = (2n-1)!! = 1 \cdot 3 \cdot \ldots \cdot (2n-1)$,

- G_n is regular of degree $2(n-1)$,
- G_n is connected.

To see that $|\mathcal{T}_n| = (2n-1)!!$, consider an element T of $\tilde{\mathcal{T}}_{n-1}$. The tree T has $2n-1$ edges, so there are $2n-1$ different ways of subdividing an existing edge and attaching an extra edge with leaf label $n+1$ to the new vertex (see Figure 3). Furthermore, each element of $\tilde{\mathcal{T}}_n$ arises exactly once in this way. Thus we have

$$|\tilde{\mathcal{T}}_n| = |\mathcal{T}_n| = (2n-1)|\tilde{\mathcal{T}}_{n-1}| = (2n-1)!!.$$

Figure 3: Five ways of attaching an extra leaf label 4 to an element of $\tilde{\mathcal{T}}_2$



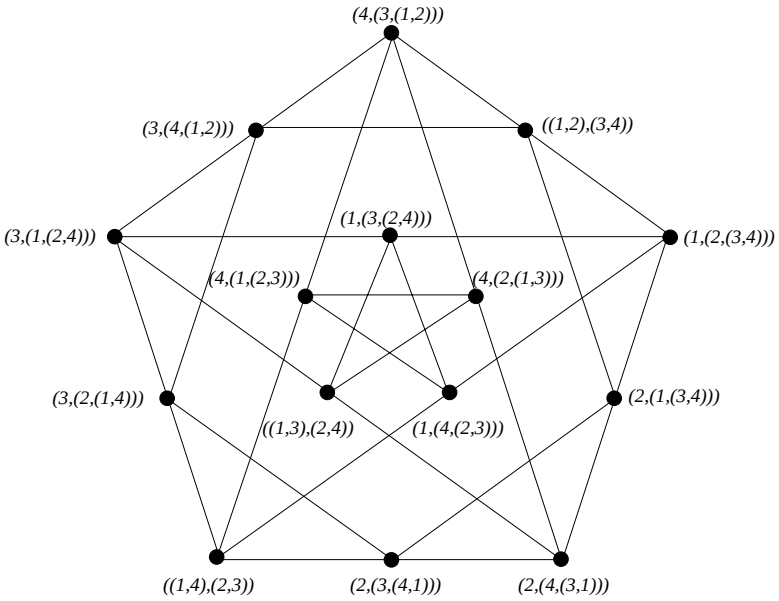
Example 2 As can be seen in Figure 4, the graph G_3 has $1 \cdot 3 \cdot 5 = 15$ vertices, while every vertex has four neighbours. In Figure 4, every vertex is labeled with a *bracket notation* of the binary coupling tree it represents. A bracket notation of a binary coupling tree gives the way in which the labeled leaves are coupled to form the binary coupling tree. Possible bracket notations of the binary coupling tree in Figure 1(a) are:

$$((1,2),(3,(4,5))) \qquad \text{or} \qquad ((2,1),((4,5),3)).$$

∎

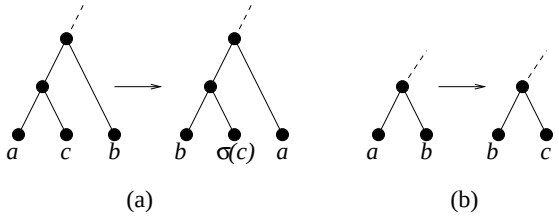
Let σ be an element of S_{n+2}, the group of all permutations on $n+2$ elements; σ acts on $T \in \tilde{\mathcal{T}}_n$ (and on G_n) by permutation of the $n+2$ leaf labels. It is clear that if T_1 and T_2 (viewed as elements of $\tilde{\mathcal{T}}_n$) are adjacent in G_n, then $\sigma(T_1)$ and $\sigma(T_2)$ are also adjacent in G_n. Thus $\sigma(G_n)$ is isomorphic to G_n. Furthermore, for $n \geq 3$ no element of S_{n+2} except

Figure 4: The rotation graph G_3



the identity permutation fixes G_n completely. Indeed, if σ has a cycle (ab) of length 2, then all trees of the form indicated in Figure 5(a) are not fixed under σ. If σ has no cycle of length 2 and $\sigma \neq \mathrm{id}$, then it must have a cycle $(abc\ldots)$ of length > 2. In this case, all trees of the form indicated in Figure 5(b) are not fixed under σ.

Figure 5: Trees that are not fixed under σ



Thus, we can conclude that for $n \geq 3$, the automorphism group of G_n contains S_{n+2}. For $n \in \{3, 4, 5, 6\}$, equality holds; we have verified this using the `nauty` program [14]. For larger values of n, the question of whether equality holds remains open.

3 Distance in G_n

In this paper, we are primarily concerned with computing or estimating the diameter of G_n (the *diameter* $\mathrm{diam}(G)$ of a graph G is the maximum over $v, v' \in V(G)$ of the distance $d(v, v')$).

The diameter and many other concepts related to distance (eccentricity, radius, center, periphery, ... [2]) follow easily if we know the *distance degree sequence* for every vertex of G_n. The distance degree sequence for a vertex v of G_n is the sequence

$$dds(v) = (d_0(v), d_1(v), d_2(v), \ldots),$$

where $d_i(v)$ is the number of vertices at distance i from v.

It is obvious that many vertices of G_n give rise to the same distance degree sequence. When two binary coupling trees differ only by a permutation of their labels, we say they have the same *type*. Clearly, such trees have the same distance degree sequence. As indicated in [5] and in Figure 6(a), there are two different types of binary coupling trees on 4 leaves, yet the distance degree sequence of these two types is identical. This can be understood by considering the corresponding elements from $\tilde{\mathcal{T}}_n$; indeed, these elements differ only by a permutation of their labels, see Figure 6(b). The *skeleton* of an extended binary coupling tree is the tree obtained by deleting all leaves from the extended binary coupling tree, see Figure 6(c). In other contexts, the skeleton of an extended binary coupling tree has been called its 'derived tree'. Two extended binary coupling trees differ only by a permutation of the leaf labels if and only if their skeletons are isomorphic. The skeletons of elements of $\tilde{\mathcal{T}}_n$ are precisely the isomorphism classes of trees with n nodes in which every node has degree at most 3.

To determine the diameter of G_n for some small fixed n, it is sufficient to calculate the distance degree sequence for all skeletons with n nodes. Table 1 lists the number of types and skeletons for values of n up to 10. The sequence giving the number of types is sequence A001190 of [19]; it is also known as the Wedderburn-Etherington sequence. The number of skeletons is sequence A000672 of [19]. The number of skeletons is (much) smaller than the number of types, yielding a substantial decrease in the required computation time. This reduction technique was used by Jarvis *et al* [8]. Distance degree sequences

4 An upper bound for the diameter of G_n

For $T_1, T_2 \in \mathcal{T}_n$, we will construct a path between the corresponding vertices in G_n. Robinson [15], Culik and Wood [3], and Li *et al* [11] used the same technique to obtain $O(n^2)$, $4n\lg(n) + O(n)$, $n\lg(n) + O(n)$ upper bounds for the diameter of G_n respectively. Here, and in the rest of this paper, lg denotes the logarithm in base 2. We will follow the lines indicated in [11] to obtain an *explicit* upper bound of the form $n\lg(n) + O(n)$ for the diameter of G_n; in particular, we will make the "$O(n)$" part explicit by performing a more careful calculation.

Our approach to obtain an upper bound is a slight modification of the standard approach to bounding the diameter by showing that all vertices are within a fixed distance of a single vertex. Here, we show that all vertices are within a fixed distance of a special set of vertices, and we give an upper bound for the diameter of this set. The reason for the variation here is the labeling of the leaves: the special set consists of different labelings of a single isomorphism class.

The *level of a node in a tree* is defined recursively as follows [10, Section 2.3]: the level of the root is zero and the level of any other node is one more than the level of its parent.

The *depth of a tree* T, denoted as $\text{depth}(T)$, is the maximum level of any of its nodes. For a rooted binary tree T with $n+1$ leaves, it is well known that

$$\lceil \lg(n+1) \rceil \leq \text{depth}(T) \leq n. \tag{1}$$

An element $S \in \mathcal{T}_n$ is a *spine* if and only if $\text{depth}(S) = n$. Spines exist for every $n \geq 1$; indeed, there are $\frac{(n+1)!}{2}$ spines in $\mathcal{T}_n$.

The path between T_1 and T_2 is constructed in three steps:

1. transform T_1 into a spine S_1,
2. transform T_2 into a spine S_2 and,
3. transform the spine S_1 into S_2 (or vice versa).

In this section, we will determine an explicit upper bound for the number of rotations needed in each step, yielding an explicit upper bound for the diameter of G_n.

Let T be a binary coupling tree that is not a spine. Choose a leaf x of T that has maximum level. Since T is not a spine, there is an internal edge of T that is not on the path from the root node of T to x, but that has a node in common with an edge on this path. Performing the appropriate rotation around this internal edge will increase the depth of T by one. Hence, one can transform an arbitrary element T of $\mathcal{T}_n$ into a spine using $n - \text{depth}(T)$ rotations.

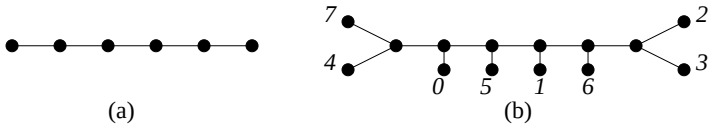
Thus, given the bound in (1), one can transform any binary coupling tree on $n+1$ leaves into a spine using at most

$$n - \lceil \lg(n+1) \rceil \tag{2}$$

rotations.

The construction of a path between two arbitrary spines from $\mathcal{T}_n$ is easier to understand when working with extended binary coupling trees, i.e. elements of $\tilde{\mathcal{T}}_n$. We say that an element S from $\tilde{\mathcal{T}}_n$ is an *extended spine* if and only if its skeleton is a path. Figure 7(a) is a drawing of a path on six nodes, while Figure 7(b) is a drawing of an extended spine of $\tilde{\mathcal{T}}_6$. Note that an extended spine corresponds to a spine if and only if the label 0 appears on a leaf at the end of the path.

Figure 7: (a) A path on six nodes and (b) an extended spine of $\tilde{\mathcal{T}}_6$



Rotations on extended binary coupling trees are rotations of the corresponding binary coupling trees. Thus the maximum distance between extended spines in $\tilde{\mathcal{T}}_n$ is an upper bound for the maximum distance between spines in $\mathcal{T}_n$ (it may be larger since the set of extended spines is larger). By symmetry (relabeling of leaves), it suffices to bound the distance of all extended spines from a fixed extended spine.

A rotation that transforms one extended spine into another performs (except at the ends) an adjacent transposition on the permutation recording the leaves. Thus $\Theta(n^2)$ rotations may be needed to transform one extended spine into another using extended spines only. This corresponds to simulating a bubble sort [9, Section 5.2.2] on the extended spines and leads to an $O(n^2)$ upper bound for the diameter of G_n. In order to reduce the bound to $O(n \lg n)$, it is necessary to use vertices outside the set of extended spines. The faster method simulates the merge sort algorithm [9, Section 5.2.4] on the set of extended spines.

An extended spine of $\tilde{\mathcal{T}}_n$ has four *end leaves*, i.e. leaves whose neighbour is an endpoint of the skeleton; in Figure 7(b), these are the leaves with labels 7, 4, 2, and 3. Let S be an extended spine, and let x be an end leaf. We say that S is *increasing* (resp. *decreasing*) *with respect to* x if and only if for all other leaves x_1 and x_2 the following property holds:

$$d(x_1, x) < d(x_2, x) \Rightarrow x_1 < x_2 \text{ (resp. } x_1 > x_2).$$

Herein, x_i denotes both the leaf x_i and the label of this leaf. If the leaf label of x is known, then there is exactly one extended spine in $\tilde{\mathcal{T}}_n$ that is increasing with respect to x; we will use this extended spine as the fixed spine mentioned before.

Let S be an extended spine of $\tilde{\mathcal{T}}_n$, and let x be an end leaf. We say that $S \in \tilde{\mathcal{T}}_n$ is *concave with respect to* x (resp. *convex with respect to* x) if and only if for all other leaves

x_1 and x_2 the following property holds:

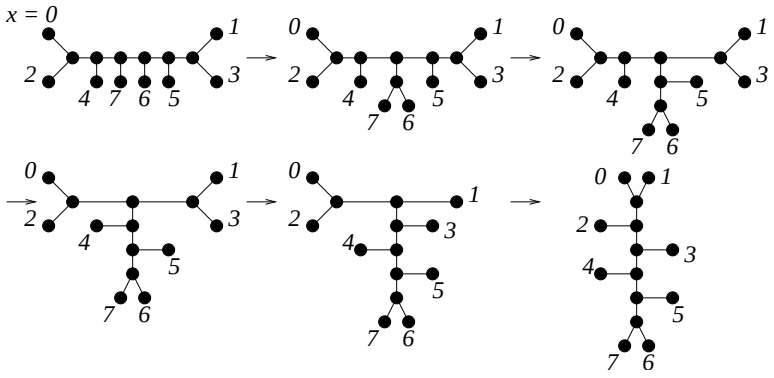
$$d(x_1, x) < d(x_2, x) \leq \left\lceil \frac{n}{2} \right\rceil + 1 \Rightarrow x_1 < x_2 \text{ (resp. } x_1 > x_2)$$

and

$$\left\lceil \frac{n}{2} \right\rceil + 2 \leq d(x_1, x) < d(x_2, x) \Rightarrow x_1 > x_2 \text{ (resp. } x_1 < x_2).$$

If $S \in \tilde{\mathcal{T}}_n$ is an extended spine that is concave (resp. convex) with respect to x, then we can transform S into an increasing (resp. decreasing) extended spine, again with respect to x, using at most $n-1$ rotations. This procedure, illustrated in Figure 8, is quite analogous to the *merge* step in the merge sort algorithm, where two sorted sequences are combined to form a single sorted sequence; it uses induction on n. When $n = 2$, at most

Figure 8: Merging an extended spine

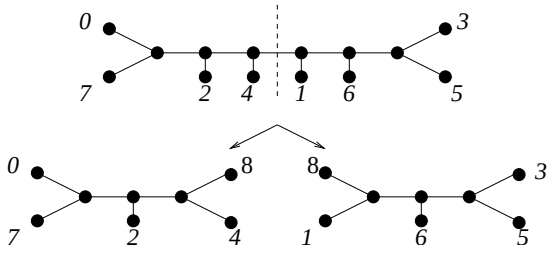


one rotation is needed (see Figure 2). For $n \geq 3$, consider the two leaves with the largest labels (excluding x) in an extended spine concave with respect to x. Since the neighbours of these two leaves are adjacent, we can perform a rotation that gives the two leaves a common neighbour. We then delete these two leaves and give their neighbour (which is now a leaf) the label of the smaller one. In this way, we have obtained an extended spine of $\tilde{\mathcal{T}}_{n-1}$ that is concave with respect to x. By induction, at most $n-2$ rotations are needed to transform this extended spine into an increasing one. Since the leaf with the largest label appears at the end of the extended spine, replacing this leaf with the two original leaves will produce an extended spine of $\tilde{\mathcal{T}}_n$ increasing with respect to x.

Also the other ideas of the merge sort algorithm apply to our problem. Let $S \in \tilde{\mathcal{T}}_n$ be an extended spine that is to be transformed into an increasing or a decreasing one

with respect to some leaf x. We make an imaginary cut on S and obtain two extended half-spines by placing an imaginary leaf on each end of the cut. The label we place on the imaginary leaves is the same for both halves and depends on whether we are transforming S into an increasing or a decreasing extended spine. In the former case the value of the label of the imaginary leaves is greater than any other label of the extended spine, while in the latter it is smaller. In this way, we get two extended half-spines: one in $\tilde{\mathcal{T}}_{\lceil \frac{n}{2} \rceil}$, containing the leaf x, and one in $\tilde{\mathcal{T}}_{\lfloor \frac{n}{2} \rfloor}$. (To really match the definition, we would have to do an order-preserving relabeling.) Figure 9 illustrates how we place the imaginary cut when the extended spine is to be transformed into an increasing one with respect to the leaf 0.

Figure 9: Placing an imaginary cut on an extended spine



If we are transforming S into an increasing (resp. decreasing) extended spine with respect to the leaf x, we *recursively* transform the extended half-spine containing x into an increasing (resp. decreasing) one with respect to the original leaf x, while we recursively transform the other extended spine into a decreasing (resp. increasing) one with respect to the imaginary leaf. Once we have done this, we can merge the two extended half-spines together.

Each time the sorted subspines double in length, at most $n-1$ rotations are performed. We thus expect that approximately $n \lg n$ rotations are needed to sort an extended spine.

Let $f(n)$ (resp. $g(n)$) denote the maximum number of rotations needed to transform an arbitrary extended spine $S \in \tilde{\mathcal{T}}_n$ into an increasing (resp. decreasing) one with respect to some fixed leaf x. By symmetry, it is clear that $f(n) = g(n)$ for all values of $n \geq 1$. Since $|\tilde{\mathcal{T}}_1| = 1$, $f(1)$ equals 0. Hence f satisfies

$$f(n) \leq f\left(\left\lceil \frac{n}{2} \right\rceil\right) + f\left(\left\lfloor \frac{n}{2} \right\rfloor\right) + n - 1, \text{ for } n > 1 \text{ and } f(1) = 0. \tag{3}$$

Let $f_u(n)$ denote the function for which equality holds in (3), i.e.:

$$f_u(n) = f_u\left(\left\lceil \frac{n}{2} \right\rceil\right) + f_u\left(\left\lfloor \frac{n}{2} \right\rfloor\right) + n - 1, \text{ for } n > 1 \text{ and } f_u(1) = 0. \tag{4}$$

This is a well-known recurrence [7, Section 3.3] and its solution is given by:

$$f_u(n) = n\lceil \lg n \rceil - 2^{\lceil \lg n \rceil} + 1, \tag{5}$$

which is indeed approximately $n \lg(n)$ as expected. As already noted, $f(n)$ is an upper bound for the number of rotations needed to transform an arbitrary spine $S_1 \in \mathcal{T}_n$ into another arbitrary spine $S_2 \in \mathcal{T}_n$. We thus have the following theorem:

Theorem 3 *The diameter of G_n satisfies*

$$\operatorname{diam}(G_n) \leq n\lceil \lg(n) \rceil - 2^{\lceil \lg(n) \rceil} + 1 + 2\left(n - \lceil \lg(n+1) \rceil\right). \tag{6}$$

Proof: This follows immediately by combining formulas (5) and (2). □

5 A lower bound for the diameter of G_n

Upper bounds on the number of vertices within distance m of an arbitrary vertex in a graph G yield lower bounds on the diameter of G.

Such a bound is easily obtained by considering the following inequalities that hold for any vertex v of a graph G with maximal degree Δ:

$$d_0(v) = 1, \quad d_1(v) \leq \Delta, \quad d_i(v) \leq \Delta(\Delta - 1)^{i-1}, \text{ for } i > 1.$$

This gives the following inequality:

$$\frac{\Delta(\Delta - 1)^{\operatorname{diam}(G)} - 2}{\Delta - 2} \geq \sum_{i=0}^{\operatorname{diam}(G)} d_i(v) = |V(G)|. \tag{7}$$

This bound on the order of graphs with fixed maximum degree and diameter is known as the *Moore bound*. Graphs for which equality holds in (7) are *Moore graphs* and are extremely rare (see [1, 2] for further discussion). If we apply inequality (7) to the rotation graph G_n, we get a linear lower bound for the diameter of G_n, namely

$$\operatorname{diam}(G_n) \geq \frac{\ln(2n) - 1}{\ln(2n)} n. \tag{8}$$

Li *et al* [11] proved an $\Omega(n \lg(n))$ lower bound for $\mathrm{diam}(G_n)$ using the results of [17]. They sketched a way, using "flips" in plane triangulations and short encodings, to derive that the number of trees within distance m from any given tree is bounded by $3^n 2^{4m}$. We will show that the number of trees within distance m is bounded by

$$\frac{2^{n+4m}}{2n}.$$

Since this is smaller than $3^n 2^{4m}$, our lower bound will be better than the one found by Li *et al*. We will prove in particular that for $n > 1$, the following inequality holds:

$$\mathrm{diam}(G_n) > \frac{1}{4}\lg(n!) > \frac{1}{4} n \lg(\frac{n}{e}).$$

In [17] Sleator *et al* provide a tool for deriving an upper bound for the number of combinatorial objects within m transformations from a given object. They take advantage of the fact that often one can interchange the order of the transformations without affecting the final outcome. This does not imply that all lists of m transformations that reach a given object are reorderings of each other: it is also possible to reach the given object using different sets of transformations.

We will apply their technique of *short encodings* to paths in G_n. We will encode every path starting from a particular tree as a list of integers in $\{0, 1, 2, 3, 4\}$, and then we will bound the number of encodings for paths of length at most m by $2^{n+4m}/(2n)$.

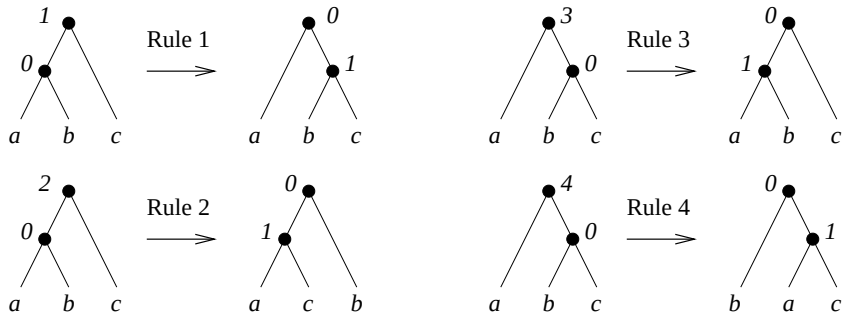
As already noted, a binary coupling tree does not change if one exchanges the "left" and "right" child of any non-leaf node. This transformation is called an *exchange* [6] or a *twist* [17]. In the technique following from Sleator *et al* [17] the trees are ordered, so the twist transformation is also counted. Here however, we do *not* want to count twists. This problem can be overcome by working with ordered trees for which a "twist-rotation-twist"-transformation is counted as one transformation only. That is why two transformations will be added to the ordinary rotation transformation (see Figure 10).

Let T and T' be elements of $\mathcal{T}_n$ with $d(T, T') = m$. This means that there exists a sequence of m rotations that carries T into T'; this sequence is called a *derivation*. Note that there may be many derivations that carry T into T'.

In a derivation, we view the trees along the way as *ordered* trees, i.e. twists are not allowed. When regarding T as an ordered tree, we denote it as $\hat{T}$. We can *apply* one of

the four *rules* (transformations) indicated in Figure 10 to $\hat{T}$ if and only if $\hat{T}$ contains a subtree identical to the tree on the left side of that rule (temporarily ignore the labels on the internal nodes). The result is $\hat{T}$ in which the left side of the rule is replaced by the right side, so the left (resp. right) side of the rule relates to the shape of the tree *before* (resp. *after*) the rule is applied. The "pure rotations" applied to these ordered trees correspond to Rules 1 and 3. The other rules correspond to a "twist-rotation-twist" transformation. For example, Rule 2 corresponds to a twist (exchange a and b), followed by a rotation, followed by another twist (exchange b with parent node of a and c). Operating on ordered trees, these four rules are necessary and sufficient to produce all possible rotations on binary coupling trees. The numbers of the nodes in the left sides of the rules are called *pre-position numbers*, while the numbers of the nodes in the right sides of the rules are called *post-position numbers*. Their use will soon become apparent.

Figure 10: The four rules that can be applied



It is convenient to think of applying a rule as destroying nodes and creating new ones. To keep track of this process, we assign distinct *names* to the non-leaf nodes in the trees produced during a derivation. An *action* is an application of a rule to particular nodes, so a derivation is a list of actions. The *required nodes* of an action are the nodes that are destroyed by that action. An action is *ready* if and only if the required nodes of that action exist.

In order to name each non-leaf node that appears in the trees produced by a derivation, we first number the actions of that derivation, beginning with 1. Each internal node of the initial tree $\hat{T}$ is named v_i, with $1 \leq i \leq n$, in some (arbitrary) order. Next, each new node gets a name of the form $v_{j,0}$ or $v_{j,1}$, where j is the number of the action that created

these nodes and where 0 and 1 refer to the post-position numbers of the applied rule.

Figure 11: A derivation of length 4

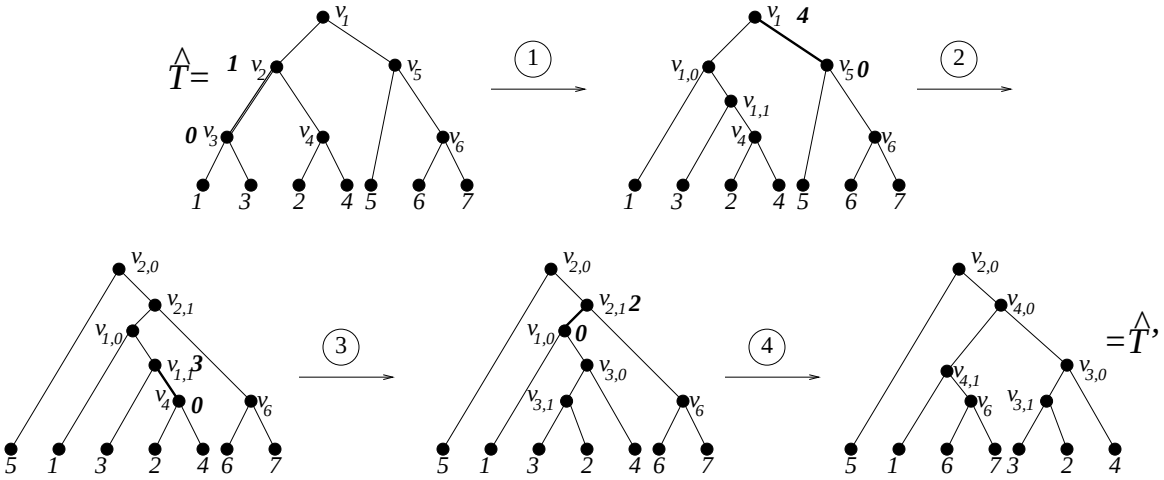


Table 3: Required nodes for each action of the derivation in Figure 11

action	required nodes
1	$v_2,\ v_3$
2	$v_1,\ v_5$
3	$v_4,\ v_{1,1}$
4	$v_{1,0},\ v_{2,1}$

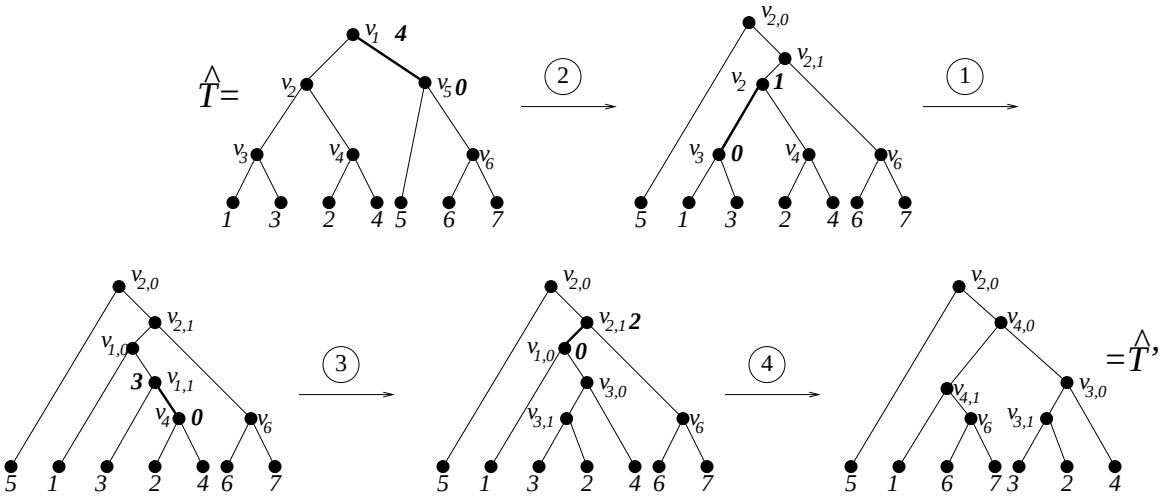
In order to build an encoding for the derivation D with initial tree $\hat{T}$, we first (a) number the actions of D, (b) give each internal node a name, and (c) determine the required nodes of each action. Furthermore, we associate with the name of each required node the pre-position number of the corresponding node in the rule applied to that required node. If no rule is ever applied to a node, then that node survives in $\hat{T}'$, and we associate 0 with the name of that node. These numbers are determined by which rule is applied, not the index of the action, so they lie in $\{0, 1, 2, 3, 4\}$.

In order to encode a derivation D, we first construct a canonical derivation D' that is a reordering of the actions of D and produces the same final outcome $\hat{T}'$. To select the next action for D' from the remaining unprocessed actions of D, at each step we choose from

the actions that are ready the action that destroys the node with the smallest name in lexicographic order. This lexicographic order treats the initial single-coordinate names as being smaller than all names that are introduced later. Having done this until all actions are applied, the encoding of D now consists of the pre-position numbers associated with the internal nodes, *in the order introduced by the canonical derivation* D'.

Example 4 For the derivation in Figure 11, Tables 3 and 4 give the required nodes of each action and the association of the names with pre-position numbers. Looking at the initial tree, or equivalently at Table 3, we see that actions 1 and 2 are ready. We choose to do action 2 first, because action 2 destroys the node with the smallest name. Thus, nodes v_1 and v_5 are destroyed and nodes $v_{2,0}$ and $v_{2,1}$ are created. Next, only action 1 is ready so we do action 1, hereby destroying the nodes v_2 and v_3 and creating the nodes $v_{1,0}$ and $v_{1,1}$. Now, both actions 3 and 4 are ready, but we choose action 3 and then action 4. This results in the encoding given in the third row of Table 5. The canonical derivation of the derivation in Figure 11 is given in Figure 12. ∎

Figure 12: The canonical derivation of the derivation in Figure 11



An internal node is required by at most one action, since it is destroyed by that action. Thus, choosing the ready action that destroys the internal node with the smallest name is well defined. Furthermore, at each stage in the encoding process, at least one action is

Table 4: Association of names with pre-position numbers

v_1	v_2	v_3	v_4	v_5	v_6	$v_{1,0}$	$v_{1,1}$	$v_{2,0}$	$v_{2,1}$	$v_{3,0}$	$v_{3,1}$	$v_{4,0}$	$v_{4,1}$
4	1	0	0	0	0	0	3	0	2	0	0	0	0

Table 5: Encoding for the derivation in Figure 11

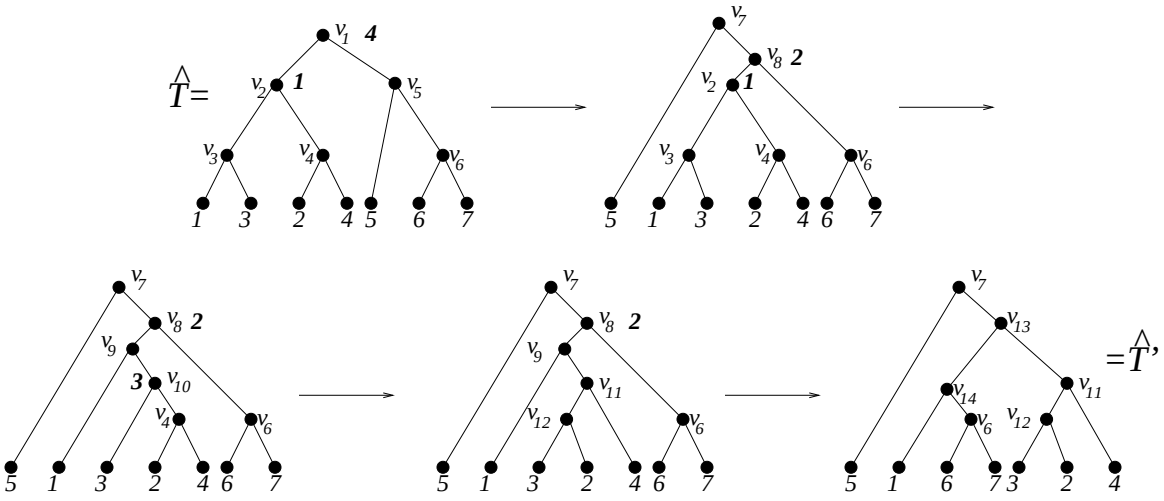
v_1	v_2	v_3	v_4	v_5	v_6	$v_{2,0}$	$v_{2,1}$	$v_{1,0}$	$v_{1,1}$	$v_{3,0}$	$v_{3,1}$	$v_{4,0}$	$v_{4,1}$
v_1	v_2	v_3	v_4	v_5	v_6	v_7	v_8	v_9	v_{10}	v_{11}	v_{12}	v_{13}	v_{14}
4	1	0	0	0	0	0	2	0	3	0	0	0	0

ready. In particular, the first action of D among those that have not yet been performed is ready. This shows that one can reorder the actions of derivation D to form the canonical derivation D'.

Furthermore, the outcome of D' is identical to the outcome of D. If actions i and j of the original derivation D are ready at the same time while constructing D', then these actions do not require a common node, since each node is required by at most one action. Furthermore, neither action requires a node that exists as a result of the other, since they are ready at the same time. Robinson [15] proved that two rotations around two edges that do not share a common node can be performed in either order without affecting the outcome. This proves that the outcome of D' equals the outcome of D.

Next, we explain how the canonical derivation D' can be reconstructed (decoded) when $\hat{T}$ and the encoding are given. The decoding procedure mimics the behaviour of the encoding procedure. The encoding is simply a list of nonnegative integers, as in the third line of Table 5. We associate names $v_1, \ldots, v_{n+2m}$ with these integers in order. The first n names are those of the initial tree $\hat{T}$. Inspecting the parent-child pairs in $\hat{T}$ identifies which actions are ready. No two actions sharing a node can be ready simultaneously. We then apply the rule that destroys the node with the smallest name. This will obviously be the first action of D'. Application of this rule will create internal nodes v_{n+1} and v_{n+2}, corresponding with the $(n+1)$-th and $(n+2)$-th entry of the code. Continuing in this manner, we can reconstruct D'.

Figure 13: The decoding procedure



Example 5 Next to the nodes of Figure 13 we have written the corresponding entries from the encoding. In order not to overload the figure, the entries that equal zero are not shown. As can be seen, rules 1 and 4 can be applied to the initial tree. Because rule 4 destroys the node with the smallest name i.e. v_1, we apply this rule thus creating the nodes v_7 and v_8. Now we can only apply rule 1, yielding the third tree. After two more actions, we arrive at $\hat{T}'$. ∎

Lemma 6 *The number of trees within distance m from any binary coupling tree $T \in \mathcal{T}_n$ is at most $\binom{n+2m}{m}4^m$.*

Proof: Each application of a rule to an ordered tree corresponds to traversal of exactly one edge in G_n, and each edge traversal can be achieved by applying one of these rules. Hence we consider the number of trees that are reachable from T via derivations of length m.

Using this technique, every tree $\hat{T}'$ with $d(\hat{T}, \hat{T}') = m$ can be encoded by an array (code) of length $n + 2m$. Since a code of length $n + 2m$ has exactly m nonzero entries, and each nonzero entry lies in $\{1, 2, 3, 4\}$, the number of codes $|C(n, m)|$ of length $n + 2m$

is bounded by

$$|C(n,m)| \leq \binom{n+2m}{m} 4^m.$$

The number of trees at distance m from any given tree is bounded by this number. We can even say more: the number of trees *within* distance m from any given tree is bounded by the same number. Indeed, if $d(T,T') = m-2l$, then there is a derivation of length m carrying T into T'; one only needs to go back and forth between T' and its predecessor on the path of length $m-2l$. If $d(T,T') = m-2l-1$, then one can construct a derivation of length $m-2l$ by adding a detour through the common neighbour of T' and its predecessor on a path of length $m-2l-1$, since every edge in G_n lies on a triangle (see Figure 2). The argument for $m-2l$ then applies. The bound holds also when $m=1$, since $1+2(n-1) < 4(n+2)$.

□

Theorem 7 *For $n > 1$, the diameter of G_n satisfies*

$$\mathrm{diam}(G_n) > \frac{1}{4}\lg(n!) > \frac{1}{4} n \lg(\frac{n}{e}).$$

Proof: Let $D = \mathrm{diam}(G_n)$. By Lemma 6,

$$\binom{n+2D}{D} 4^D \geq (2n-1)!! = \frac{n!}{2^n}\binom{2n}{n}. \tag{9}$$

Using asymptotic expansions (Stirling's formula),

$$\frac{2^{2n}}{\sqrt{\pi n}} > \binom{2n}{n} > \frac{2^{2n}}{\sqrt{\pi n}}\left(1 - \frac{1}{8n}\right). \tag{10}$$

From (10) and $\binom{n+2D}{D} < \binom{n+2D}{n/2+D}$,

$$2^{4D} > n! \left(1 - \frac{1}{8n}\right)\sqrt{\frac{1}{2} + \frac{D}{n}}.$$

For $n \geq 5$, the elementary lower bound (Moore bound) $D \geq n(\ln(2n) - 1)/\ln(2n)$ in (8) now yields $2^{4D} > n!$. One can check directly that this bound also holds for $2 \leq n \leq 4$. □

Remark 8 One slightly improves the lower bound from Theorem 7 when bounding the left side of (9), for $n > 0$ and $D > 1$, by

$$\frac{2^{n+2D}}{2n} > \binom{n+2D}{D}, \tag{11}$$

and the right side of (9) by

$$\frac{(2n)!}{2^n n!} \geq \sqrt{2} \left(\frac{2n}{e}\right)^n \left(1 - \frac{1}{24n}\right). \tag{12}$$

instead of by (10). Inequality (12) is proved using Stirling's formula. ∎

Combining Theorem 3 and Theorem 7 yields Theorem 1.

FUN WITH THE $\sigma(n)$ FUNCTION

by Andrew Feist

Department of Mathematics
Duke University
Box 90320
Durham, NC 27708
andrewf@math.duke.edu

Notation (Standard and Otherwise). The function $\sigma(n)$ is one of the basic number-theoretic arithmetic functions. It is defined as:

$$\sigma(n) = \sum_{d|n} d.$$

Some values of $\sigma(n)$ for small n can be found in [2, sequence A000203]. (Note: It is known that $\sigma(n)$ is also multiplicative, i.e., if j and k have no factors in common other than 1, $\sigma(jk) = \sigma(j)\sigma(k)$.) The Dirichlet convolution of two arithmetic functions $f(n)$ and $g(n)$, itself a function of n, is defined as:

$$f * g = \sum_{d|n} f(d)g(\frac{n}{d}).$$

And I will be using $\perp$ to denote relative primality.

Sigma-Primes. I will call a number n *sigma-prime* if and only if $n \perp \sigma(n)$. The sigma-prime numbers below 100 can be found in [2, sequence A014567]. Two rather straightforward theorems are:

Theorem 1. *All powers of primes are sigma-prime.*

Theorem 2. *No perfect numbers are sigma-prime.*

To build this theory, I shall, in the time-honored tradition of mathematics, start with the simple examples and move up. If a number n is the product of two primes, say p and q, then $\sigma(n) = 1 + p + q + pq = \sigma(p)\sigma(q)$. Now, the only divisors of pq are p and q. Clearly, $p \perp \sigma(p)$. Thus, $p \perp \sigma(pq)$ if and only if $p \perp \sigma(q)$. Similarly, $q \perp \sigma(pq)$ if and only if $q \perp \sigma(p)$. Assuming $p < q$, we can see that (unless $p = 2$ and $q = 3$), $p + 1 < q$ and from that $p + 1 \perp q$. Note also that in the case of the above exception, $q + 1 \not\perp p$. Thus, we can generalize and say that $n = pq$ is sigma-prime if and only if $q + 1 \perp p$. This easily extends to the following:

Theorem 3. *If $n = p_1 p_2 \cdots p_k$, where $p_1 < p_2 < \cdots < p_k$, , and each of $p_1, \ldots, p_k$ is a prime, then n is sigma-prime if and only if $p_i \perp 1 + p_j$ whenever $i < j$.*

This also leads to:

Corollary 1. *If k is odd and greater than 1, then $2k$ is not sigma-prime.*

Proof. Since k is odd, it has (at least) one odd prime factor p; thus $2k$ has 2 and p for prime factors. But, $2 \not\perp 1 + p$.

Now we come to the cases where n has prime powers as factors. Thus, if $n = \prod_i {p_i}^{e_i}$, then $\sigma(n) = \prod_i \sigma({p_i}^{e_i})$. Then if n is to be sigma-prime, each of the factors of the first product must be relatively prime to each of the factors of the second product. Unfortunately, the trick we used in the single-power case will not work here; $p_i < p_j$ will not imply that ${p_i}^{e_i} < {p_j}^{e_j}$.

Theorem 4. *A number $n = \prod_i {p_i}^{e_i}$ is sigma-prime if and only if for every i, j,*

$$p_i \perp \sum_{k=0}^{e_j} {p_j}^k.$$

We close this section with a surprising theorem and a conjecture.

Theorem 5. *The square of an even perfect number is sigma-prime.*

Proof. According to a famous result of Euler, every even perfect number is of the form $(2^{p-1}(2^p - 1))$, where $2^p - 1$ is prime. Thus the square of an even perfect number is of the form $(2^{2p-2}(2^p - 1)^2)$, where 2 and $2^p - 1$ are its prime factors. Thus we have two things to check: (1) $2 \perp 1 + (2^p - 1) + (2^{2p} - 2^{p+1} + 1) = 2^{2p} - 2^{p+1} + 2^p + 1$. This is obvious, as the left-hand side is 2 and the right-hand side is odd; and (2) $2^p - 1 \perp 1 + 2 + 2^2 + \cdots + 2^{2p-2} = 2^{2p-1} - 1$. We will prove this by contradiction. Assume that, in fact, $2^p - 1 | 2^{2p-1} - 1$. We know that $2^p - 1 | (2^p - 1)^2 = 2^{2p} - 2^{p+1} + 1$. By our assumption, we also know that $2^p - 1 | 2^{2p} - 2$ (by multiplying the right-hand side by 2, which is relatively prime to the left-hand side). Then $2^p - 1$ must divide the (absolute) difference of these two numbers, which is $2^{p+1} - 3$. But this is $2(2^p - 1) - 1$, and this implies that $2^p - 1 | 1$. This is a contradiction (as $2^p - 1 \geq 3$), and the theorem is proved.

Conjecture. *The natural density of the set of sigma-prime numbers is zero.*

This seems a reasonable conjecture to make; the set of prime powers has density zero and the set of sigma-prime numbers is not much larger. However, no proof has been forthcoming.

Dirichlet Inverse of $\sigma(n)$. To discuss an inverse, we must first have an identity. Looking at the definition of Dirichlet convolution, after a little thought we see that the value of the identity function must be one at $n = 1$ and zero elsewhere. This tells us immediately that $\sigma^{-1}(1) = 1/\sigma(1) = 1$. It has been shown that the inverse of a multiplicative function is itself multiplicative (for a proof, see [1, Theorem 2.16]), so we need only concern ourselves with the prime powers.

Theorem 6. *$\sigma^{-1}(p) = -p - 1$, where p is a prime.*

Proof. Since $p > 1$, the identity value under Dirichlet convolution has the value 0 at p. Then, $0 = \sigma(p)\sigma^{-1}(1) + \sigma(1)\sigma^{-1}(p) = (p + 1) + \sigma^{-1}(p)$, and therefore $\sigma^{-1}(p) = -p - 1$.

Theorem 7. *$\sigma^{-1}(p^2) = p$, where p is a prime.*

Proof. Again, the identity value is 0. Then,

$$\begin{aligned} 0 &= \sigma(p^2)\sigma^{-1}(1) + \sigma(p)\sigma^{-1}(p) + \sigma(1)\sigma^{-1}(p^2) \\ &= (1 + p + p^2) + (p + 1)(-p - 1) + \sigma^{-1}(p^2) \\ &= p^2 + p + 1 - p^2 - 2p - 1 + \sigma^{-1}(p^2) \\ &= -p + \sigma^{-1}(p^2) \\ p &= \sigma^{-1}(p^2). \end{aligned}$$

Theorem 8. *$\sigma^{-1}(p^k) = 0$, where p is a prime, for all integer $k \geq 3$.*

Proof. We will prove this using induction, so let's start with $k = 3$.

$$\begin{aligned} 0 &= \sigma(p^3)\sigma^{-1}(1) + \sigma(p^2)\sigma^{-1}(p) + \sigma(p)\sigma^{-1}(p^2) + \sigma(1)\sigma^{-1}(p^3) \\ &= (1 + p + p^2 + p^3) + (1 + p + p^2)(-p - 1) + (1 + p)(p) + \sigma^{-1}(p^3) \\ &= (1 + p + p^2 + p^3) + (-1 - p - p^2 - p^3 - p - p^2) + (p + p^2) + \sigma^{-1}(p^3) \\ &= \sigma^{-1}(p^3). \end{aligned}$$

That takes care of the base case; let's assume that $\sigma^{-1}(p^n) = 0$ for all n, $3 \leq n < k$ and see what

happens.

$$\begin{aligned}
0 &= \sigma(p^k)\sigma^{-1}(1) + \sigma(p^{k-1})\sigma^{-1}(p) + \sigma(p^{k-2})\sigma^{-1}(p^2) + \cdots + \sigma(1)\sigma^{-1}(p^k) \\
&= (1 + p + p^2 + \cdots + p^k) + (1 + p + p^2 + \cdots + p^{k-1})(-p - 1) + \\
&\qquad (1 + p + p^2 + \cdots + p^{k-2})(p) + \sigma^{-1}(p^k) \\
&= (1 + p + p^2 + \cdots + p^k) - (1 + 2p + 2p^2 + \cdots + 2p^{k-1} + p^k) + \\
&\qquad (p + p^2 + \cdots + p^{k-1}) + \sigma^{-1}(p^k) \\
&= \sigma^{-1}(p^k).
\end{aligned}$$

These are all the cases; thus we can generate the sigma inverse function for all n. If we write n in canonical prime factorization form, $n = \prod_i {p_i}^{e_i}$, and define the sequence $\{a_i\}$ as

$$a_i = \begin{cases} -p - 1, & \text{if } e_1 = 1; \\ p, & \text{if } e_1 = 2; \\ 0, & \text{if } e_i > 2. \end{cases}$$

Then, $\sigma^{-1}(n) = \prod_i a_i$.

Note. This sequence, which starts 1, -3, -4, 2, -6, 12, ..., has now been added to Sloane's *Encyclopedia* [3, sequence A046692].

Abstract

We analyze how difficult it is to synchronize to a periodic sequence whose structure is known, when an observer is initially unaware of the sequence's phase. We examine the transient information **T**, a recently introduced information-theoretic quantity that measures the uncertainty an observer experiences while synchronizing to a sequence. We also consider the synchronization time τ, which is the average number of measurements required to infer the phase of a periodic signal. We calculate **T** and τ for all periodic sequences up to and including period 23. We show which sequences of a given period have the maximum and minimum possible **T** and τ values, develop analytic expressions for the extreme values, and show that in these cases the transient information is the product of the total phase information and the synchronization time. Despite the latter result, our analyses demonstrate that the transient information and synchronization time capture different and complementary structural properties of individual periodic sequences --- properties, moreover, that are distinct from source entropy rate and mutual information measures, such as the excess entropy.

Mathematical Constants

by Steven R. Finch

Cambridge University Press, 2003

My website is smaller than it once was. Please visit again, however, since new materials will continue to appear occasionally. It's best to look ahead to the future and not to dwell on the past. *

My book *Mathematical Constants* is now available for online purchase from Cambridge University Press (in the United Kingdom and in North America). It is far more encompassing and detailed than my website ever was. It is also lovingly edited and beautifully produced - many thanks to Cambridge! - please support us in our publishing venture. Thank you. (If you wish, see the front cover and more text.)

Several Sample Essays from the Book (in PDF)

- Kalmár's composition constant
- Optimal stopping constants
- Reuleaux triangle constants

Supplementary Materials (omitted from the book for reasons of time and space)

- Bipartite, k-colorable and k-colored graphs (6/5/2003)
- Transitive relations, topologies and partial orders (6/5/2003)
- Series-parallel networks (7/7/2003)
- Knots, links and tangles (8/8/2003)
- Hardy-Littlewood maximal inequalities (10/12/2003)
- Bessel function zeroes (10/23/2003)
- Nash's inequality (11/4/2003)
- Uncertainty inequalities (11/7/2003)
- Two asymptotic series
- Constant of interpolation
- Integer partitions
- Class number theory
- Hammersley's path process
- Constant of Theodorus

A PROBLEM IN STATISTICAL CLASSIFICATION THEORY

Philippe Flajolet

(Version of January 14, 1997)

This problem discussed here is at the origin of the whole Combstruct package. On October 8, 1992, Bernard Van Cutsem, a statistician at the University of Grenoble wrote to us:

In classification theory, we make use of hierarchical classification trees. I would need to generate at random such classification trees according to the uniform law. The elements to be classified may be taken as distinguished integers say from 1 to n *. Do you know of an algorithm for doing this?*

This led to a cooperation involving Paul Zimmermann, Bernard Van Cutsem, and Philippe Flajolet, out of which the general theory and the algorithms of Combstruct evolved, see *Theoretical Computer Science* , vol. 132, pp. 1-35. A first implementation was designed by Paul Zimmermann in 1993, under the name Gaia (*Maple Technical Newsletter* , 1994 (1), pp. 38-46).

Van Cutsem's original question was motivated by the following problem: Classification programmes in statistics build classification trees, usually proceeding by successive aggregations of closest neighbours amongst existing classes. How can we measure the way a classification carries useful information and not just "random noise"? Certainly, "good" classification trees should exhibit characteristics that depart significantly from random ones. Hence the need to simulate and analyse parameters of random classification trees.

Statistics and classification theory

Specification

We start by loading the combstruct package.

```
> with(combstruct);
```

```
[allstructs, count, draw, finished, gfeqns, gfseries, gfsolve,
iterstructs, nextstruct, prog_gfeqns, prog_gfseries, prog_gfsolve]
```

A classification is either: 1) an atom; 2) a set of classification trees of degree at least 2. Atoms are distiguishable, hence we are in a labelled universe. Note that the Set construction translates a pure graph-theoretic structure with no ordering between descendents of a node.

```
> hier:=[H,{H=Union(Z,Set(H,card>1))},labelled]:
```

The original problem of Van Cutsem is solved by single commands like

```
> draw(hier,size=10);
```

```
Set( Set( Set( Set( Z6, Z2, Set( Z4, Z8 ) ), Z7 ), Z1 ), Set( Z5, Z3, Z10 ),
Z9 )
```

We may adopt a more concise representation format:

```
> lreduce:=proc(e) eval(subs({Set=proc() {args} end, Sequence=proc() [args] end},e))
end:
```

```
> lreduce(draw(hier,size=20));
```

$\{\{\{\{\{\{\{\{\{\{$

$\{\{\{\{\{\{\{Z_9, Z_{13}\}, \{Z_7, Z_{17}\}\}, Z_{14}\}, \{Z_2, Z_{16}\}\}, Z_{20}\}, Z_6\}, Z_{15},$

$Z_{19}\}, Z_3\}, Z_{12}\}, Z_{10}\}, Z_5\}, Z_8\}, Z_{18}\}, Z_{11}\}, Z_1\}, Z_4\}$

Random generation takes only a few seconds while counting tables (that serve to determine splitting probabilities) are set up on the fly.

```
> for j from 20 by 20 to 100 do j,lreduce(draw(hier,size=j)) od;
```

$20, \{\{Z_6, Z_3, Z_{13}\}, \{\{\{Z_7, Z_{11}\}, Z_{16}\}, \{\{\{\{Z_2, Z_{18}\}, Z_{17}\},$

This appears to be sequence **M3613** of the *Encyclopedia of Integer Sequences* and it corresponds to "Schroeder's fourth problem". When the count is not too large, we can do exhaustive listings. This is made possible by Combstruct that is able to build canonical forms and generate elements under unique standard forms.

> **for j to 4 do map(lreduce,allstructs(hier,size=j)) od;**

$$[Z_1]$$

$$[\{Z_2, Z_1\}]$$

$$\{Z_2, Z_3, \{Z_4, Z_1\}\}]$$

Asymptotic analysis

We get generating function equations by combstruct[gfeqns]

> **gfeqns(op(2..3,hier),z);**

$$[Z(z) = z, H(z) = Z(z) + e^{H(z)} - 1 - H(z)]$$

And combstruct[gfsolve] attempts different strategies to solve the system

> **gfsolve(op(2..3,hier),z);**

$$\{Z(z) = z, H(z) = -\text{LambertW}\left(-\frac{1}{2}e^{(1/2\,z - 1/2)}\right) + \frac{1}{2}z - \frac{1}{2}\}$$

The solution involves Lambert's W function that is known to Maple: by definition, this is the solution of

$$W(z)\,e^{W(z)} = z\,.$$

> **H_z:=subs(",H(z));**

$$H\_z := -\text{LambertW}\left(-\frac{1}{2}e^{(1/2z-1/2)}\right)+\frac{1}{2}z-\frac{1}{2}$$

Objects being labelled, this is an exponential generating function (EGF).

> **H_ztayl:=series(H_z,z=0,20);**

$$H\_ztayl := z+\frac{1}{2}z^2+\frac{2}{3}z^3+\frac{13}{12}z^4+\frac{59}{30}z^5+\frac{172}{45}z^6+\frac{4901}{630}z^7+\frac{10313}{630}z^8+\frac{400591}{11340}z^9+\frac{8816807}{113400}z^{10}+\frac{27108976}{155925}z^{11}+\frac{1473954553}{3742200}z^{12}+\frac{43885539223}{48648600}z^{13}+\frac{710119934413}{340540200}z^{14}+\frac{12409621176731}{2554051500}z^{15}+\frac{35834430733963}{3143448000}z^{16}+\frac{9346699791424817}{347351004000}z^{17}+\frac{199627883623263677}{3126159036000}z^{18}+\frac{695699572204213751}{4569001668000}z^{19}+O(z^{20})$$

As usual, we also obtain the corresponding ordinary generating functions by a Laplace transform applied to the series expansion

> **series(subs(w=1/w,w*inttrans[laplace](H_ztayl,z,w)),w,20);**

$$w+w^2+4w^3+26w^4+236w^5+2752w^6+39208w^7+660032w^8+12818912w^9+282137824w^{10}+6939897856w^{11}+188666182784w^{12}+5617349020544w^{13}+181790703209728w^{14}+6353726042486272w^{15}+238513970965257728w^{16}+9571020586419012608w^{17}+408837905660444010496w^{18}+O(w^{19})$$

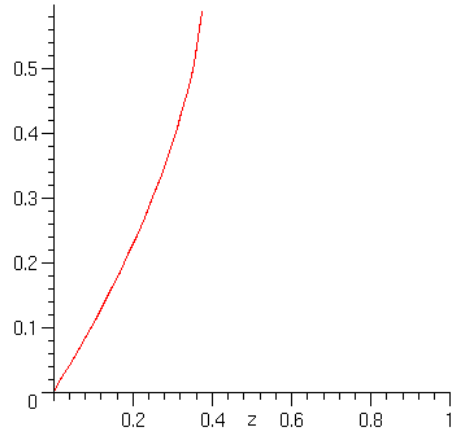
The result is then directly comparable to the counting coefficients:

> **seq(count(hier,size=j),j=1..18);**

1, 1, 4, 26, 236, 2752, 39208, 660032, 12818912, 282137824, 6939897856, 188666182784, 5617349020544, 181790703209728, 6353726042486272, 238513970965257728, 9571020586419012608, 408837905660444010496

In order to analyse the number of hierarchies, we must find the dominant singularity of their generating function. A plot detects a vertical slope near 0.4

> **plot(H_z,z=0..1);**



Here is a cute way to get the singularity "automatically". We express that the function ceases to be differentiable at its singularity.

> **diff(H_z,z);**

$$-\frac{1}{2}\frac{\text{LambertW}\left(-\frac{1}{2}e^{(1/2\,z-1/2)}\right)}{1+\text{LambertW}\left(-\frac{1}{2}e^{(1/2\,z-1/2)}\right)}+\frac{1}{2}$$

> **rho:=solve(denom('')=0); evalf(rho,30);**

$$\rho := -1 + 2\ln(2)$$

$$.386294361119890618834464242 92$$

Next, we know that the singular expansion determines the asymptotic form of coefficients. Thus, we look at

> **H_s:=subs(z=rho*(1-Delta^2),H_z);**

$$H\_s := -\text{LambertW}\left(-\frac{1}{2}e^{(1/2\,(-1+2\ln(2))\,(1-\Delta^2)-1/2)}\right)+\frac{1}{2}(-1+2\ln(2))\,(1-\Delta^2)-\frac{1}{2}$$

> **H_sing:=map(simplify,series(H_s,Delta=0,5));Delta=sqrt(``(1-z/rho));**

$$H\_sing := \ln(2)-\sqrt{-1+2\ln(2)}\,\Delta+\left(\frac{1}{6}-\frac{1}{3}\ln(2)\right)\Delta^2-\frac{1}{36}(-1+2\ln(2))^{3/2}\Delta^3+O(\Delta^4)$$

$$\Delta = \sqrt{\left(1 - \frac{z}{-1 + 2\ln(2)}\right)}$$

With this, we can get an asymptotic expansion for coefficients to any order, which is an interesting fact per se. Here is the first one:

```
> H_n_asympt:=n!*asympt(coeff(H_sing,Delta,1)*rho^(-n)*subs({cos(Pi*n)=1,O=0},
simplify(asympt(binomial(1/2,n),n,2))),n);
evalf(",20);
```

$$H\_n\_asympt := \frac{1}{2}\frac{n!\sqrt{-1 + 2\ln(2)}\left(\frac{1}{n}\right)^{3/2}}{\sqrt{\pi}\,(-1 + 2\ln(2))^{n}}$$

$$.17532920044983416513\,\frac{n\,\Gamma(n)\left(\frac{1}{n}\right)^{3/2}}{.38629436111989061 88^{n}}$$

And for n=50, we get

```
> round(evalf(subs(n=50,H_n_asympt),20)); count(hier,size=50); evalf("'"/");
```

68007324036664681787000000000000000000000000000000
00000000000000000000000000000000

68500011739739047489576366079817479093395106351830
93671870187559786896636537470976

.9928074800

The error is of about 1% for $n = 50$. A complete asymptotic expansion can be obtained by this method, by taking successive singular terms into account.

The number of classification stages

We examine the number of internal nodes in a classification. This corresponds to the number of classes actually created. The idea is to make use of "marks" in the form of Epsilon structures that have size 0 (and thus do not affect the combinatorial model).

```
> hier2:=[H,{H=Union(Z,Prod(class,Set(H,card>1))),class=Epsilon},labelled]:
```

Such marks do not affect the combinatorial model:

```
> seq(count(hier,size=j),j=0..11);
```

0, 1, 1, 4, 26, 236, 2752, 39208, 660032, 12818912, 282137824, 6939897856

```
> seq(count(hier2,size=j),j=0..11);
```

0, 1, 1, 4, 26, 236, 2752, 39208, 660032, 12818912, 282137824, 6939897856

(We change the formatting procedure to take Prod into account.)

```
> lreduce:=proc(e) eval(subs({Set=proc() {args} end, Sequence=proc() [args] end,
Prod=``},e)) end:
```

Here is a random object with "class" marking classification nodes:

```
> lreduce(draw(hier2,size=20));
```
